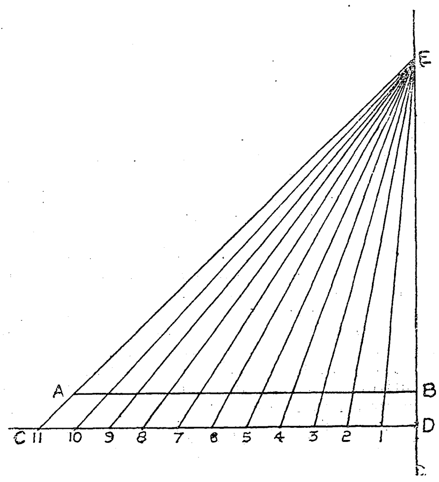
[60700.]—**To Draughtsmen, &c.**—"Workman," having objected to geometrical methods of dividing a straight line into a number of equal parts, will account for the fact that neither "E. L. G.," nor any other of your able correspondents, should have given an adequate reply. At the same time, the proceeding is very simple, though geometric. Will he accept the following: Let A B be a line which it is desired to divide into eleven equal parts. Draw a perpendicular at either end of, and touching the, line; now, starting from the perpendicular, and beneath, and parallel to the first line, draw a longer line of any length, C D; then take the compasses, measure out from the perpendicular on the lower line eleven spaces of any size, the only necessary condition being that the whole space measured out must be longer than A B. Now, from the last point the compasses have touched, draw a line to touch A, and continue it on till it reaches the perpendicular, which it will do at E. All that now remains to be done is to draw diagonal lines from the various points marked by the compasses to E, and the line A B is divided into 11 parts. When the lines 11 and 10 are drawn, you have got your gauge between these lines; but it is as well to draw the others, because you have thus the means of dividing into 10, 9, 8, &c., parts, according to the line you measure from. You can also divide shorter lines by adjusting them higher up against the diagram, or lines of any length by prolonging the diagonals downwards. This would be a useful gauge to keep in the workshop; but would be better with 12 divisions. This is extensively available, even for high numbers. Supposing we wanted 56, we should take 7 and 8, and, having first divided the line by one of these numbers, we should take one of the divisions, and divide that with the other number, and there we



have our gauge. High prime numbers would require a separate diagram, the five lines of which could be constructed in two or three minutes. I have written at a greater length than I intended, and so must defer the division of circles to another occasion, should it be desired.—F.R.C.S., Eng.

[60744.]—**Question in Dynamics.**—No; I cannot admit that the monkey can rise at all; his pull and the motion are simultaneous—an upward motion on the part of M, and a consequent downward motion on the part of the monkey. No work is done, the centre of gravity of the system remaining motionless throughout. Evidently, if both rose, the centre of gravity would rise, and work would be done against gravity. As for "M.I.C.E., Bath's," illustration of the two chairs, the cases are similar only so long as the chairs are not on level ground; on a level there is this all-important difference, that the force of gravity is eliminated; the chairs will approach and meet in the middle—the centre of gravity of the system—but no work in the strict sense of the term will be done because there is no resistance. If "M.I.C.E." still thinks that "Nephesh" is right, why not try the experiment I have suggested? Why think when you may know? as the great John Hunter said to a friend. Let him stand on the scale of a large balance—a see-saw plank would do—and either try to pull himself up by his arms to the beam, or first bend and then straighten his knees; so doing, he will give an upward motion to his body, which, as I assert, will cause an increased pull or pressure on the beam or scale. Then let him observe whether the effect is to raise or depress his end of the beam, remembering always that under the conditions of the problem the motion once started will continue and be uniform (I hope "M.I.C.E." will not attribute to me the very blunder I attempted to correct in another), unless it is possible for the monkey in his descent to repeat his effort to rise, in which case the same cause which started the motion will accelerate it. The case is conceivable where the motion is very slow, as it would be if the monkey's first effort was feeble.—W. A. S.

[60756.]—**Battery and Lamp.**—See p. 44, this volume, and the indices of previous volumes. I think the querist would find the Schanschieff battery the best for his purpose, though charging once a week only to give two hours' work each night means 14 hours altogether. However, there is plenty of information in back volumes, and the querist has only to read up and select which battery he likes best.—J. T. M.

[60757.]—**Revolving Wood Stand.**—If this querist cannot make one of these stands at sight, no number of sketches will assist him. He had better use clockwork for driving it. It is cheaper than electricity, and not so much trouble.—J. T. M.

[60771.]—**Ventilation.**—If "A. A." gets a house built and fitted with elaborate ventilating arrangements for the price and of the cubic contents he mentions, his experience will be interesting, I imagine, even to architects reputed good. Allowing for structural requirements, the spaces given work out at about 5d. the foot cube; remarkably low for bespoke goods. I have never had the luck to meet with a scientifically ventilated room; it is very common to see an unsightly patch in the wall which represents an Arnott outlet; but I never observed that they were effective. The plan suggested by "Medium" and "Sigma" of openings in door heads may often succeed, especially for bedrooms; but if the staircase is heated there is a risk of the pull of the air in it overcoming the draught in the fireplaces, I quote from Dr. Galton's article in "Our Homes." The fact is that there is usually little trouble from foul air during daylight. When rooms are shut up, lighted, and perhaps crowded, it is then that the ordinary provision of fresh air becomes inadequate. One hint I have to offer is, open the lower sash 6in. or so, and close a half shutter against the sash bead, with its top from 6ft. to 7ft. from the floor. A piece of stout cloth, which might be of an ornamental fabric, pinned to the bead with drawing pins does instead of a shutter. To a bedroom I have just fitted an arrangement of double windows, which appears likely to answer several requirements. I have a gas burner with an escape flue between the two frames; but the experiment is of too short duration for a full report as yet.—W. A. S. B.

[60803.]—**Wheels and Axle.**—I would advise you to get a good wheelwright to help you, and let him take the lead of the work. You will see how he does the work, and it will pay you better than to spoil good timber for a pair of wheels. As you say you are a novice in the trade, there are cross lines and V lines used in setting axles. If you give the height of wheels, dish and spoke and length of box, if patent axle, diameter of stock, I will see if I can help you.—J. C.

[60855.]—**Pulleys.**—If the planing machine is for metal, why not fit it with a clutch reversing motion? To drive it with a flywheel and pulleys is a roundabout proceeding, and causes a loss of power through friction. There are not enough particulars to enable one to advise in the matter.—A. F. SHAKESPEAR, Lüttichaustrasse 14 III., Dresden.

[60856.]—**Battery.**—TO MR. BOTTONE.—Many thanks for description of battery. If it is not in-

truding too much, I should be glad of dimensions of a different sort of battery, as I am afraid the contents would run out in my pocket from the bottle. As to size, nothing could be more desirable. If there is no other sort available, I should like to know how long the battery described will run with one charge, and can carbon be replaced by copper in the sulphate of mercury cell?—ROUGE GORGE.

[60862.]—**Parallel Motion.**—TO "GLATTON" AND "T. C., BRISTOL."—Thanks for your kindness in answering my query. You were quite right—it should have been 16ft. 8in., half-length of beam; the brasses are very little the worse for wear. It has been working like this ever since it started new. The piston rod is $\frac{3}{4}$in. out of upright towards centre of beam when out of cylinder, and goes in the same direction at the bottom, as far as glass will let it. I do not know how to carry out your instructions, as it is difficult to keep the engine still with 50 tons of rods pulling at it.—C. ENSOR.

[60883.]—**Building Amateur Workshop.**—As you do not give the lengths of the "two or three lathes, gas-engine, bench, &c.," it is quite impossible to say what space is required. Iron buildings for workshop are best lined with wood, with a space of, say, $\frac{3}{4}$in. between. You must expect to see quite as much rust in it as in the house, and perhaps more, unless you have a cement floor. Engines are always best on a solid foundation; it had better stand on brick foundation. If you must have a wooden floor, let it be not less than 18in. from the ground. Bricks covered with Portland cement would be much better, and would keep the damp down.—A. F. SHAKESPEAR, Lüttichaustrasse 14 III., Dresden.

[60884.]—**Textbook on Mechanics.**—I do not think you will obtain any book that will give what you require; the market is flooded with books on lathes, but there is not one book on either planing, shaping, or milling machines, though planing and shaping is more difficult to do well than turning. Even if you get a book, it will not give you confidence, and I know by experience how much nervousness is conducive to failure. I have been in your position, and I know pretty well where the shoe pinches.—A. F. SHAKESPEAR, Lüttichaustrasse 14 III., Dresden.

[60894.]—**Varnish Brush.**—Put the brushes into alcohol. If the brushes have got hard and dry, heat the alcohol, but be careful and not bring a light anywhere near it.—A. F. SHAKESPEAR, Lüttichaustrasse 14 III., Dresden.

[60903.]—**Motions of Earth and Moon.**—I see on referring to Chambers's "Descriptive Astronomy" that my explanation on page 269 is incorrect. I found it stated in Routledge's "History of Science," page 200, that the earth's mass is forty times that of the moon, and naturally supposed it was correct. The author seems to have confused its *volume* with its *mass*, the former being ·02034 of earth, the latter only ·0128. No one has yet pointed out the error, so I hasten to correct it.—R. E. F.

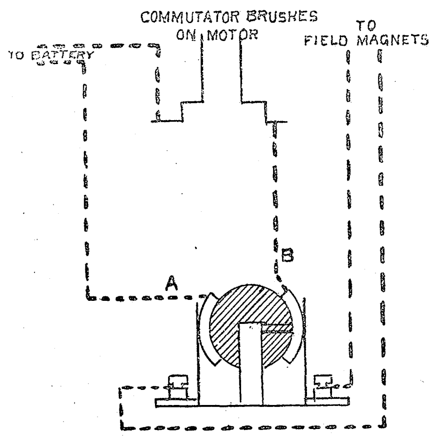
[60906.]—**Lens.**—TO T. PERKINS.—Wray's 5in. by 4in. rapid rectilinear is well suited for ordinary landscape work, as well as instantaneous effects. Using the smallest stop but one, $\frac{f}{16}$, it will cover a half plate well. The definition is excellent. The front combination will screw off, leaving the stops in the slot and the back lens intact. This forms an excellent landscape lens of about 11in. focus, and will cover a whole plate; this whole plate will contain exactly the same amount of the landscape as the lens in its ordinary condition would give on a quarter plate, the objects being doubled in size in every direction. The exposure, using the same stop, must be quadrupled, as since the focal length is doubled, the light is spread over an area four times as large. The advantage of using the back lens alone is not only that it covers a larger plate if desired, but that if we use a small plate, distant objects come out so much bigger, less of the landscape, of course, being included. The back combination alone is not rectilinear; but this is of no importance unless the subject is purely architectural. The outside diameter of lens mount is $1\frac{1}{2}$in.—T. PERKINS, M.A., Shaftesbury.

[60927.]—**Re-cutting Chasers.**—There is only one satisfactory way of doing it, i.e., on a hob.—A. F. SHAKESPEAR, Lüttichaustrasse 14 III., Dresden.

[60929.]—**Aluminium.**—TO "DAVID."—In this week's *Electrician* (or rather last week's by the time this appears in print) you will find a description of the "Brush Colossus" at work, which will probably interest you. The article referred to will be found on page 50.—W. HOLDER, Newport, Mon.

[60929.]—**Nickel-Plating.**—Nickel may be dissolved in hydrochloric acid, and then by addition of potassic cyanide, a ppt. is formed soluble in excess of the potash salt. This would answer the purpose; but the article to be nickel-plated must be removed now and again and polished, as nickel has a tendency to deposit unevenly. I do not think aluminium has been deposited.—E. F. S.

[60928.]—**Reversing Gear to Motor.**—If a "Country Parson" will get a barrel commutator (such as are put on Ruhmkorff coils to reverse current), and connect it the way shown in sketch,



he will find that on turning the commutator half round, it will reverse his motor. Wires marked A and B should be connected to supports of commutator.—JOHN H. B. GARBUTT, Leeds.

[60932.]—**Inlaid Veneers.**—I have read somewhere of a simple process by which cheap veneers can be, and perhaps, are, made; the pattern is cut out of a sheet of zinc. The sheet of veneer is laid on the plank destined for the table-top, and the zinc pattern on this; then the three together are passed through a powerful rolling press, so that the pressure forces the zinc and that portion of the veneer under it into the plank. The zinc is then picked out and will serve again, and a few strokes of the plane over the wood remove the ragged edges of veneer and disclose the inlaid design.—CALCULUS.

[60935.]—**Aluminium.**—Books of aluminium leaf may be obtained; but I cannot say whether suitable for gilding. They appear from catalogues about three-fourth price of same in gold.—E. F. S.

[60936.]—**Oxygen.**—Put MnO_2 in iron retort, and heat in fire to dull red. The gas is equally valuable as that from $KClO_3$, and need not be purified.—E. F. S.

[60944.]—**Copper Green.**—Procure either arsenite of copper (Scheele's green) or oxychloride of copper (Brunswick green), and bring to a state of fine powder, and mix with candle material.—E. F. S.

[60949.]—**Repolishing Gunstock.**—With some small pieces of window glass scrape off all the old polish. Next dip a piece of rag in water and wet your stock all over, and allow it to dry. But the way we do in the trade is to light a handful of shavings and run the stock through the blaze. But to let it stand and dry will do. Now, when dry, go over the stock with a 2nd cut file (or bastard), then with a smooth. Of course you will want two or three different kinds of files. This done, take some No. 2 glasspaper, and with it take out all the marks left from the smooth file. Now No. $1\frac{1}{2}$ glasspaper, then No. 1, and so on down to No. 0. About using the glasspaper, you may use it doubled three or four times to about 4in. square. But we use pieces of flat cork, round which we wrap the paper; but you may do it with your hand. A good substitute for the cork is a piece of $\frac{3}{4}$in. deal, about 3in. or 4in. square, around which wrap three or four thicknesses of flannel or baize, then round that put your paper. For round the corners you may use your finger, or a piece of wood or cork filed to suit the shape of work. Now, if you wish to make a good job of your work, never leave off till the present tool has removed all the marks of the previous one. This is the real secret of well finished work, whether applied to metal or wood. When you have done your last glasspapering, take a piece of wood harder than the stock, no matter what shape or size, for the plain part of the stock—for the corners you will know what to do—and well burnish your stock (with the grain); you ought now to have a fine gloss on. Now oil your stock with raw linseed oil, and let it stand all night. To-morrow proceed to French-polish just as you would a piece of furniture. If you don't understand polishing let me know, and I will give the key. You want to know the way in which the stock is cut. I suppose you mean those little lozenge-shaped figures on the part of the stock which is grasped by the hands when in the act of firing? We, in the trade, call it chequering. I can't draw much, I am not good at description. Give your name and address, and I will lend you one of the tools, from which you will be able to make your own. That will beat a wheelbarrow full of talking. Now for the *red* substance which you think is run into the *nicks* or *cuts*. The red substance you mention is the most sure sign of a common gun. If ever you are about to buy a gun, and you see that red substance about the chequering, take my advice and turn down or up another street. I hope I shall not be misunderstood. I don't mean that common guns won't shoot, or that they are not safe. What I mean is, if you want a gun that will not be always taking you to the gunsmith's, shun those with the red about them. That red is nothing more than the so-called dragon's blood put into the polish for redness sake. There should be nothing run into the cuts of the chequering. And now allow me to tell you that at the present day no good gunstock is ever French polished. There is a fashion even in gunstocks. Here is how modern gunstocks are polished—I mean good ones, and those pretending to be good—viz., when you have prepared your stock for polishing, put a pinch or two of powdered rottenstone in your hand or on the stock. Mix with raw linseed-oil, and simply rub up and down with your hand round the corners with your finger. You must have patience, and you will get that quiet modest polish which you may see on the good gunstock of the day—a polish which will not fade or chip, and which can always be improved by an occasional rub with the hand and a few drops of oil.—ARMOURER.

[60952.]—**Lathe Matters.**—With deference to Mr. F. R. Davis, I think he is in error. An eccentric cannot, of course, convert reciprocating into rotary motion when arranged as in the steam-engine, the friction is, of course, too great; but when the strap of the eccentric is replaced by a band or chain which runs on a roller playing loosely on an axle in the treadle of a lathe, the eccentric will certainly drive very well; the only (sliding) friction here being that of the roller on its axle.—CALCULUS.

[60953.]—**Lathe Matters.**—The substitution of an eccentric for the crank, as suggested by "S. H. R.," is not new to me, as it is used by a German firm. I don't know how it answers; but I should fancy it increased the friction. Have thought of trying it once, but had no opportunity.—A. F. SHAKESPEAR, Lüttichaustrasse 14 III., Dresden.

[60954.]—**John Wilkinson, Iron Master.**—I think I have one, too. Mr. Wilkinson was so fond of his iron that he had his coffin made of it; but, strange to say, although he invented and introduced a new boring machine, and cast cylinders for Watt, and was first of the great iron masters, he did not have it made large enough, for when he came to be placed in his narrow bed it was found too small, so he had to be temporarily interred till another could be made. When placed in the ground a second time, it was found the grave was not deep enough; it had to be taken up, and an excavation made in the rock, when it was buried a third time, within thirty yards of his mansion at Castlehead. The Castlehead estates were sold in 1828, when the coffin was taken up and buried a fourth time, but in the chapel yard of Lindale.—EDWARD R. DALE, F.S.Sc.

[60956.]—**Corn Thresher.**—Perhaps the following may be of use to "J. P." Procure two pieces of round-edged spring steel 2in. in width and, say, 2ft. long; two pieces of wood, say, $3\frac{1}{2}$in. or 4in. broad and 3in. thick. Groove them to suit the steel, and fasten the steel in the groove by means of tabs at the ends. When the foregoing apparatus is completed, get two trestles, place the blocks on the tops (of the trestles), and set them at the proper distance to receive the journals of the drum-shaft; level them perfectly. Now take your drum properly keyed on the shaft, and place it on the pieces of steel so that the journals will run on the steels (which, you will understand, must be edgeways in the wood blocks). The heaviest side will, of course, fall to the bottom. Get some pieces of lead and nail on to the light beaters, and proceed in the same manner till your drum will stand with any one beater at the top.—STOKER.

[60959.]—**Chuck.**—How would the "Hartford" or "Little Giant" suit you?—A. F. SHAKESPEAR, Lüttichaustrasse 14 III., Dresden.

[60965.]—**Saxophone.**—In reply to "Sax's" query, he had better buy Book 6 of "The Bandsman," published by Rudall, Carte, and Co., in which he will find a diagram of the instrument and full directions for learning it.—GERION.

[60967.]—**Revitalising the Ferrous Oxalate Developer.**—There are several methods by which the photographer may restore the energy of his developer, one and all of which are conducted by a process called "reduction," and he may be right in believing that "if any simple or compound body accelerates or restores this developer, it must

be accompanied by reduction." The first process of restoring energy is conducted by following out these principles:—Into a stoppered bottle pour a sample of the spent developer, previously acidified by means of oxalic acid, snap off a dozen or more pieces of clean iron piano wire, introduce these into the bottle (which, by the bye, should be filled to the stopper), leave to digest for 24 hours, frequently shaking at intervals so as to detach the ferrous oxalate from the iron wire as it is reduced from the solution, giving fresh surface to the wire for further reduction. If an element is liberated in the elementary state from a compound body it is termed "nascent," or said to exist in a "nascent condition," and in this state it possesses a greater affinity for other bodies than it does normally. Nascent hydrogen shows a marked degree in its reducing powers, removing the whole of the C_2O_4 molecule present, and reducing ferric salts to ferrous. If we pass hydrogen gas through a solution of ferric oxalate we fail to reduce it; but if we generate it in the solution itself, reduction takes place, the nascent gas uniting with the C_2O_4 molecule, and thus this change must inevitably ensue:—

$$\overbrace{Fe_2(C_2O_4)_3}^{\text{Ferric oxalate.}} + \overbrace{H_2C_2O_4}^{\text{Hydrogen oxalate.}} + \overbrace{Fe}^{\text{Iron.}} = \overbrace{3FeC_2O_4}^{\text{Ferrous oxalate.}} + \overbrace{H_2C_2O_4}^{\text{Hydrogen oxalate.}}$$

Now I think I have made this perfectly clear that the increased affinity of nascent hydrogen for the C_2O_4 molecule brings about a rearrangement atomically, and yet molecularly, which we may theoretically assume is due to the hydrogen atoms that are vastly superior in power, and that have not yet partly spent their energies in coupling together to form bonded atoms or, more correctly, molecules. Another mode of revitalising our developer is as follows:—Expose the sample of spent developer to strong sunlight, previously acidified with tartaric acid (this acid is added to prevent precipitation), for 24 hours or more. One grain to a pint of developer may be used. Below will be seen what reaction occurs when ferric oxalate (which is the result of the ferrous oxalate developer) is exposed to sunlight:—

$$* \overbrace{Fe_2(C_2O_4)}^{\text{Ferric oxalate.}} + \text{light} = \overbrace{2FeC_2O_4}^{\text{Ferrous oxalate.}} + \overbrace{2CO_2}^{\text{Carbonic anhydride evolved.}}$$

(* Slightly corrected from "Treatise on Photography," by Capt. Abney.)

The carbonic anhydride evolved escapes in the form of hundreds of minute bubbles rising from the bottom of the containing vessel, and when this action has apparently ceased, after being exposed to further sunlight we may conclude that our developer is again fit for use. I may say that, if exposed to weak diffused daylight, this decomposition of light-shaken molecules takes place much more slowly than in strong sunlight. Still another and yet more perfect way, which will be more fully dwelt upon in the subject of an article to the coming *Year Book*, and that is the precipitation of the developing principle in this specific developer, whilst ferric oxalate, its resultant, remains in solution, thereby effecting a total separation.—A. TREYER EVANS, Newport, Mon.

[60982.]—**Chronic Inflammation of the Nostrils.**—"Misery" may perhaps find relief from aconite (homœopathic tincture 3) and arsenicum tinct. 3; but he should consult a qualified homœopathic medical man.—PONTO.

[60982.]—**Chronic Inflammation of Nostrils.**—Get a nasal douche or syringe and syringe the nasal passages twice a day. Whilst engaged in the Paris hospitals I found iodoform snuff useful. Recipe as follows:—Iodoform, two drachms; camphor, one drachm; gum arabic, one drachm. Pulverise very fine, and snuff every half-hour.—B.SC., Plymouth,

[60982.]—**Chronic Inflammation of Nostrils.**—Try washing out the cavity by means of the nasal douche with water containing two grains of sulphate of zinc to the ounce, and at the same time improve the general health by means of tonics. Any medical man would show you how to use the douche, after which you can use it yourself. The inflammation proves very intractable after it has been long neglected.—R. E. F.

[60982.]—**Chronic Inflammation of Nostrils.**—I am troubled similarly to "Misery"; but not so badly perhaps. I consulted a surgeon of eminence, and he prescribed benzoated zinc ointment; it cured me for a long time, but a recent cold left me as bad as ever. I obtain relief from a course of aperient pills and the zinc ointment. I fancy, like many others, I am afflicted with a humour which must have (and had better have) a vent somewhere. I should be grateful if some doctor among your readers would kindly advise whether having the ears bored would be likely to divert the ailment from the respiratory passages. I believe ears are pierced to ameliorate chronic inflammation of the eyelids.—A. E. O.

[60982.]—**Chronic Inflammation of Nostrils.**—Querist is evidently suffering from an unhealthy condition of the nasal mucous membrane, and in the absence of evidence as to the hereditary or acquired taint, gouty, tubercular, or such like, it is difficult to advise him. If there is any constitutional disease, the local one is secondary to it, and the former must be treated first. However, I may suggest a few remedies: astringent snuffs, e.g., alum, tannin; painting with glycerine of tannic acid, solution of biborate of soda, nitrate of silver, sulphate of zinc. Internally, arsenic and cod-liver oil. If querist finds his influenza cold coming on, he should try to cut it short by small and repeated doses of aconite; ten grains of Dover's powder at bed-time, or some similar remedy. In any case, he will derive more benefit from the judicious treatment of his medical attendant than from remedies prescribed by those who cannot see him.—DOCTOR MEDICINÆ.

[60982.]—**Chronic Inflammation of Nostrils.**—I think "Misery" has got hold of the right remedies if he uses them right. Like "Misery," I was a martyr to this complaint; but by having a cold bath every morning, and injecting oil of eucalyptus up the nostril once every twelve hours or so when inflammation comes on, I have quite regained my former health. To apply the eucalyptus, get a small piece of glass tube drawn out to a point; break off the point, and fix a bit of indiarubber tube tied up at one end to the other end of glass tube; press the indiarubber tube, dip point of glass tube into eucalyptus, release rubber tube, and several drops of oil will be drawn up into glass tube. Now insert glass tube in nostril as far up as possible, and press rubber tube sharply. This will send oil well up the nostril. Now snuff the oil up into the back nasal passages.—CURED AND THANKFUL.

[60983.]—**Chloride Battery.**—This battery, also known as the "Fuller" cell, is stated in advertisements to remain in action for three months. Practically, its duration depends upon whether it is worked much or little. My own experience is, that when used for lighting lamps it completely runs down in about 30 or 35 hours. Local action does take place; but not very much.—S. BOTTONE.

[60983.]—**Chloride Battery.**—This is a ridiculous name to give to a cell which is purely a bichromate of potash one, in which hydrochloric acid is used instead of sulphuric. The chloride of zinc takes no part in the action except that of conductor of current and keeping the nitric acid out of contact with the zinc. It cannot be usefully compared with the Leclanché, as the properties of the two cells are entirely unlike. The Leclanché has no local action to speak of, and can only give a small and intermittent current. The other has a great deal of local action, and will entirely waste itself away, in no long time, without doing any work; but it can give a much greater current. The advantage it has over the sulphuric-acid form is that the solutions do not crystallise; but, on the other hand some acid fumes are given off. As I have been asked in a private letter to give this reply, and the writer refers to my "Electricity," I may say that the whole of the facts concerning this battery are fully explained there; seeing someone is every day inventing what he calls a new battery and gives a special name to, if he does not patent, it, it is useless to look in any book for a special mention of any special form; but I have not yet seen anything new in any recent battery, or anything the full explanation of which will not be found in my chapter on Batteries. On p. 146 I show why hydrochloric acid and chloride of zinc may be used. In reply to a further question, salammoniac would not be good: it would creep and produce crystals as it does in the Leclanché; the chloride of zinc, being highly deliquescent, does neither. The strength of solution should be such as to bring the specific gravity of both solutions nearly alike, so as to resist endosmose.—SIGMA.

[60986.]—**Waggon Grease.**—I take the following from "Barry's Railway Appliances"; perhaps it may suit "R. J. C.":—Russian tallow, 214lb.; palm oil, 240lb.; soda (? caustic), 20lb.; water, 640lb.; above is for winter. For summer, the quantities given are: 322lb., 210lb., 18lb., and 480lb. respectively.—T. C., Bristol.

[60986.]—**Waggon Grease.**—"R. J. C." should have stated whether he wants to make waggon grease for sale or only for his own occasional use. For a common grease, dissolve half a pound of soda in a gallon of water, add 4lb. of tallow, 6lb. of palm oil, and a gallon of mineral oil. Melt and mix all together in a boiler in a safe place. A much superior "grease" is composed of tallow 8lb., palm oil 1 gallon, mineral oil 1 gallon, and plumbago 1lb.—SAML. RAY.

[60987.]—**Organ Query.**—I would recommend you to have the following stops—viz., open diapason to tenor C, carried down with open or stopped wood pipes; gedact, through; gamba to tenor C; flute, wood or metal, to C C, with stopt bass, and a small pedal bourdon. It is not advisable to build one-manual organs; but, if you wish to do so, inclose all but the open diapason in a box, with vertical shutters at each. There is great objection to the reservoir being under the soundboard, and to be any use it must be made as ordinary, and properly weighted with iron or lead. If you have the reservoir attached under the soundboard, you will require springs, when your pipes will never be in tune. Always make the bellows as large as possible. I would rather lose a stop than be "scant o' wind." If your available space is 4ft. 6in. by 2ft. 3in., make the bellows 2ft. by 3ft. 9in. This sized bellows, when fully inflated, would require 2ft. 2in. in height, including two feeders and weights. The underside of the keyframe may be 2ft. 8in. from the floor, which will leave room for keys to project backwards over bellows, and also for manual to pedal coupler. A small oboe might be added if you inclose in swell box.—URANIUM.

[60988.]—**Loans to Building Societies.**—To answer this query thoroughly one would require to see the rules of the building society referred to, the mortgage signed by A., and the agreement relative thereto. Roughly, however, I would say (following upon a decision given by the Supreme Court in Scotland), that if the society becomes insolvent, A. can claim his property on paying up the balance of his shares. The society cannot make over to B. more than it legally possesses, consequently he (B.) will be bound to disencumber A.'s property on the same terms.—B.SC., Plymouth.

[60989.]—**To Mr. Wimshurst and Others.**—"N. P., London," says: "He has made an influence machine, as described in the 'E. M.' a few weeks ago." This is too indefinite, and, furthermore, must be wrong, because if he had followed all the instructions it is simply impossible for it to remain without full excitement after about two revolutions, notwithstanding it being in the cold and on a November day. The warming and the duster are not needed in a properly fitted machine. The combs are by no means necessary to the working of the machine; but there is no reason why it should not work with them in place. It may be that in addition to the combs you short-circuited the machine by closing the terminals; if short-circuited, the degree of excitement is very much reduced. The bosses very clearly are not true, a professional wood-turner would no doubt finish them up prettily; but the truth part of the business I should try myself before accepting it as a fact. It is very well to try experiments with cements, even though it costs us a few glasses. In the description I think it was stated that a vulcanised fibre washer was to be cemented to the glass, and then the washer to be screwed on to the boss; but be particular to follow the description, and use Rockhill's tricycle cement. The fact is, that unequal-sized balls on the terminals give the best results; the why, no person knows. I have no agent; each maker uses his own pleasure freely: hence the ungainly forms of the machine which may daily be seen. It would require many of your pages to contain the theories in respect to "How is the Electricity Formed"; besides, after giving the theories, it seems to me we should still be in ignorance as to what electricity is. We should first settle that point—that is, if we can. It may be a "manifestation of energy"; but admit even that, and the view carries us no further. Your non-success seems to me to arise from want of actual metal connection between the brushes. Make quite sure of this; it may be a little lacquer, or polish, breaks the metal contact. Have actual metal touch, and even that under pressure.—J. W.

[60993.]—**Permanent Way.**—One of the places where stone sleepers were used, before it was found that they knocked the plant to pieces, was the Edinburgh and Glasgow, now North British Railway. I recollect about 40 years ago being jolted along this line in an open carriage with seats. The old stone sleepers are still to be seen in many places along the line, being used up for repairs.—B.SC., Plymouth.

[60997.]—**Cranks.**—Providing the length of spoke also $= r$, the cases would be exactly the same as regards the moment $w\ r$, and the very slight side twist which results if either w overhangs but a little may be neglected; results, therefore, are the same.—T. C., Bristol.

[60999.]—**Condensing Engine.**—If you have a sufficient supply of condensing water ($=$ 30 times amount of feed per hour) you can have a separate air-pump and condenser, the pump being driven by means of a strap and a pulley with crank. I remember seeing a compact combined condenser and pump in Tangye's small catalogue. I should advise you to get this, as it will also give you some idea of probable outlay.—T. C., Bristol.

[61000.]—**Pipe Moulding.**—If you will refer back to Vol. XXXVIII. Nos. 978, p. 334; 981, p. 400; and 985, p. 493, I think you will find your queries answered.—J. H.

[61001.] — **Landscape Painting in Oil Colours.**—A very excellent guide for a beginner

is "The Art of Landscape Painting in Oil Colours,' one of the shilling handbooks on art, published by Winsor and Newton, Rathbone-place, London, also a "Guide to Oil Painting" in two parts, G. Rowney and Co., Rathbone-place. The former I found most useful when I commenced without the help of a teacher. Both firms have good illustrated catalogues of artist's materials.—BRUSH.

[61001.] — **Landscape Painting in Oil Colours.**—As a beginner, "Welsh Hog-air" may purchase the following elementary books: "Hints on Sketching from Nature," in three parts, or the three bound in one volume, by Green; "Guide to Oil Painting" in two parts, published by Rowney, 29, Oxford-street, London, W., price 1s. a part. The oil colours can be used, as they come out of the tube, occasionally softening them if hard from age or other causes, with a little linseed oil. As a rule, no other vehicle is now used, megilp and other mediums being discarded, as pictures painted with them invariably crack after the lapse of a few years. For outdoor sketching, however, where rapid drying is desirable, some drier must be used, among the best of which is *Siccatif de Courtrai*. Still, like all other arts, more of the handling, and use of the materials, can be learnt in a few hours with a master, than in lengthened periods of practice based only on a knowledge derived from reading.—EYE-WITNESS.

[61001.]—**Landscape, &c., Painting in Oil-Colours.**—It is a great pity that "Welsh Hog-hair" cannot get a few lessons from a practical hand. It would save him from many a heartache, as well as a great loss of time and material, because printed instructions are really of little or no use to a beginner in such a difficult art as painting in oil-colours. As it is, I would recommend him to begin by practising the laying-in of sky, middle distance, and foreground in flat, even tints on oil-sketching paper with French tools, flat, Nos. 0 to 9, along with a badger, softened about 8 or 9 (sables, megilp, and gold size are for afterwards). "A Guide to Landscape in Oils" can be got from any artists' colourman for 1s. and postage; but for practical use "Hog-hair" should get the numbers of Vere Foster's "Landscape in Water-Colours," as also those of the Messrs. Cassell, Galpin, and Co. (they do just as well for oils), which contain a series of sketches from the first ground-tint to the finished picture, along with directions as to the colours needed and the order of using them. As they are done in a fine, free, broad style without much detail, a six months' practice would bring "Hog-hair" on so far as to enable him to begin the study of trees. Tree studies are to be had in numbers belonging to the same series. The only mediums required are light drying oil and spirits of turpentine. Given the ability to draw well, the great desideratum in oil-painting is to be able to handle the brushes—as purely a mechanical art as learning to use tools in a workshop, combined with the ability to lay-in the different tones flat, even, and free from smudge, only to be acquired by long, patient, determined practice. And it is the want of that severe training that makes the pictures of so many amateurs so feeble and raw, and "Hog-hair" should take at least two years on oil-paper and academy boards before taking to canvas. It will give me much pleasure to answer any questions or give further information.—DENS.

[61002.]—**Dynamo and Storage Battery.**—We should say that you would find it hard work to charge a storage battery from a foot-lathe. If you have not a gas-engine or power of some kind, we are afraid you will not find any satisfactory means of charging your cells. Why not try lamps of lower candle-power, and more of them? Light with a Bunsen battery; but you must not expect a 30 hours' light.—WARNE AND CO.

[61002.]—**Dynamo and Storage Battery.**—TO MR. BOTTONE.—You will find a description of a very efficient form of storage battery, the making of which is well within the grasp of an amateur, in the ENGLISH MECHANIC, Vol. XL., page 28. If you had a good dynamo that you could drive from the lathe (and the utmost you could get would be about 140 watts), you would need to treadle away for about 45 consecutive hours to light the lamps for 30.—S. BOTTONE.

[61002.]—**Dynamo and Storage Battery.**—Two 16c.p. lamps would (taking them at about the lowest generally-used resistance) require a current of over two ampères at an E.M.F. of something like 40 volts. Thus, for 30 hours you would require about 70 ampères at 40 volts, for which you would want 20 storage cells each of 70 ampères capacity—that is to say, you would want a cell with, say, 15 plates, seven positive and eight negative, each of about 12in. by 18in. immersed surface. You would have to "form" your plates from the plain lead; for putting on minium is protected under the E.P.S. Co.'s patents, which they are very rigorous in guarding. With no other motive power than a treadle-lathe, the formation of these cells would be such a long job as to be practically impossible—it would take years to do. If you can avail yourself of steam or water power, that is another matter altogether, and I can then send you all necessary instructions; but for the present will forbear describing a dynamo for the purpose, as you could not work it with a treadle-lathe, for to put into the storage cells a charge sufficient to enable them to give 70 ampère hours out, you would require to put 100 ampère hours in, and this with well-constructed cells. This would require, even spread over a period of 10 hours' charging, the continuous exertion for that time of $\frac{3}{4}$H.P., which is about five times the strength of an average man; and this is allowing nothing for loss of power in its conversion from mechanical to electrical force through the dynamo; so you see the treadle-lathe is out of the hunt altogether. If, however, you bring steam or water power into the case, it is another story altogether. A very small engine, a veritable mite of a thing, would put your 100 ampères into the storage cells in five hours with an exertion of only about 2H.P., which, for a steam-engine is little indeed, and with a more powerful one you could, in one hour, put enough into the cells to light the two 16c.p. lamps for 30 hours, though such heavy charging would not be advisable at all.—E. CONRY.

[61003.]—**Boiler Flue.** — If no flame could touch girders, they would be quite safe, and the draught would not be affected if you did not contract area of flue. Heat in chimney is about 600° F.; but much more in the first flue, probably 800° F.—T. C., Bristol.

[61004.]—**Italian Language.**—TO MR. BOTTONE.—The *s* is called impure when it is followed by a consonant. In the regular verbs the present participle is formed from the infinitive by striking off the terminations *are*, *ere*, and *ire*, and substituting for them *ando* for the first, and *endo* for the two latter. But the present participle is not always used in Italian where it is in English. It is generally translated by the infinitive. The past participles, in the same manner, are formed from the infinitive by the substitution of *ato*, *uto*, or *ito*. The personal pronoun is left out at all times, unless it be desired to emphasise the person. *Coloro* is third person plural of either gender; *eglino* is masculine only; *elleno*, feminine. *Da* means "at the house of," the same as *chez* in French. A very excellent grammar, if you can get it, is Angelo Cerutti's "Abridgment of the New Italian Grammar." Biajoli's is also a good one. As for reading books, try Goldoni's "Commedie," Botta's "Guerra d'America," Bentivoglio's "Guerra di Fiandra," Darra, "Republica di Venezia."—S. BOTTONE.

[61006.]—**Influence Machine.**—If one terminal ball be large, and the other ball be small (say, $1\frac{1}{2}$in., $1\frac{3}{8}$in.), the sparks, or brush discharge, ought to be fully 3in. in length. Then, for condensers, "Nil" should use two 2oz. phials of good quality glass, the tinfoil being about $1\frac{1}{2}$in. only in height. With these in circuit he should get snapping sparks from 5 to 6in. in length, with less than two revolutions of the handle. Of course, this all depends upon the proper design of the machine: he should refer to your back pages, see where his may differ from those described, and, if necessary, alter till his works essentially the same.—J. W.

[61008.]—**Length of Belting.**—Reducing all dimensions to inches, $D = 79$, $d = 41$, and $c = 145$. Sin. $\phi = \frac{120}{290} = \cdot41379$, whence $\phi = 24° 26'$, and cos. $\phi = \cdot91044$, and $\phi = \cdot42644$. Then $60\,\pi + 120\,\phi + 290 \text{ cos. } \phi = 188{\cdot}49 + 51{\cdot}17 + 264{\cdot}03 = 503{\cdot}69$ inches. The length of the belt will therefore be 41ft. $11\frac{1}{2}$in.—R. E. F.

[61008.]—**Length of Belting.**—A "Chap," of Oldham or anywhere else, may well be puzzled by the slovenly users of that most careless jargon, "circular measure," misapplied to what is the least circular, or differs from ordinary use by substituting a straight unit for a circularly curved one! When we call a right angle or a quadrant 90°, that measurement, if any, is "circular," at least circumferential. When we have to turn 180° into 3·14159, &c., or 1° into ·01745329, &c., we make the radius our unit, and are surely going from "circular" to straight or "radial" measure. In the wheels of "Oldham Chap," $D + d$ being 120in., and $C = 145$in., we may as well work in inches. Then the two straight lines are plainly $= 290 \text{ cos. } \phi$, the two semicircles $= 60\,\pi$, and the excess curves over them $= 60 \times 2\,\phi$, or 120 arc ϕ. We find ϕ by its being the arc whose sine is $60 \div 145 = 12 \div 29$.

From log. 12 =	1·07918125
Take log. 29 =	1·46239800
	9·61678325
	= log. sin. 24° 26′ 36″
To corresponding log. cos. =	9·9592184
Add log. 290 =	2·4623980
	2·4216164
	= log. 264·002in.

This is the length of the two straight parts. That of the two semicircles is $60 \times 3{\cdot}14159$, &c. $= 188{\cdot}49556$in., and that of the four arcs of 24° 26′ 36″ is $60 \times$ arc 48° 53′ 12″. Most trigonometric tables give such values as—

48° =	0·837758, &c.
53′ =	·015417, &c.
12″ =	·000058, &c.
	·853233
	60
	51·193998
Add semicircles =	188·495559
And straight parts =	264·002
Total length =	503·691in.

The two axes should be inclined at a small angle so as to have the wheels not in one plane. This is supposing the belt of the common kind, having two surfaces. But you may make a belt with only one surface, which will do for two wheels at right angles to each other's planes, or the more inclined the better.—E. L. G.

[61008.]—**Length of Belting.**—From $\frac{D + d}{2\,c} = \text{sin. } \phi = 0{\cdot}4$ or 24°; so that arc embraced of each pulley $= 180° + 48° = 228° = \frac{228}{360}\,(3{\cdot}1416 \times 10) = 19{\cdot}9$ft., including both pulleys, to which must be added $2c = 24'24''$, or 44ft. in all.—T. C., Bristol.

[61009.]—**Induction Coil**—TO MR. BOTTONE.—Primary, four layers of No. 16; secondary, 4lb. of No. 38 silk covered, most carefully insulated. Length of iron core, 12in.; diameter, $1\frac{1}{2}$in.; diameter of circular heads, $4\frac{1}{2}$in.; six or eight quart bichromates.—S. BOTTONE.

[61011.]—**Faulty Dynamo.**—Expect you are driving dynamo the wrong way. The question is very vague. You say the F.M.'s have 6in. jaws (we presume you mean pole-pieces), and the armature is 2ft. 6in. There is a considerable discount to be taken off somewhere. If you like to send us full particulars, we shall be pleased to put you right if possible; or, if in London, will send and examine machine for you gratis. Address, see Sale Column.—WARNE AND CO.

[61011.]—**Faulty Dynamo.**—I presume the armature dimensions given are wrong. Should they not be 2in. by 6in.? If so, the amount of wire is about right. Supposing you have everything really well insulated, then the fault may depend upon one of three things. 1. It is a series-wound dynamo, and you have not connected the terminals whilst running it, or else have used too great a resistance. 2. The brushes are placed at the wrong angle of commutation. 3. You are driving the dynamo the wrong way. Try to reverse the direction of rotation.—S. BOTTONE.

[61013.]—**Physics.**—Woodward's "Arithmetical Chemistry" is published in London by Simpkin Marshall; also, in Birmingham, by Cornish Bros., 37, New-street.—KENSINGTONIAN.

[61013.]—**Physics.**—Presumably the querist desires the co-efficients of "cubical" as distinguished from those of "linear" expansion. If so, he need only multiply the linear co-efficient as given in Ganot by 3 to obtain approximately the corresponding cubical one. If, however, he desires the precise figures as determined by experiment, I may refer him to Balfour Stewart's excellent "Elementary Treatise on Heat," pp. 35 to 38, where he will find numerous tables and comparisons. The publishers of Woodward's "Arithmetical Chemistry" are Simpkin, Marshall, and Co., of London, and Cornish Brothers, of Birmingham.—B. A., Handsworth.

[61013.]—**Physics.**—If a length, 1, of a substance at 0° centigrade becomes $1 + 8$ at 1° centigrade, and then its volume evidently increases to $1 + 38 + 38^2 + 8^3$; but 8 is a very small number, so small that its square, and still more its cube, may be neglected in practice. Hence, it is customary to take only the second term of the above expression, and to say that the co-efficient of cubical expansion of a substance is thrice its linear co-efficient. The density as compared with water at 4° will, of course, be inversely as the volume. In the case of silver, for example, the density is 10·5, its co-efficient of linear expansion is ·000019 (approximately); hence its cubical expansion is ·000057, and its density at a temperature t as compared with water at 4° centigrade is $= \frac{10{\cdot}5}{1 + (\cdot000057 \times t)}$. This expression is, however, only an approximation, for the co-efficient of expansion is not uniform, but increases with the temperature. The exact value in the case of silver is given by the formula

$$E = \cdot00001809\ t + \cdot0000000135\ t^2.$$

I do not know who are the publishers of Mr. Woodward's book, but that gentleman's address is given in a reply to query 60940, p. 290.—WM. JOHN GREY, F.C.S., Analytical Chemist, Newcastle-on-Tyne.

[61015.]—**Magnets.**—It will make all the difference. The leg with double the quantity of wire will have greatly increased power—not exactly double, but something like it.—E. CONRY.

[61015.]—**Magnets.**—Certainly not. The force of the magnet depends on the number of ampère turns, and if short magnets, it matters but little where the coils are located.—S. BOTTONE.

[61016.]—**Organ.**—I advise "J. H. C." to make his wood pipes of the best material—pine for the sides, back, and front; for the blocks, solid mahogany from tenor C, and from tenor C to CC face them with ½in. mahogany upon good foreign oak or pine, the material to be thoroughly well seasoned, or good results may not be expected. Let your wood be well stoved for two or three weeks before put together. You can cut your stuff out for all your pipes, which will be far much the better. The feet of pipes to be turned out of mahogany 6 or 7in. long from tenor C up, and from tenor C to CC down deal. Have nothing to do with paper tubes, nor yet zinc, but get organ metal for them, which one may do anything with. In regard to the notching, I have seen it done both ways in England and America. I hardly know which is the best. I have seen vertical notches made with a fine tenon saw about $\frac{1}{16}$in. deep, 1in. long, and about ½in. apart for CC, which gave good results—a fine, round tone. Can give "J. H. C." more if he requires, with our kind Editor's permission.—S. ARLIDGE.

[61017.]—**Incandescent.**—I do not know about this being a "German invention"; but I know that an Englishman residing at Southampton has discovered some such device. Whether it is a commercial success I am at present unable to decide. I have been promised a sight and description of it, and live in hopes.—S. BOTTONE.

[61019.]—**Brazing Band Saws.**—An answer to this query will be found in the same number, on p. 278. The method has also been frequently described in back volumes.—SAML. RAY.

[61019.]—**Brazing Band Saws.**—Prepare the ends in the usual way with spelter and borax, and squeeze them together with a pair of heavy tongs made red hot. There is no better way than this.—998.

[61019.]—**Brazing Saws.** — "G. M. W. W.' will have noticed that in the articles on "Amateur Workshop" the very information for which he asks appears in the same number as his query, so far, at least, as writing can do so.—T. C., Bristol.

[61019.]—**Brazing.**—You will find instructions for brazing in the number in which your query appeared, under the head of "Amateur Workshop." There are special appliances for brazing; but they are to be regarded as compact conveniences, rather than necessaries. An ordinary piece of apparatus consists of a small portable forge, comprising a spring circular bellows, worked by treadle placed underneath an iron forge top or table, containing hollowed out receptacles for water and charcoal, and the little hearth in which the saws to be brazed are laid after being bound round in the manner described in "Amateur Workshop." The blast is then directed on the joint, and being concentrated more than in an ordinary forge, there is less risk of burning the adjacent portions of the blade.—J. H.

[61019.]—**Brazing.**—The apparatus used our way for brazing saws is what the blacksmiths call "lump tongs," and the jaws of the tongs are made very thick so as to retain the heat. The ends of the saw are filed down thin, and placed one on the other, which part will then, if properly done, be of the same thickness as the rest of the saw. On this place a strip of thin brass, bind the parts together with thin iron wire. Sprinkle a little borax over part to be joined, then heat the tongs to a white heat, and hold the saw between the jaws till brass is melted. A friend of mine who had no tongs or proper forge has lately brazed some band saws with an arrangement he made himself. He had a small tinpot concern in which he put some charcoal, and cut a notch each side of tin in order that saw (which he held in a little iron frame) might come on the charcoal; he also cut a hole near the bottom of the tin in which he placed the nozzle of a home-made fan, lit the fire and began to blow, and in a few minutes was agreeably surprised (it was the first attempt) to find the saw properly joined. The fan he made some years ago out of wood and sheet iron; it is driven by a set of wood wheels covered with rubber on the friction principle and is self-contained; so much so, in fact, that his dear missus takes it on her lap to blow the fire with instead of a pair of bellows. I must tell you that the beef-tin looking arrangement that held the charcoal had such a scorch as to render it unfit for further service. The man now uses firebrick hooped with a little band of sheet iron, but still sticks to the same little fan.—ROUGE GORGE.

[61020.]—**Electrical Paper.**—Soaking the paper in nitrate of silver solution might do, if it did not destroy the fabric of the paper altogether. For the surface conductor, rub the paper well with plumbago dust if you want a partial conductor, or paste thin tinfoil on to it for an entire conductor. For a partial conductor, note also the tinned paper with which tea-packets are lined. — E. CONRY.

[61021.]—**Induction Coil.**—(1) No. 20 iron wire; (2) No. 18 silk covered; (3) No. 36, if a thick, fat spark be desired; No. 38, if a longer, but thinner, spark is the desideratum, about 1lb.; (4) two layers of good, stout cartridge paper, laid on so as to break joint between each layer of secondary; nearly $\frac{1}{16}$ thick between primary and secondary; (5) you will probably get 1in. spark.—S. BOTTONE.

[61021.]—**Induction Coil.**—(1) For core, 20in. wire. (2) For primary, 18 single silk-covered; double-covered may reduce the efficiency of the coil, as the thick insulation increases the distance between the wire and the core. (3) For secondary, 36 or 38 silk-covered; the quantity cannot be stated; it is usual to fill the reel. (4) Having thoroughly baked the secondary before winding, and painted each layer with shellac varnish, one thickness of paraffined paper will be enough; between primary and secondary, two thicknesses. (5) Length of spark depends upon length of secondary and battery power. 1in. per mile is the result usually expected, but not always reached. Efficient insulation of the secondary layers is the main thing.—BOBADIL.

[61023.]—**Reducer.**—I have found the following formula very good: Ozone bleach, 1oz.; water, 4oz. It is rapid in action, and must therefore be carefully watched; the negative should be well washed afterwards.—GLAUCUS.

[61023.]—**Reducer.**—I have used most of the reducers, and find none to equal the one sent out with the Paget plates. Not having their instructions in front of me, I can only give a brief outline of the process which I believe was introduced by Mr. Farmer. Immerse the negative in a solution of ferricyanide of potash, leaving it for, say, three or four minutes, drain or blot off with bibulous paper the surface moisture; then, by means of a camel's-hair brush dipped into a weak solution of sodium thiosulphate, touch out those portions that have to be removed or reduced; and at the same time remembering that the stronger the solutions used the more intense their action upon the silver particles with which the developed image is composed.—A. TREYER EVANS, Newport, Mon.

[61024.]—**Sensitising Drawing Paper.**—The paper is first of all floated upon a bath of plain albumen made as follows. Beat up to a froth the whites of six eggs, allow to settle, mix with one drachm of alcohol, and filter into the dish to be used. When the sheets are dry, float upon the following bath, which, of course, must be kept hot during the operation, as the gelatine will set if allowed to cool: ammonium chloride, 150gr.; gelatine, 10gr.; water, 10oz. Dry the sheets thus coated with the warm gelatino-saline solution, float upon a 50 or 60gr. bath of silver nitrate, and dry. This last bath renders them sensitive to white light, therefore should be conducted in a yellow light; ruby glass will do, but yellow is sufficiently non-actinic, and at the same time allows the maximum of light, so that the sheets can be manipulated more easily. Difficulty will be found in floating upon the gelatine solution, as air-bubbles prevent it uniformly covering the paper. This may be overcome by "scraping" the sheet over the edge of the dish.—A. TREYER EVANS, Newport, Mon.

[61025.]—**Platinotype Printing.**—Yes, the quality of daylight does affect printing by this process, as ferric oxalate has its maximum intensity between the G. and F. lines of the solar spectrum —*id est*, the blue portion, whence it is more sensitive to the blue rays than any other part. In winter, when the sun is near the horizon, his rays have to penetrate a much greater stratum of atmosphere than in summer time, when it will be seen that the atmosphere cuts off the rays of high refrangibility: hence a relative diminution of blue-violet rays, and consequently a longer exposure is necessary. It may be noted that feebly actinic light is favourable for printing from weak negatives, and vice versâ, when the picture is contrasted and harsh.—A. TREYER EVANS, Newport, Mon.

[61026.]—**Smoking Fish, &c.**—The sawdust used is either damp or spread out too thinly. Try a thicker layer, and start the fire with some sticks. —W. H. S.

[61026.]—**Smoking Fish, &c.**—Steep a small quantity of the sawdust in a saturated solution of saltpetre, allow it to dry, and then mix with the plain. I have forgotten the exact proportions, but these will be easily found by experiment. Say you dissolve two-pennyworth of saltpetre in half a pint of water, and then put in a good handful of sawdust, you will find this when dried about right for half a pail of plain sawdust if well mixed. If it burns too fast add the plain; if too slow, add the salted stuff, until you have a nice slow smoulder in a mixture.—H. S.

[61028.]—**Etching.**—Hydrofluoric acid which I have, sold by Townson and Co., bites easily enough if the glass is clean—i.e., free from oil or grease or other foreign matter, which may be wax. If you want to make your own acid, take some fluor spar (blue John is one name) and put it into a beaker, then pour strong sulphuric acid on to it; then put the glass to be etched face downwards over the beaker and leave it. It will do its work and eat the beaker as well. So if you like, use a gutta-percha vessel instead of glass.—R. S. T.

[61030.] — **Cleaning and Tapping Brass Nuts.**—Pass a bolt through a dozen or more at a time, screw up tight face to face, and plane off all together, setting the angles with a gauge. Tap the threads by hand.—J. H.

[61030.]—**Cleaning and Tapping Nuts.**—Have a special tap for these, having room at the small end for, say, half a dozen nuts, put tap in lathe, and run nuts right off tap. Take tap out and repeat. You must face each up separately on a stud fixed in chuck. Now thread a lot—say eight or a dozen—on a steel screw held between milling centres on machine, and plane each lot of flats, having a division plate on screw for angles. T. C., Bristol.

[61030.] — **Cleaning and Tapping Brass Nuts.**—The best method that can be adopted is—Tighten as many nuts under the clamps of the tool rest as possible, then put a mandrel through them the same size as tapping hole to see if they are square with the centres, then get a tap true in the bell chuck and put a train of wheels on as though you were going to cut a ½in. pitch screw, then proceed at slow speed with back gear. Get a long taper tap. For cleaning them, put as many as you can on a screwed mandrel and put the mandrel between the centres of the shaping machine, and then proceed.—WALLACE NEWLAND.

[61031.]—**Brass Boiler.**—How on earth can anyone answer this question when even size, to say nothing of shape of boiler, is omitted?—T. C., Bristol.

[61032.]—**Winding Dynamo.**—TO MR. BOTTONE.—Theoretically, a dynamo double the size of any given one gives 32 times the current. Practically, we may say it should give about 16 times the current. Hence, if you double the linear dimensions of the dynamo described in my book, "The Dynamo: How Made and How Used," you should be able to light easily 64 5c.p. lamps. You would want No. 16 wire on the armature, between 2lb. and 3lb., and No. 12 on the fields, say about 20lb. It would need from 1 to 1½H.P. engine to drive it. —S. BOTTONE.

[61033.] — **Ampere's Theory.** — Neither Ampère himself nor anyone else explained the origin of the imaginary currents. All that Ampère did was to show that if such currents existed they would explain magnetic actions; that is to say, as he saw certain results from currents circulating around helices, he said that the same results would arise from infinitesimal molecular currents, if such existed. Others assume that they do exist, and profess to explain magnetism: they assume that they are part of the constitution of matter, or, in other words, they create a form of matter which will suit their purposes. This is the regular process of hypothesis, and it is always going on. Sir W. Thomson, for instance, who never saw or handled a particle of "ether," says that it acts like a jelly, filling space; then others, equally ignorant whether such a thing as ether exists at all, say that it is a jelly-like substance, not having any of the other known properties of matter; then someone says that electricity is probably the same thing as ether, and a lot of "professors" begin to calculate out what other properties must be attributed to this precious jelly, in order to explain the facts of electrical action. They have a perfectly unlimited credit on the Bank of Imagination, so they need not restrain themselves. Having thus constructed a perfectly imaginary matter, and given it whatever properties they choose, they are good enough to present it to the world as explaining all about electricity. Why not? If any difficulty arises, they have only to tack another property on to their jelly, and people will swallow it.—SIGMA.

[61034.]—**Boiler.**—The feed-valve is exactly like a stop-valve, except that the spindle is not fixed to valve, and so can only press it down, but is unable to lift it—the water does that. You, therefore, screw the spindle down, so that valve can only lift a certain height and so regulates quantity of water to that boiler, there being probably more than one, and a safety-valve on supply main. Only one pump required to economiser, and that must be engine side of economiser.—T. C., Bristol.

[61035.]—**Observatory Shutter.**—I do not quite understand "C. T.'s" query. If he will send sketch to 28, East Claremont-street, I will try to help him.—H. A.

[61037.]—**Marking Ink.**—TO MR. SAMUEL RAY.—The only further information desired is as to the best mode of thickening the ink, so that it may

not run when used with a pen on linen. It is supposed that gum might interfere in its permanency, and I am in doubt whether more gelatine may be added without adding a proportionate quantity of bichromate of potash.—L.

[61038.]—**Ampere's Theory.**—Prof. Marco Felice propounded (1860) a theory to account for all the "imponderables," which briefly is as follows:—"Each atom possesses motion on its axis; this motion manifests itself, according to its direction, as heat, light, electricity, or magnetism. When the atoms are rotating all in the same direction, and with their axes all directed to the same point, then, as the electric current is flowing in the same direction, magnetism is displayed at right angles to this flow, or, to speak more correctly, at right angles to the direction of the rotation of the particles." I shall be happy to lend J. J. H., Prof. Marco's work, if he cares to advertise his address; the work is in Italian.—S. BOTTONE.

[61039.]—**Electric Light Battery.**—An ordinary double-fluid bichromate will do it as well as almost anything else; but to light 10 lamps for 60 hours should be rather larger than 1 cubic foot, 12in. × 12in. × 18in., so that each would contain two carbon plates, say, 15in. × 5in. each, and three zincs.—E. CONRY.

[61039.]—**Electric Light Battery.**—I believe no battery yet made will, in practice, light ten 15-candle lamps for seventy hours at a stretch; still, although the Daniell cell is low in E.M.F. and rather high in resistance, it would be to this, or some similar battery to which I should have recourse, if I wished to perform the feat regardless of cost. Large cells, so as to contain large zincs, and to expose a large surface of negative element, would be necessary. It would be well to couple them partly in series and partly in parallel, so as to bring the E.M.F. up to the requisite point.—S. BOTTONE.

[61040.]—**Levelling Glass Cells.**—Put in a layer of warm dry sand, and then saturate it with melted paraffin wax.—SIGMA.

[61040.]—**Levelling Glass Cells.**—May I venture to suggest pitch or marine glue for this purpose, as I am told these are used in battery boxes, and that the solutions generally used have no effect on them.—ROUGE GORGE.

[61040.]—**Levelling Glass Cells.**—I should suggest powdered chalk mixed with just as much hot paraffin wax as will consolidate it, and put in hot into heated cells and allowed to cool, or else hot pitch with plumbago dusted over the top after it has cooled.—E. CONRY.

[61044.]—**Band Saws.**—I should think two months a reasonable period; but it depends on what you mean by "life," since you could go on mending *ad infinitum*. I seldom find new band saws run more than two or three weeks at the most without breaking, and after the first fracture they go more rapidly in other parts (seldom in the brazed joints) due to crystallisation; and I should say that after two months there would be little economy in rejointing and continued running of a saw.—J. H.

[61047.]—**Multiplex Copying Ink.**—I have used the following with success:—Nelson's gelatine, 2oz.; water, 4 fluid ounces; glycerine, 8 fluid ounces. Macerate together for four hours, then melt at a low temperature and pour into a shallow tin to set. For the ink, use either Judson's liquid violet dye *per se*, or aniline violet (powder), one ounce dissolved in half a pint of water.—S. HENRY SMITH.

[61047.]—**Multiplex Copying Ink.**—In which number did this "Sigma" (he is evidently not a reader, or he would use another signature) find any mention of "violet methylated aniline"? However, all he need do is to procure some aniline violet and dissolve it in methylated alcohol (he can use spirits of wine, if he likes) and dilute it with water—not much. The writing, when dry and ready for transferring to the "jelly," should have a greenish-gold metallic lustre. The recipe for preparing the "jelly" has been given many times since Vol. XXIX., wherein it first appeared. Briefly, it is one part of good pale glue soaked in water until soft (water to be poured away) and then melted with four parts of glycerine; add sufficient whiting to make it the colour of cream, and a few drops of carbolic acid to preserve it.—SAML. RAY.

THE Mont Cenis and Mont St. Gothard Railway crosses the Alps at elevations of 4,379ft., with ruling gradients of 1 in 33 in the case of the Mont Cenis line, and 1 in 40 and 1 in 38 in that of the St. Gothard. The Brenner and the Semmering Railway have ruling gradients of 1 in 40 to 1 in 43. The railway over the Blue Mountains, Australia, attains the summit by an almost continuous gradient of 1 in 30 to 1 in 33.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last "J. C." has replied to 60592.

QUERIES.

[61048.]—**Electric Conductors.**—I shall be obliged if someone will kindly give information as to size of conductors and leakage of electricity in the case stated below. The main conductor would be 25 miles long, supplied with electricity, conducted to it through branch conductors from dynamos driven by turbines of various power, and at various distances—viz., one turbine of 60 H.P. at four miles from the main; one of 40 H.P. at two miles; one of 30 H.P. at one mile; and two of 20 H.P. each at half a mile from the main; total, 170 H.P. given off at the turbines. The main conductor must not be coated with a non-conducting substance, but the branches may be. Required to know—1. The best material, size, and shape of such a main conductor for supplying the motors of a tramcar or train. 2. Sizes and kind of branch conductors (coated) for conveying electricity from dynamos at the turbines to the main conductor. 3. Loss of power from that given off at the turbines; *a*, through or at the dynamos; *b*, leakage from the branch conductors; and, *c*, leakage from the main conductor (or formula for *a*, *b*, *c*), so that I may calculate the available power at the main conductor. The terms I have used above will probably betray my ignorance in electrical engineering.—ACIER.

[61049.]—**Electric Lighting.**—To F. L. STRIFFLER.—I read your description (26479, No. 1,129) of the "Scrap Daniell cell" with interest, and should feel much obliged if you could help me in the following:—For some time past I have been using a 5 volt Woodhouse and Rawson lamp to light my bedroom, worked by four small accumulators, so giving it 8 volts. I charge the accumulators by means of 6 Daniell cells, consisting of small zinc rod in porous pot, 6in. high, inside a glass jar containing a copper cylinder. On reading your letter I coupled up the six Daniells in series and tried the effect on the 5 volt lamp, but it did not even turn the colour of the carbon. I have never been able to get more than 4 or 5 minutes' work out of the accumulators, after having charged them each for twelve hours with three of the Daniells—i.e., three Daniells on each of two accumulators for twelve hours, and then on the other two for the next twelve hours, and the Daniells are always getting out of order. Now, should I get a better result if I converted them into "scrap cells," or would the six so converted be strong enough to work direct, dispensing with the accumulators altogether? I forgot to say that my porous pots are very narrow, only about $1\frac{1}{4}$in., How is the zinc kept from touching F (in your drawing) by a wooden cap? If I make the outside cell of copper by soldering a bottom to it, could I use ordinary solder or would it be affected by the sulphate? I quite agree with you about overworking lamps slightly, and have always found it economical where battery power is used. I may mention that after working for a day or two I always find that the liquid in the porous pot has sunk below the level of the outside jar liquid. Can you explain it? It is more marked in narrow pots than in wider ones.—HARRY.

[61050.]—**Pigs.**—My house is in a public street, the back yard of which I have kept pigs in for ten years without any complaint from the neighbours; but the other day a friend living opposite told me he could remove my pigs any time he wished as they were too near the houses. Is this true? If so, how many yards should they be from any house? My yard is 15 yards long and sty very clean. Also, if he failed to get the inspector to remove them, could he go to anyone higher than him and demand it?—ONE WILLING TO LEARN.

[61051.]—**Lens Shutter.**—I use a large French portrait lens in studio. I want to fix a flap shutter to use regularly instead of cap; but the hood of lens is 6in. diam., and to fix it on this would make such a ponderous affair, as well as very heavy. If I do away with hood, and fix the flap shutter on the lens where the hood screws on, will it answer and work properly?—COUNTRY PHOTOGRAPHER.

[61052.]—**Accumulators.**—To "SIGMA" OR OTHERS.—Can "Sigma," or any other of the correspondents of the "E. M.," kindly give me any rough rule for judging the amount of current necessary to be put, by the regular process of reversal, through accumulators formed of the plain lead plates, in order to produce a certain discharge when the practical maximum of formation is reached—some such rule, for example, as: If 2,000 amp. hours are put through, assuming the best treatment, they will then be in a condition to return a discharge of 100 ampère hours upon receiving a charge of the same quantity, + the necessary margin to allow for loss in the accumulators. I have not been able to get any data as to the amount of electrical current that it will take to form a set of accumulators to give, say, 80 ampère hours, and, consequently, cannot calculate what the approximate cost of forming any particular set would be. I see in *E. Review*, 13, 377, "To transform by electrolysis 1 kilogramme of lead into binoxide of lead, it requires 1,855,000 coulombs of electricity. . . . The plates of the + electrode are formed of two parts of lead and one part of minium; therefore, in order to completely peroxidise 1 kilog. of the + electrode, it would require 1,425,000 coulombs of electricity"; but this does not say what charge such kilog. would hold if so treated, or what discharge it could be got to give. Again (also from *E. Review*): "However, when the external approaches the internal resistance, the E.M.F. of the cells will be reduced, and if the external was made = to the internal resistance, the E.M.F. would be but half that indicated when the external resistance is high." How is this? I thought the E.M.F. of an accumulator was always 2 volts—in fact, I understood from more than one source, including the "E. M.," that the E.M.F. of any cell depended solely on the materials composing the two plates, and the composition of the battery acid as representing electro-chemical actions of various kinds, each of which produced its own particular E.M.F. I could understand the "total output" varying with the external resistance. Will someone be good enough to enlighten me?—TORBAY.

[61053.]—**Preparation for Mixing Bronze Powders.**—Will someone kindly give the composition of the preparation used in mixing bronze powders, such as Judson's gold paint? Also composition of any kind of varnish to protect the gold paint when used for outside work?—SHODOONKEH.

[61054.]—**Magnets and the North Pole.**—Why do magnets always turn towards the north in preference to the other points of the compass when floated in water or nicely balanced in air?—SHODOONKEH.

[61055.]—**Varnish for the Bright Parts of Bicycles.**—Anyone who can give the composition of a varnish for varnishing the bright parts of bicycles to prevent them from rust will be conferring a boon on some readers of this paper, not excluding—SHODOONKEH.

[61056.]—**Connection of Hasp and Staple of Door with Galvanic Battery for Shocks.**—To MR. BOTTONE, MR. LANCASTER, AND OTHERS.—The door of my laboratory, being fastened with a hasp and staples, is always invaded by the curious when I am absent. I wish to prevent them doing so by giving them a shock whenever they lay hands on the hasp to open the door. How shall I proceed? Shall I connect the staple of the post with the carbon and zinc wires of the battery, so as anyone putting on or taking off the hasp will receive a shock, or can I fix an electric bell, and connect the staple with it by means of a wire from a burglar alarm, made to form contact when the door is fastened, or lead two wires to the staple from a charged Leyden jar or magneto-electric machine? In any case I shall be glad to receive details of procedure. What cells will be best—Leclanché or bottle bichromate? What size and how many cells shall I form the battery of, size of wire, &c.? I shall be glad to be able to regulate the current.—SHODOONKEH.

[61057.]—**Steam Launch.**—I have a sailing yacht 22ft. 8in. stempost to sternpost, and 8ft. beam, displacement, 4 tons, which I wish to convert into a steam launch to run at about 7 knots an hour. I propose a single high-pressure engine, and want somebody to help me as to dimensions of boiler, engine, and propeller, and show how each result is arrived at.—ITCHEN.

[61058.]—**Glass Embossing.**—I am an engraver and thoroughly understand the art of etching on copper and am desirous of learning glass embossing. I have tried many processes as described in various encyclopædias, &c., but with no satisfactory results, the varnish given for the protection of the glass having in every experiment "lifted" bodily off the face soon after the application of the acid. Can any of your readers tell me the cause, or help me in any way to overcome the difficulty? If so, I shall be very grateful.—PERSEVERANCE.

[61059.]—**Photography.**—Thanks to "B.SC." for his reply to my query; but he only says Dallmeyer R.R. and Ross R.S. are equal in angle, without saying what the angle is. Can he or any other expert photo. give me an opinion as to comparative quality of the above lenses and Lancaster's new "Rectigraph"? I should prefer the wet collodion process; but for me it is almost impossible, as, travelling in the interior of Asia Minor, I sometimes do 12 hours' journey on horseback, and have to carry my baggage in pack-saddle. A tourist camera and a few plates is all very well, but bottles are troublesome companions on such a journey. I have just found a German work by Schnauss, in which he recommends, after washing the gelatine emulsion, to re-dissolve and pour out on a glass plate very thin, allow to dry, scratch together, and keep in dry form till required. Has anyone tried this? If so, what result?—HAZIR-IM.

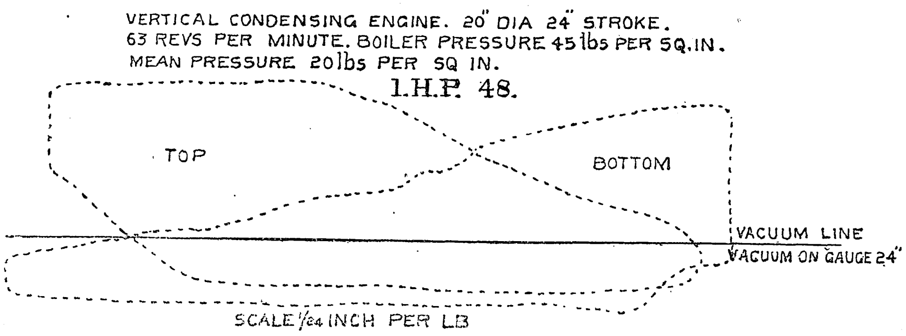
[61060.]—**Gut v. Leather Bands.**—Which will give most driving power—two bands of $\frac{5}{8}$in. gut running in double-grooved pulleys, or one 1in. flat leather belt on flat pulley, the above to be used for the slow motion of a foot lathe? Also, is there any kind of fastening for leather belts which can be attached and detached with the same facility as the ordinary hooks and eyes for gut?—OMNIUM GATHERUM.

[61061.]—**Engine and Boiler.**—Can any kind reader inform me if steam from a locomotive engine would do to test a small boiler with to turn it on gently, and what amount of pressure would it stand with safety? It is cylinder shaped, 3ft. long, 14in. diam., made of iron $\frac{1}{8}$in. thick. It is well riveted, and a $\frac{5}{8}$in. iron stay goes from end to end. I have a small horizontal engine, $3\frac{1}{4}$in. cylinder, 5in. stroke, 16in. flywheel, 4st. weight. What size circular saw would be suitable for it to drive to split beech wood 7in. square?—NOVICE.

[61062.]—**Cheap Dynamo.**—To MR. BOTTONE.—As I am unable to get the numbers you mention in Edinburgh, I have got your book on the dynamo; but should like something, as I stated in the last issue, that would be of more use than just experimenting. Would you kindly describe a good way of lighting up an office 44ft. sq. on the primary system? Would it do to charge secondary from primary cells?—C. GUNN.

[61063.]—**Wheat Straw.**—Will some chemical friend kindly tell me how to make short pieces of straw permanently flexible? Damping with water answers for a time, but they soon become dry and are brittle again.—A. B. C.

[61064.]—**Vertical Engine.**—I shall feel obliged if any of your readers will kindly inform me how to increase the power of the vertical condensing engine; diagrams and particulars I inclose. I cannot increase the boiler pressure; and there is no room in chest to put on a cut-off valve.



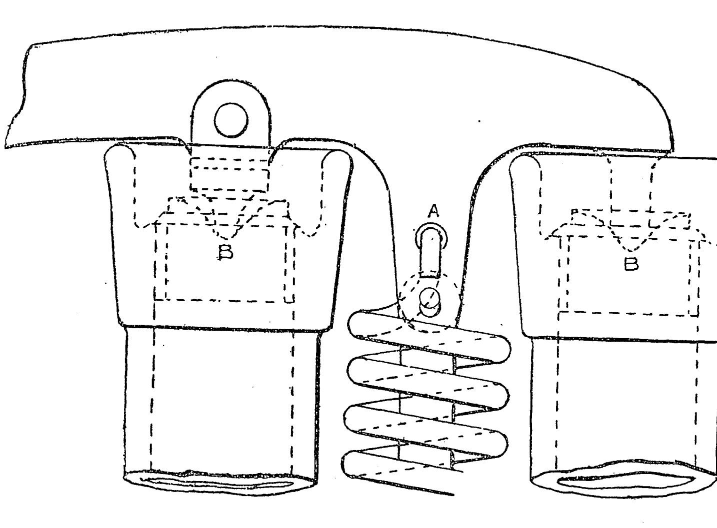
The pressure in the cylinder is only a little more than half of that in boiler. This I attribute to throttling by the governor, which is one of the old type. This I thought of replacing by a high-speed one, and shall be obliged if any of your engineering readers will kindly give opinions on this point and any others that may occur to them, the object being to increase the power and save fuel. Present consumption of good coal is 6lb. per I.H.P. per hour. Single-acting vertical air-pump, 10in. dia. by 12in. stroke. Is this large enough?—J. W. R.

[61065.]—**Electrical.**—Will some reader kindly tell me how to solve these two problems? (1) A sphere is charged with a given quantity of electricity. Show that the work done in moving a particle from an external point to an infinite distance is $\frac{a m^2}{2(f^2 - a^2)} - \frac{Q m}{2 f^2 (2 f + a)}$, Q being the charge, a radius of sphere, f the distance of the point from the centre of the circle. (2) An insulated, but unelectrified, sphere is brought near an electrified particle. Show that distance of line of neutral electrification from the point is $\sqrt[3]{f (f^2 - a^2)}$. Notation as before.—NO SIG.

[61066.]—**Electric Lighting.**—I have now made a dynamo that will work, thanks to ENGLISH MECHANIC friends who gave some useful information through your columns. I now want to arrange wires and lamps to light up the house. Suppose I have 20 lamps, each 20c.p., what size of wire should I use for the leads, or main wires, and will it do to have the main wires of the same thickness from beginning to end? What size of wire should I use from the leads to the lamps? If I want to light, say, 10c.p. lamps off the same main wires, should I use a finer wire than for a 20c.p., and of what size?—BRIAN BORU.

[61067.]—**Casting Name Plates.**—Will some kind friend tell me how to make moulds for casting name plates, same as used for boilers, engines, &c., in brass?—CEDAR.

[61068.]—**Ramsbottom Safety Valve.**—I have seen these constructed with the suspension point of the spring somewhat above the bearing point of lever on the valves; but have recently seen the statement that it should be about the same height—that is, in the sketch



herewith, the point A should be level with the points B B. Is this correct, and, if so, for what reason should they be so placed?—W. H. THURLOW.

[61069.]—**Telegraph Wires.**—When going over Glossop Moor some time ago, I noticed, in the open and exposed situations, some metal flaps suspended on the telegraph wires. Are they for any purpose connected with the telegraph linemen, or are they for preventing the lodgment of snow by the wind causing them to keep the wires in a constant state of vibration?—W. H. THURLOW.

[61070.]—**Lathe.**—Would "J. H." kindly say how to make a reversing gear to a screw-cutting lathe? I don't see anything about it in articles which appeared lately.—A. F. SHAKESPEAR.

[61071.]—**Planing-Machine Tools.**—Will "J. H.," or some other reader, kindly tell me why curved right and left-handed tools while cutting vertically will not lift properly during the return of table, but bind hard against the work, causing gashes. I have one right-handed tool which lifts all right; but its pair will do nothing of the sort. I find I am not the only one who has experienced this defect in this town; but no one can tell the cause or the cure. At present I have to lift the tool-box by hand during the return to avoid damage.—A. F. SHAKESPEAR.

[61072.]—**Motor for Bottle Brush.**—I am desirous of getting a machine that will rotate a spindle carrying a brush for washing bottles. What will be the relative cost of an electric and a water motor? I do not know how to estimate the water pressure available, and I have applied in vain to the officials of the water company for information on this point.—S. H. W.

[61073.]—**Electric Boat.**—I am going to make an electric boat, but before commencing I would like to have the following queries answered. (1) What would be the best dimensions for one 2ft. long? (2) Would the motor described on Oct. 1st do if made less (it is rather discouraging to make one like this when we hear that "it will not work, much less drive a boat")? (3) Would it be better to use secondary, or primary batteries? I may say that I have a fairish knowledge of electricity.—E. D. C.

[61074.]—**Organ Tremulant.**—Would some kind correspondent give me particulars to make a tremulant for a 10-stop pipe organ, which will have good effect, and whether the wind trunk is the best place to fix it? My pressure of wind is 3in. A small diagram would be of valuable advantage, if some of our organ students would oblige—BELL DIAPASON.

[61075.]—**Magneto-Electric Machine.**—TO MR. BOTTONE.—Could you or anyone kindly give me a diagram and description of a commutator for a small magneto-electric machine, to give a continuous current required for small experiments where no battery can be used?—AMATEUR.

[61076.]—**Typewriting Ribbons.**—Can anyone inform me how to manufacture these, and whether the aniline red and blue can be used as well as the purple? When one expends such a sum as £20 on a Caligraph or Remington, he ought not to be always dependent on the makers for the use of it, as is now the case, by having to buy his ribbons from them.—J. W.

[61077.]—**Sympathetic Vibration.**—Prof. Tyndall in his work on "Sound" says that if two clocks with pendulums of the same period of vibration be placed against a wall, and one be set going and the other not, the tick of the going clock will so act on the other as to set it going when sufficient impulse has accumulated. Has anyone repeated this experiment? I have been trying very carefully, but with only partial success.—S. H. W.

[61078.]—**Red Rust from Sheet Tin.**—Can any of your numerous correspondents inform me whether rust can be removed from sheet tin with anything like cleanness? Perhaps some reader of the "E.M." knows of some recipe for same?—J. C. MORRIS.

[61079.]—**Lathe.**—In turning studs or shafting after I have finished with scraper, the surface is all scratched. It seems to me the fault is in the tool, for it goes too deep in some places, so that the scraper does not take it out. Perhaps some kind reader will explain.—BURGH.

[61080.]—**Small Organ.**—Will anyone kindly give me the most suitable scale for a barrel organ with 18 levers, and for sacred music? I have thought of having it in C. This applies to what reeds to use only.—J. C.

[61081.]—**L. and N.W. and G.W.R. Co.'s Engines.**—Would any reader kindly inform me how many engines the above companies have got, and also the approximate cost of a G.W.R. double bogie carriage?—KNOCKHAM.

[61082.]—**Embryo Rats.**—Can some correspondent inform me if I can dissolve the shell that covers the above, and how to determine the age?—W. S. S.

[61083.]—**Axles Breaking.**—Would Mr. C.E. Stretton kindly say if his patent system of crank-webs is in practice somewhere? Meanwhile, as he is one of the principal officers of the A.S.R.S., would he please to say if the president of that society has received my letter of the 31st July last, of which I received no acknowledgment? In several of his writings, Mr. C.E.S. said: "There will be growing flaws." Admitting the existence of flaws in the metal, is it impossible to prevent their growing? Should a means exist of preventing it, would it be of any value? Although the thing may appear impossible, let us suppose that there exists a means of rendering axles, cranks, webs, piston and connecting rods, rails, &c., unbreakable under the circumstances in which they actually break, would it deserve attention?—CH. RABACHE.

[61084.]—**Fireclay.**—Would any reader who knows kindly give the chemical composition of the best British fireclay, such as is used for retorts, crucibles, bricks, &c.? Where is it to be found?—M. E.

[61085.]—**Flameless Combustion.**—Some time ago, Mr. T. Fletcher, of Warrington, made experiments on flameless combustion at Owens College which were very successful. Can any fellow reader say if there has been any industrial application of the process, and what were the results?—A FOREIGNER ANXIOUS TO KNOW.

[61086.]—**Wimshurst Electric Machine.**—I thank Mr. J. W. for his answer to my query (No. 60780, Oct. 29), but I am sorry he did not reply fully. I have got the pamphlet on the Wimshurst machine by Mr. Thos. Gray, and I have been fully satisfied with the results obtained from my machine after following the instructions therein contained; but, if possible, I would like to arrange my machine in such a manner as to obtain a shock from it similar to that got from the medical or shocking coil (this part of my last query Mr. J. W. omitted replying to). Could such a result be obtained from it, and, if so, how shall I arrange matters? Could a coil be attached somewhat on the same principle as the electro-medical apparatus? Can any reader enlighten me?—ELECTRIC.

[61087.]—**Metallic Fire-Alarms.**—TO MR. BOTTONE AND OTHERS.—I want to make some electrical fire-alarms, based upon the principle of the unequal expansion of two metals, for my own use. What metals are used and how arranged to make them very sensitive?—ELECTRICAL.

[61088.]—**Dynamo.**—In the MECHANIC for April 23rd Mr. Bottone gave dimensions of two dynamos. I am making one on size of the smaller machine, a 50c.p. Instead of castings I am constructing it of wrought-iron, and the field-magnets are 1½in. diameter instead of 1¼in. I want to know if I shall have to make any alteration in the quantities of wire given or the speed, so as to give 60c.p., which I should like to get instead of 50c.p. Will you kindly give sketch of the method of joining coils on armature as I am unable to find out? I have been told that one end of a coil is joined at the pulley end, to the end of the coil opposite, and then the other ends of the two coils are fixed to two sections of commutator, which are also opposite each other, but should like to be sure.—ST. ANDREW'S CROSS.

[61089.]—**Coils.**—Which of the undermentioned coils will give the strongest shock?—First coil, primary ¼lb. B.W.G. 20, core 4in., secondary ½lb. 38; second coil, primary four turns of 18 B.W.G., core 4in., secondary ½lb. 38; third coil, primary ½lb. 24, core 4in., secondary ½lb. 36; excited with one battery.—R. M.

[61090.]—**Electric Scarf-Pin.**—TO MR. BOTTONE AND OTHERS.—I have tried the semi-dry sulphate of mercury battery with the above, but find that after working well for about a quarter of an hour, it dims and ultimately extinguishes. Is it because the batteries are not large enough (I use two with plates 4in. by 1¾in., and the lamp requires about two volts), or that they get dry? Or do I not use enough paste (about ¼in. thick)? I shall be obliged for any suggestion on the subject.—AERONAUT.

[61091.]—**Curious Phosphorescent Insect.**—While sitting in the dark in my garden one night early in November, my attention was attracted to a small luminous object in gradual motion near my feet. I found it to be an insect about 1in. long, and as big round as an ordinary pin. It had about a hundred short legs, and its back was curiously raised or "humped" in the middle. I brought it indoors, and found that in the dark it glowed most perceptibly, and as it wriggled about it occasionally radiated sparks of phosphorescence. Can "F.R.A.S." or some other naturalist give me some information as to the singular creature I have described?—W. E. D.

[61092.]—**Hot-Air Motor.**—TO MR. SEAL.—Having made a small dynamo, I should like to make a hot-air motor, as illustrated on p. 148 of "Ours" of April last. Will you please give dimensions of cylinders suitable for driving the same? I think half-man power would be sufficient.—S. HEVEY.

[61093.]—**Hexagonal Nuts.**—I would be much obliged if any readers of the MECHANIC could inform me where I could obtain an absolutely correct list of Whitworth's standard sizes for hexagonal nuts.—BEN BOLT.

[61094.]—**Æolian Harp.**—I have an Æolian harp for repair; will some correspondent give me a little instruction? There are twelve pegs to pull up the strings, but only one bridge. Ought there be two—viz., one at either end? Should the strings be all of gut, or are there some wire-covered ones? How is it tuned—that is to say, in thirds, fifths, or one note after the other—and in what key?—COUNTRY WATCHMAKER.

[61095.]—**Incandescent Light.**—I am wanting to light my two shop-windows with the incandescent light for Christmas. I should want about 24c.p., and wish to light them by batteries. Would Mr. Bottone or Mr. Eaves kindly tell me how many batteries I shall want, and what sort, and how to make them? The lights would be lit for about three hours.—NO SIG.

[61096.]—**Organ Building.**—I am building a small organ containing open diapason 44 pipes, dulciana 44 pipes, clarabella 44 pipes, stop diapason (bass) 12 pipes, and I wish to arrange it so that the stop diapason (bass) will be acted upon (i.e., either opened or closed) by any of the treble stops, so that whichever treble-stop is being used it will appear to run through to CC. I see this plan adopted by organ-builders, but do not know how it is managed. I should be glad if some kind contributor would favour me with a sketch of the arrangement of slides or other required mechanism.—PEDAL.

[61097.]—**Coil.**—Have made a coil two layers No. 24 and 4oz. 38 silk-covered, insulation between each layer

one sheet shellac-varnished paper. Am driving it with a pint bichromate battery, two carbons, one zinc. I want it to give an irresistible shock, but it does not. Can it be expected? Would a 3in. square condenser make sufficient difference, have no room for larger? Will some kind reader come to my aid?—NOVICE.

[61098.]—**Invalid Carriages.**—How can a person whose legs are both useless steer one of these, and at the same time propel it himself by means of two hand-levers? I have heard it is done by means of a kind of swivel handle attached to one of the hand-levers. Can anyone kindly tell me how this works?—COTTON.

[61099.]—**A Rule of Grammar.**—I am anxious to obtain the opinion of the readers of "E.M.," especially the philological ones, upon a rule of grammar. Does the verb "to be" always take the same case after it as it has before it? Should we say "It is I," or "It is me." "That is him," or "That is he," or are both modes of speech correct? Strict grammarians abhor such forms of speech as "It is me," while custom certainly favours this expression. When the monks of Rheims, "Regardless of grammar . . . cried 'That's him,'" it has often struck me if grammar did not agree with them. So much the worse for grammar; custom certainly does. This fighting against custom appears to me to be absurd. The grammarians among our Anglo-Saxon forefathers fought equally hard, I suppose, against the dropping of inflexions, and regarded those who disused them as beneath contempt, and yet custom conquered, and the inflexion only survived in a very modified form. Will anyone assert that "you was" was bad grammar in the latter part of the 18th century, when, if I mistake not, the best authors employed it, and I have often wondered why it fell into disuse. It appears to me that grammar is only a theory constructed to describe, arrange, and systematise spoken and written language, just as logic systematises modes of thought; but that as we never think in syllogisms, so we never speak with the rules of grammar before us, and that modes of speech are no more to be governed by the hard-and-fast rules of grammarians than modes of thought are by the fancies of the school men.—DOCTOR MEDICINÆ.

[61100.]—**Thin Steel Pipes.**—Could any of your numerous readers kindly give me any information as to steel pipes, or where I can find information on the subject? I would also like to know if they are used to any extent in England, and where?—F. H. S.

[61101.]—**Stars Visible from Bottom of Well.**—What stars would be visible from the bottom of a well in the daytime and during an eclipse of the sun in our latitudes?—FACIEBAT.

[61102.]—**Bending Beech.**—I have a quantity of thin strips of Beachwood $\frac{1}{8} \times \frac{5}{8}$ to bend in circles of 5in. Which is the best way to proceed?—S. HEVEY.

[61103.]—**Bath Chair.**—Can any of your readers furnish a rough drawing of an invalid's bath chair, to double up? I only want sufficient indication to make a sketch for me to work from, as I can understand the principle, but have no opportunity of getting the proper distances of the bolts, &c.—S. STEVENS.

[61104.]—**Steel Band.**—Will someone say what is the smallest size pulley I can with safety run a band 2in. broad and 32in. thick? It has to do work somewhat after the manner of a band saw, and should like to run it on 4in. and 12in. pulleys. Length of band 7ft., and as it is somewhat costly I fear to destroy it on too small pulley.—BAND.

[61105.]—**Exhaust Pipe.**—I have a 4H.P. vertical boiler with exhaust pipe from cylinder opening into chimney. When engine is started the water from exhaust comes down and puts out the fire. The same thing occurs when steam is drawn off for boiling water. There is no hollow in exhaust where condensed water could lodge. Can any correspondent tell me the cause or suggest a remedy? Would there be draught enough if exhaust was removed from chimney?—DOCTOR MEDICINÆ.

[61106.]—**Cheap Disinfectant.**—Half a drachm of nitrate of lead dissolved in a pint of boiling water to be mixed in a pail of water in which two drachms of common salt have been dissolved. Will someone kindly say if the above ingredients will keep mixed as one powder, and be equally effective if the mixture be simply dissolved in water as wanted? If so, it would be more simple to weigh up a quantity of single powders and keep for use as wanted than to make up a quantity of double powders. An expression of opinion as to the value of the above for sinks, drains, &c., would be valued. Also information as to the compounds formed by the mixed solutions.—SANITARY.

[61107.]—**Small Coils.**—Will Mr. P. Ward or others inform me what is the smallest section-wound spark coil I can make? I wish to use No. 40 wire as secondary. Should the primary be wound in the partitions or grooves? What number wire should be used for primary, and how many layers? When the secondary is wound in the first groove, how is it brought into the next? Should the sections be the same diameter as the reel ends? The above information would much oblige.—COIL MAKER.

[61108.]—**Oil for Cycles.**—Can anyone give me a recipe for removing the disgusting smell from sperm oil without injuring its quality, or tell me of a suitable oil not liable to become thick and clog, and at the same time free from offensive odour? Rangoon oil is too thin, and when thickened with vaseline is a failure.—LUBRICATOR.

[61109.]—**Defective Brickwork.**—I have a coach-house, on one side of which some of the bricks are both sandy and imperfectly baked. In consequence of this the whitewash is constantly peeling or scaling off, leaving ugly patches of red brick, and in no very long time many of the bricks will evidently perish entirely. Can anyone oblige by informing me how this can be prevented? I have tried thin shellac varnish applied after well brushing the defective bricks, but this coating only lasts a few months. Something seems to be needed which will soak in and combine with the sand and clay of the bricks so as to form a durable surface. As the area of defective wall does not amount to many square yards, a remedy which would be too expensive to use on a large scale will serve my purpose.—CLAYFIELD.

[61110.]—**Dynamo.**—I have a dynamo of a capacity of 100 volts and 50 ampères charging at a distance of 335 yards through No. 5 solid wire, 27 accumulators. The lamps are 52 volts. What is the formula for ascertaining the size and length of iron wire coil to act as a resistance coil so as to run lamps direct from dynamo, and how can the various circuits be coupled so as to charge the accumulators and run the lamps at the same time?—STELLA.

[61111.]—**Hand-Saw.**—Can the contributor of the clever and useful paper on Saw-Teeth (page 233), or any other correspondent, tell us the difference, if any, in form or method of using, between the ordinary hand-saw of our British workman and that of an Eastern one? The teeth of our saw lean at an angle inclined from the handle; as if we refer back to engraving 328, p. 233, and imagine the handle to be on the left-hand side, where the figures are; but the teeth of the saw represented in the large picture, "The Shadow of Death," by Holman Hunt, are leaning in the opposite direction, that is, assuming the handle to be at our right-hand side of above engraving, thus requiring the acting force to be applied in the direction of a pull, and not as a thrust, as in the case of our hand-saw.—T. P.

[61112.]—**Fletcher's Muffle and Air Furnaces.**—These I have had some years—say, four or five, and perhaps more. The other day I had new grids from Fletcher, and they came with gauge of a larger mesh. First time of lighting a blow-down; but on stopping off the air they lighted well, and then—oh! the heat was splendid. Last night I took 550 grains of Brazilian pebble, a piece of large crystal of quartz, and I put this and 2,250 grains of dry carbonate of soda into a platinum cup and put all into the muffle. This was at a quarter-past ten p.m., and at eleven the contents of the P. crucible were all melted—i.e., to the eye. Shortly afterwards boiling commenced, and as the crucible was full I had to lower the heat to prevent boiling over. After a time I put on again full gas, and at 12 p.m. (one hour and three-quarters after starting from the cold) all was quiet, and I stopped all action. On dissolving in water I found all the pebble (quartz) dissolved except a few grains, which are pure white water-worn (like) pieces of quartz. Never have I seen quartz thus treated, which show a crystal properly-shaped left. The fracture of quartz is conchoidal.—Question: Do quartz crystals grow?—R. S. T.

[61113.]—**White Enamel Paint.**—What can I use to rub down the work with that will not discolour it? I have tried the finer pumice or glass paper, but both slightly stain.—DANDIE DINMONT.

ANSWERS TO CORRESPONDENTS.

⁎⁎ All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, *332, Strand, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

⁎⁎ Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

BACK NUMBERS.

WE receive so many queries asking for directions how to make many instruments and appliances which have been fully described in back volumes, that we have compiled a list, which we shall insert in this column at intervals, of those most frequently sent, and as the numbers are still in stock, new subscribers should consult the list before sending their questions.

Bookbinding: No. 613.
Electric machines: Nos. 1,009, 1,025.
Electro-magnets: Nos. 772.
Lacquers: No. 866.
Pattern Making: Nos. 938, 941, 943, 945, 948, 950, 952, 954, 955, 956, 958, 959, 962, 963, 969, 974, 978, 986, 989, 993, 995, 998, 1,000, 1,001, 1,003, 1,004, 1,008, 1,009, 1,010.
Silver-plating: Nos. 1,009, 1,010.
Varnishes: Nos. 478, 619, 675, 723, 775.

The following are the initials, &c., of letters to hand up to Wednesday evening, Dec. 1, and unacknowledged elsewhere:—

LT. BASSET.—W. Coleman.—J. Boggis.—M. W. Stevens.—J. Mason.—J. and H. Grace.—T. Plunkett.—Amateur.—Chaser.—Ajax.—G. H. V.—Short Spark.—W. W. N.—One in a Fix.—Electricity.—Poor Potter.—A. J. W.—A Dunlop Steward.—J. C., Southport.—A Young Fitter.—Sodium.—Milverton.—G. M. S.—J. G. Winton.—N. H.—T. Prince.—C. M. Gaudibert.

G. CHARLTON. (If you refer to Langdon's "Application of Electricity to Railway Working," you will find illustrations of various forms of repeaters. They all work on the same principle—that is to say, the arms of the indicator or repeater in the signal cabin are actuated by the armature of an electro-magnet. To take the simplest form, the heel of the semaphore arm has a contact piece so placed that when the arm is down (signal off), the spring piece attached to the post is free, and no current passes through the wire connecting the post to the repeater. When the arm is raised contact is made with the spring piece; a current traverses the wire, excites the electro-magnet of the repeater, which attracts its armature, and so the miniature signal is put "on" in the repeater.)—C. W. V. (The sun does not put out a fire upon which it shines brightly.)—BRUSH. ("Case-hardening" means technically converting the surface of cast or wrought iron into hard steel The term cannot be appropriately applied to hardening steel, which is "tempered" by having its hardness reduced.)—A ANXSOWS SUBSCRIBER. (The liquid you saw used to harden iron equal to case-hardening was probably made by adding a pint of oil of vitriol and a quarter of a pound of saltpetre to six gallons of water. Heat the iron to a cherry-red and dip as usual.)—W. NICHOL. (The *American Monthly Microscopical Journal* can be had in this country of W. P. Collins, 157, Great Portland-street, W., 5s per annum.)—ZERO. (There is no other substitute than that mentioned. Old vulcanised rubber is mixed with fresh caoutchouc for some purposes. See indices. 2. There is no useful dipping process for nickel-plating. A dynamo is the only cheap agent in the plating of such goods. Battery work is expensive. See indices.)—J. G. J. G. (Surely you do not want an 8 horse-power engine to drive a wood lathe! A vertical boiler would probably be the best to supply an 8-horse engine; but it depends on conditions, which you do not state. 2. We think you can get all the information required about the lantern from Lancaster and Son, Birmingham.)—T. J. L. (If you cannot see back volumes, refer to Molesworth's Pocketbook for the required data. You do not give the maximum gradient, or is the load always on the level? Compressed air would give sufficient power, but how you are to compress it depends on circumstances. Water power would probably be cheapest; but at any rate you must have air-pumps, and some kind of engine to drive them.)—LIMELIGHT. (See what was printed about the ethoxo-limelight in No. 887, 889, 892. The inventor's description appeared in No. 832.)—AN INQUIRER. (You will probably be able to remove the varnish from the globes by means of warm alcohol.)—S. B. R. M. (No, not if silk-covered wire is used; but it is advisable to do so in the case of motors. 2. No.)—PHOTO. (See indices and recent back numbers. You should use a primary battery for such purposes, unless you have a dynamo to charge the secondary battery.)—FRED. (See pp. 73, 93, this volume. You could probably do what you want by drawing air through a coil of pipe immersed in a freezing mixture.)—PHOSPHORUS. (You can keep phosphorus under water and in sealed bottles from which the air has been extracted, provided they are stored in a cold place.)—FRANK GILBERT. (The vibrations of the diaphragm of the transmitter set up undulations in the current, and the vibrations are consequently reproduced by the diaphragm of the receiver. See indices. Du Moncel's "Telephone, Microphone, and Phonograph," Kegan Paul and Co., 5s., will possibly suit you.)—ALICE. (Do you mean the black japan or the light-coloured enamel inside? It would scarcely pay to re-enamel; but a substitute for the japan will be found in Brunswick black.)—W. M. (Glass is frosted by exposing to the fumes of strong fluoric acid. If immersed in the acid it is dissolved. Watch for replies to query 61028, inserted last week.)—PLATO. (See p. 158, this volume, for a horizontal sundial, p. 394, No. 1058, p. 316, No. 924, and many other back numbers.) CLANDEBOYE. (The process of preserving has been frequently described. In addition, the meat is pressed into the tins. See p. 42, this volume.)—EM QUAD. (It would be better to place the flywheel in the position designed, unless the shaft can have another bearing beyond the wheel; but it is really a matter for experiment.)—ALTROY. (There are many recipes in back volumes; but you must say what it is to "cement" before an answer can be given. Perhaps plaster of Paris would do, perhaps Portland cement; and perhaps, again, only solder.)—FRANCOIS. (Given many times. See replies in this No.)—X. (Bicarbonate of soda $\frac{1}{2}$lb., tartaric acid $7\frac{1}{2}$oz., pure chlorate of potash $2\frac{1}{2}$ drachms. Powder and dry thoroughly; mix intimately; keep in well corked bottles. No doubt you would find yourself a great deal better if you lived on simple wholesome food and took plenty of outdoor exercise. At any rate, quinine and saline are not articles of diet, and are useless, if not worse, when taken regularly.)—A YOUNG BEGINNER. (What battery is used? See No. 1088, p. 454, and the indices generally of the last nineteen volumes. 2. Thompson's or Guthrie's; but if you want to go thoroughly into the matter, procure Sprague's "Electricity: its Theory, Sources, and Application," E. and F. N. Spon, 125, Strand, W.C.)—DRYSALTER. (Slater's "Manual of Colours and Drywares," Crosby Lockwood and Co., 7s. 6d., may suit you; but we suspect you are seeking for something which does not exist.)—VARNISH. (Stain and French polish, or procure some of the varnish sold by Mr. Wood, post-master, Blindley Heath.)—ALPHA. (Geikie's "Lessons in Physical Geography," and Huxley's "Physiography," both published by Macmillan and Co. 2. Wright's book on "Poultry," published by Cassell and Co.)—RICARDO. (See indices. Before a remedy can be devised, the cause must be known. You already object to the best. 2. Procure the catalogues of makers who advertised in these pages, or look through back volumes.)—C. E. ABBOTT. (We have not had experience with all; but think that illustrated in No. 928 as good as any.)—IGNORANTIA. (The only way is to be apprenticed, and you are rather too old for that, especially as there are plenty of younger candidates.)—SCOTCHMAN. (If you cannot refer to back volumes, you should procure Graham's "Brass Founders' Manual," 2s., Crosby Lockwood and Co. See indices to Vols. XL. and XLII.)—AERONAUT. (Much useful information about "Analytical Chemist" was given so recently as the last volume. See pp. 421, 443, 465, 486. 2. Reckon 14 cubic feet of hydrogen to each pound weight. If coal-gas is used more will be necessary. We never heard of a "balloon factory," but no doubt a small advertisement in the Wanted Column would produce plenty of offers to construct any number of balloons.)—WOLLASTON. (Remedies for worms given many times; but as you do not say what worms you mean, you had better consult a medical man.)—C. K. C. (You cannot make it. You will find something about it in Vol. XXX. p. 570.)—GAS-FITTER. (Simple photometer described in any textbook of physics. See back numbers. 2. It consists in charging the gas with naphthaline, a wax-like substance put into little reservoirs, which act as carburetters. See indices.)—OMICRON. (Use a pale lacquer.)—PERPLEXED. (See p. 564, No. 988, for something about consumption, and pp. 477, 527, Vol. XXXIII., for new inhaler.)—COIL MAKER. (You require nothing more than a roller on which the bobbin can be slipped, and to which a crank can be attached. That is supported in two end pieces on a base, one of the end pieces being made removable so as to enable the

bobbin to be put on and taken off.)—EBONITE MAKER. (Ebonite is made from indiarubber and sulphur, just the same as vulcanised rubber, but the curing temperature is much higher—up to 350° Fahr. Rather brown than black when cut. Cannot be joined. The tubes must be moulded up before the composition is cured.) — VESUVIANS. (Made of charcoal, saltpetre, and gum water, scented with Cascarilla tincture or infusion.)—BARIUM. (Yes, just the same. Strength will come in time; but you should not practise after the lip fails.)—I. C. (Why not read an elementary textbook of physics? No; heat is not a substance, and it has no weight of its own. Heat is a "mode of motion.")—A CONSTANT SUBSCRIBER. (The blades are rubbed on strong glass plates, with fine emery and oil. Of course, it requires some little practice.)—INQUIRER. (Answered many times. See indices. You must specify the resistance of the lamps before a definite answer can be given. 2. To show vacuum tube effects to perfection, a coil giving an inch spark is advisable; but smaller ones will answer many purposes.)—R. H. (Answered recently. See pp. 43, 244, this volume, and refer to other replies of same numbers.)—CHEMIST. (You do not say what quantity is required. If small, use an ordinary glass retort with water case to cool the long limb; if large, use a copper still and worm, or tinplate. Drawings in any catalogue of chemical apparatus.)—E. J. DAVIS. (We do not know the actual importers; but a little inquiry in Hatton-garden or Clerkenwell would, no doubt, be successful. A sixpenny advertisement in the "Wanted" column would probably procure you the desired information.)—FORCE. (Yes, it was used for boring the tunnels through the Alps and at the Channel Tunnel Works. You will probably find some information of a suitable kind in the *Transactions* of the Institute of Civil Engineers; but a scheme for supplying Birmingham with compressed air is on foot. See indices. It does not compete with steam when that can be applied direct.)—EDWARD M. NELSON. (Manuscript to hand with thanks; but you have only sent sketch of Fig. 3. Please send Figs. 1 and 2.)—VULCAN AND OTHERS. (We have really had enough of the Falling Bodies discussion. Some of our readers—you and "Dubliniensis" among them—would do well to remember that queries are put in to elicit replies, not to furnish pegs round which to twist and untwist endless knots. Our space is too precious.)

USEFUL AND SCIENTIFIC NOTES.

The Work of the Heart.—In Dr. B. W. Richardson's recent Cantor Lectures on "Animal Mechanics," speaking of the mechanism of the heart, he described the number of the pulsations of the heart in different animals—in fish, frog, bird, rabbit, cat, dog, sheep, horse—and made a few comments on the remarkable slowness of the heart —40 strokes per minute—in the horse. Then the number of pulsations in man at various periods of life and at different levels, from the level of the sea up to 4,000ft. above sea-level, was brought under review, and was followed by a computation of the average work performed by the heart in a healthy adult man. The work was traced out by the minute, the hour, and the day, and was shown to equal the feat of raising 5tons 4cwt. one foot per hour, or 125 tons in twenty-four hours. The excess of this work under alcohol in varying quantities formed a corollary to the history of the work of the heart, Parkes's calculation showing an excess of 24 foot-tons from the imbibition of eight fluid ounces of alcohol. The facts relating to the work of the heart by the weight of work accomplished was supplemented by a new calculation, in which the course of calculation was explained by mileage. Presuming that the blood was thrown out of the heart at each pulsation in the proportion of 69 strokes per minute, and at the assumed force of 9ft., the mileage of the blood through the body might be taken at 207 yards per minute, 7 miles per hour, 168 miles per day, 61,320 miles per year, or 5,150,880 miles in a lifetime of eighty-four years. The number of *beats* of the heart in the same long life would reach the grand total of 2,869,776,000.

THE production of metallic aluminium in America last year increased from 1,800 troy ounces in 1884 to 3,400 ounces in 1886, valued at 2,550dol. Aluminium bronze, containing 10 per cent. aluminium was made to the amount of about 4,500lb., valued at 1,800dols.

IT is reported that street car directors in Brooklyn, U.S., are considering the adoption of electric motors. The question of establishing an electric railway to connect Cedarhurst, the Isle of Wight, and Far Rockaway, the terminus of the latter to be somewhere near the Long Island Railroad station, is also being discussed.

THE production in the United States last year of Portland cement amounted to 150,000 barrels of 400lb. each, with a total value of 292,500 dols. The total production of cement of all kinds was 4,150,000 barrels, valued at 3,492,500 dols., against 3,720,000 dols. in 1884.

CHESS.

1. Q-Q B sq.	1. B-R 8.
2. Q takes P.	2. Anything.
3. Mates accordingly.	

NOTICES TO CORRESPONDENTS.

CORRECT solutions to 1,018, by G. A. A. Walker, A. Bolus, F. Krasser, A Beginner (but main play omitted); to 1,017, by A. Bolus (very interesting); to 1,019, by Black Pawn.

G. A. A. WALKER.—We regret that we shall not be able to adopt your suggestion. A Game Tourney lasts about two years.

BLACK PAWN.—Problem received, last version.

J. MACKENZIE AND T. H. BILLINGTON.—Names entered for A and B; A. Bolus for A, Captain Pochin for B. At present 10 have entered for A and 11 for B, so that the numbers are not yet quite complete.

V. S. P.—Thanks for suggestions, which shall have due consideration.

A. BOLUS.—The solution shows that in 267 the K at K R sq. should be White.

LINK.—How do you mate in your attempt at 1,017 if $1. \frac{}{B\ Q\ 5}$?

A. DEAN.—You have overlooked in 1,018, if $1. \frac{B\text{-}Kt\ 6}{R\ takes\ Kt}$ $2. \frac{Kt\ takes\ R}{P\ takes\ Kt}$.

HAMPSTEAD HEATHER.—In 1,019, if $1. \frac{Q\ takes\ P}{B\text{-}Kt\ 3}$ $2. \frac{Q\ Q\ 4}{B\text{-}K\ 8\ (ch)}$. The problem cannot be done this way.

J. MACKENZIE.—If in 1,017 $1. \frac{}{R\text{-}Q\ 5}$ there is mate next move by Q-K 6.

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a PINK Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

6s. 6d. for Six Months and 11s. for Twelve Months, Post Free to any part of the United Kingdom. For the United States, 13s., or 3 dol. 25c. gold; to France or Belgium, 13s., or 16f. 50c.; to India (via Brindisi), 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office Order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 4d. each to cover extra postage.

Messrs. JAMES W. QUEEN and Co., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes, they must be paid for at the rate of 4d. each copy, to cover extra postage.

Vols. IV., VII., XXVI., XXVIII., XXX., XXXII., XXXIII. XXXIV., XXXV., XXXVI., XXXVII., XXXVIII., XXXIX., XL., XLI., XLII., and XLIII., bound in cloth, 7s. each. Post free, 7s. 9d.

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in February and August, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d. each, through any bookseller or newsagent, or 2½d. each, post free from the office (except index numbers, which are 3d. each, or post free, 3½d.).

Indexes for Vols. I., VI., VII., VIII., and IX., 2d. each. Post free 2½d. each. Indexes to Vol. XL., and to subsequent vols., 3d. each, or post free, 3½d. Cases for binding, 1s. 6d. each.

CHARGES FOR ADVERTISING.

ADVERTISEMENTS in the SIXPENNY SALE COLUMN.

	s.	d.
Sixteen words	0	6
For every succeeding Eight words	0	6

⁂ It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions and in cases where the amount sent exceeds One Shilling, the Publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement, and charged for.

Advertisements *must* reach the office by 1 p.m. on Wednesday, to insure insertion in the following Friday's number.

OUR EXCHANGE COLUMN.

The charge for Exchange Notices is 3d. for the first 24 words, and 3d. for every succeeding 8 words.

Good Value Offered (cash or instruments) for all kinds of sound or repairable Scientific Appliances.—CAPLATZI, Science Depot, Chenies-street, near British Museum. Established 1862.

Wanted, **Photo Apparatus**, wet or dry, cameras, sundries, &c., in exchange for Microscopic or Magic Lantern Slides.—Apply, PIGGOTT, Chemist, Huddersfield.

Tricycle, Coventry lever, double steering, two track, adjustable pedals, cushioned seat, good condition, newly painted, Offers.—FORD, 75, St. Paul's-road, Camden, N.W.

Wanted, **Launch Boiler**, Engine, Propeller, &c., for 16 by 5ft. boat. Can offer lot new Hammers, Axes, Planes, Ironmongery, Cutlery, &c.—HARRISON, Devoran, Cornwall.

Seven volumes of "**The Engineer**," range from 1860 to 1867, well bound and clean. What offers?—W. MOSS, 18, Croton-place, Armley-road, New Wortley, Leeds.

Sewing Machines, fifty, by various makers, Thomas, Wheeler, and Singer systems. Must be sold. What offers to one-third value.—GOLDEN SHUTTLE, Colchester.

Electromotive Power.—A series of Experimental Models, which cost £100, offered for £20, or exchange anything useful.—Wellesley House, Colchester.

Dynamo, laminated armature, 4½in. by 5½in., splendid machine. Photo., 6 stamps. Good exchange.—E. THORNTON Barrow-in-Furness.

Aconite, strong tincture. Grand remedy for toothache, Neuralgia. Exchanged for Aconite Seeds by the MEDICO-BOTANICAL GARDENS AND FREE DISPENSARY COMPANY, Lydney.

Aconite, strong tincture. Grand remedy for urinary troubles. Exchange for Aconite Seeds by the MEDICO-BOTANICAL GARDENS AND FREE DISPENSARY COMPANY, Lydney.

One 4in. **Electric Bell**, 3-cell battery indicator, 8 holes, 9 china pushes, all new. What offers? — BARNS, 13, Remington-street, City-road, London.

38in. Facile Safety **Bicycle**, thorough condition, all accessories. Offers.—F. STRANGE, 92, Hatcham Park-road, New Cross.

Gas-Engine (Bisschop). 1 man power, cost £25; Water Engine, 1 horse, by Ramsbottom, working order; 2,000c.p. Arc Lamp. Offers.—W. HUTCHINSON, Liversedge.

Dynamos, four, two by British Electric Light Coy.; 3 Serrin Arc Lamps, switch boards, brushes, carbon, speed indicator, coil, &c. Offers.—W. HUTCHINSON, Liversedge.

Will give a three-cell **Bichromate Battery**, with lifting apparatus, cost 25s., for a good set of boxing gloves.—MACGEORGE, School House, Sevenoaks.

Wanted a 4½in. or 4in. Iron **Lathe**, or pair 4½in. Lathe Heads, cheap, in good condition, in part exchange and part cash.—A. TURNER, Roydon, Ware, Herts.

Offers in **Lantern Accessories** wanted (Gas-bag, slides, &c.) for following:—lantern, 2¾in. condenser, and 1 doz. slides, splendid concert flute, silver keys, about 4 doz. lantern photographs, or singly. — Address G. M., care of Edgar Neale, Chippenham.

Exchange **Biunial Lantern**, 3½ condensers, splendid jets, lot of slides, want Facile bicycle, 40in. or 42in. What offers?—PRICE, 28, Mayer-street, Hanley, Stoke-on-Trent.

English Concertina, 48 keys, in mahogany box, cost 4 guineas. Wanted small bench lathe. No cards. — C. BLANCHARD.

Diamond Drills for china, glass, stone, &c., as used by china riveters.—C. BLANCHARD, 29, Earl-street, Lisson-grove, London.

Pipe Organ, 3 stops, £25; Harmonium, 8 stops, £10; Cottage Piano, £15, in good order; wanted in exchange good sitting or bedroom furniture.—JOHN H. FAWCETT, St. James'-green, Thirsk, Yorks.

"**English Mechanic**," last 8 Vols., two bound, others unbound. Exchange "Amateur Work," up to date, or cash offers.—W. PREWETT, Winton, Bournemouth.

Photographic Rolling Press, size of steel plate 18in. by 12in.; exchange for back-geared lathe, 5in. centres, iron bed with slide-rest.—C. H. HATCH, Photographer, Alderley Edge.

Wanted, **Double-barrelled Gun**; exchange tools, excellent books, £7 worth. Send stamp and details for list.—BLAND, 182, Regent-street, South Shields.

Wimshurst **Electric Machine**, will give a 5in. spark, with four condensers, cost short time £3 8s. What offers?—R., 64, High-street, Clapham.

Dynamo (6-c.p.) and Electromotor (powerful); also 6 powerful batteries and several incandescent lamps. Offers.—CHARCOAL WORKS, Hodson-street, Liverpool.

The English Mechanic
AND WORLD OF SCIENCE AND ART.
FRIDAY, DECEMBER 10, 1886.

HAND-PLANING MACHINE CONSTRUCTION.—II.

THE first step towards making the machine illustrated in the number for Nov. 26th is to get out a set of working drawings, complete in all details, so as to know exactly really what is to be done. These drawings must show the form and sizes of each part, and then there will be no occasion to waste time in trying fits whilst the work is progressing. Highly-finished drawings are not at all necessary, and neatly-drawn figured sketches will answer every purpose, providing they completely indicate every detail. The printed illustrations, published in connection with these articles, would serve most purposes, if all the dimensions given in the text are carefully figured, so as to show sizes to work to.

Planing the castings will be the first procedure. The bed will be the piece to be first operated upon. Place the casting, top upwards, on the table of the planing machine on which it is to be fixed, see that there are no fins in the casting to prevent it bedding fairly, and with a surface gauge try the height of the top all round, using wedges where necessary to level it and to make fair bearings; then fix to the table. Use a firmly-fixed stop to plane against, and do not screw the bolts very tight, or the casting will be strained. See that each clip takes a firm hold and has a solid bearing under it, but do not bend the casting by overtightening the bolts. Take one rough-cut all over the surface of the casting, this will be over the tops of the brackets and over the ways on which the table will slide. These parts form one level plane. Use a broad round-nosed tool, see that it is set to cut below the skin all over, give it a cross feed of about 3-16in., bevel off those edges where the tool will finish its cut, so as to save breakage at the end of each trip, and start the planing machine. One cut all over should leave the surface a series of somewhat coarse furrows. If the tool has a wide cutting edge, and has been set deep enough, the surface will give a good bearing all over when turned upside down on the table. But a second cut may be requisite: if so, it should be made with the tool acting midway between its former trips. When all the skin has been cut off the top of the casting, unfix it, and clear the chips off the planer. Refix the casting upside down, resting fairly on the planer table, and plane those parts of the bottom which bolt against the standards. One rough-cut set deep enough and one finishing cut will suffice; then remove.

The bed casting has now to be carefully fixed right side up and parallel with the ways of the machine, so that its undercut slides may be planed and the top surface finished. Use a pair of side, or knife, tools to plane down the inner sides of the slides. Set the vertical slide of the planer over 35° from the perpendicular, so as to make the dovetails an angle of 55°; also set the tool-box over in the same direction to allow the tool to clear during the back traverse. Two or three cuts may be necessary to finish one side; a keen tool should be used for the last. Then shift the vertical slide over to the corresponding angle in the opposite direction, alter the swing of the tool-box, replace the tool by its fellow, and plane the other side. The surface has next to be finished. If every trace of the skin of the casting has been removed in the first rough cuts, a finishing tool may be used at once. A strong tool $\frac{1}{2}$in. wide, with a straight cutting edge, finely set on an oilstone, will produce a better surface than a spring tool. The inner arrises are cut off both sides, to leave a facet about $\frac{1}{8}$in. wide. This is best done with side tools. The bed will now be finished so far as planing is concerned.

The table will be the next casting for treatment. Place it on the planing machine bottom upwards; level the outer surfaces by aid of a surface gauge and wedges, and fix—always recollecting to have a good firm stop to plane against. Take a rough-cut all over the two projecting strips deep enough to get them quite clean. Unfix, and turn over the casting. Take a rough-cut all over the top surface, and then with a grooving tool, $\frac{1}{2}$in. wide, plough out the grooves of the four ⊥ slots, making a plain slot 1in. deep, without any undercutting. Then with a pair of L tools, barely $\frac{1}{4}$in. wide on the edge, undercut the grooves $\frac{1}{4}$in. on each side, making the wide part of the ⊥ 1in. All these ⊥ slots will be finished to size when the bed is fitted on its place, and our hand planing-machine is complete; but the bulk of the metal would be cut out with considerably less labour on a heavier machine. The side-edge of the table should then be planed with a knife tool, and if the top surface is not smooth take another cut over it, and make it so. Remove the table, turn it over, and refix carefully with the planed edge parallel with the ways of the machine; then with a pair of bent tools, rough plane the surfaces on both sides which will form the bearings of the table on the bed. Get as far under the angle as possible, but do not expect to finish right in the corner with rough cuts. A knife tool will plane the side of the under cut, and the reverse knife tool will plane the side of the rib against which the loose strip will bear when bolted in position; this right angle must be finished before the table is removed. The central part against which the rack is to be screwed may also be planed smooth, and the table may then be put aside till the loose strip is planed.

This strip must have a rough-cut taken all over it, and must have the edge opposite the slant and both sides finished, making it the correct thickness to lie level with the rib against which it rests. It is then ready for bolting on the table. Mark the positions for the six $\frac{3}{8}$in. bolts, placing two within an inch of each end, and the other four equidistant between—viz., about 5$\frac{5}{8}$in. apart. It will be best to mark these centres on the narrow side of the strip, and to place them $\frac{1}{4}$in. from the obtuse angle; use a fine prick punch and scribe the circumference of each hole to see that it is correctly placed, then enlarge the centre dots with a strong punch. Drill through the strip to clear the $\frac{3}{8}$in. bolts; 1-64in. is enough clearance, if the tapping holes in the table are drilled exactly in position, but a hole 13-32in. diameter will be less likely to give trouble. See that no burrs are left round the edges of the drilled holes, and file off that corner of the strip which fits in the angle of the table. The strip may be conveniently drilled in the lathe, but the table is too heavy and too awkward to handle nicely on most lathes. A vertical drilling machine will do the work best; but, failing that, a ratchet brace may be used. Place the drilled strip in its place on the table, and fix with a couple of clamps close against the rib; then mark the positions of the tapping holes for the bolts in the table. A centring drill is best to use for this purpose: its shank should fit the clearing holes drilled in the strip, and its point should drill a hole about $\frac{1}{8}$in. diam. and $\frac{1}{8}$in. deep. Having centred the six holes, remove the strip, and drill each to the tapping size for $\frac{3}{8}$in.—viz., 9-32in. and 1in. deep. The three holes for the screws that hold the rack should be drilled at the same time. They are $\frac{1}{2}$in. diam.; one through the exact centre of the table, the other two, 2in. from each end. See that all the holes for the fixing bolts on the loose strip have gone in fairly, according to the marking, and tap straightly one of the best placed. To fix the strip, six $\frac{3}{8}$in. by 1$\frac{1}{2}$in. bolts will be wanted. Machine-made, bright finished, mild steel, hexagon-headed bolts, to Whitworth's dimensions, can be bought for much less than the cost of making by hand. Fix the strip close against the rib with one bolt, and tap the other holes, proceeding first with those that are best placed, and screwing in a bolt as each hole is threaded. Should either hole be misplaced so much as to prevent the tap screwing in upright, it will be best, before proceeding to tap, to ease the hole in the strip with a round file as large as the hole will admit. The hole in the strip assists in showing the uprightness of the tap.

Having bolted the strip firmly on the table, this will be ready to be completely planed, so as to finish the surfaces and the undercut dovetails which form the sliding-fit of the table. Fix the table very carefully, the planed edge parallel with the ways of the machine, and with a pair of knife tools plane both the undercut surfaces, so that the table will very nearly fit in its place on the bed; then a special tool is wanted, having a broad edge that will reach under the dovetails, and finish both surfaces at one setting, and so insure their absolute levelness. The table should now fit very tightly on the bed. The bulk of the metal may be ploughed out to form the small ⊥ groove in the edge of the table, using an L-shaped tool, and cutting a straight groove $\frac{1}{4}$in. wide and $\frac{1}{2}$in. deep. The undercutting of this groove can be done at the same time that the other ⊥ grooves are finished—viz., when the machine is complete.

The pair of standards may next be planed. Commence by tooling the surfaces against which the ends of the cross-bar will bear; then bolt the two standards very firmly together with these two faces in contact, and the lower parts separated the requisite space by packing. The two standards thus bolted together are thenceforward in planing treated as one piece. The bases may be planed first, and then the front faces against which the cross-slide rests. There is a channel cast in this face where it joins the base (shown in the side view, page 374), which allows the planing tool to drop out of cut at the end of each stroke. By planing the pair of standards together as one, any slight error in the uprightness of the planed faces, caused by want of accuracy in setting them for planing, is of no consequence, since the error must be alike in both. The cross-bar to connect the standards is planed at both ends to an exact length (as shown in the drawing). The bolts to fix the bar to the standards are $\frac{1}{2}$in. diameter put through the ends of the bar and tapped into the standards. Fix these together tightly and see that their bases stand level. The bolt-holes in the cross-bar will most likely require enlarging considerably to allow this, as it is rather awkward to mark the positions of the holes quite truly. Pins may be put in after the standards are bolted on the bed to insure the accurate replacing of the cross-bar.

The main cross-slide may be planed next. Fix it level face upwards, and plane the surface, always using a stop to plane against; then turn over, and plane the high parts at each end which rest against the standards. Again reverse the casting, and fix carefully parallel with the ways of the machine, and plane the slide part, undercutting both sides to the angle of 55°, same as on the bed. The saddle for the main slide, having a large round hole in the middle, has the loose strip fixed with three $\frac{3}{8}$in. bolts, and has to be planed all over. The back, with the under-cut dovetails to fit on the cross-

slide, is most important, as the front may be finished on the lathe when the casting is chucked for turning out the central hole. The four edges, also, should be planed. The fiddle piece has its front and its inner slides planed; but its back is finished on the lathe when the central disc is turned to fit the hole in the saddle. The slider in the fiddle and its loose strip is planed all over. The strip is fastened by three ¼in. screws tapped into it, and having their heads sunk in the front side of the slider. The cradle is planed all over, as is also the swinging plate which carries the tool-holder. The planing of the castings is now completed.

The boring has next to be done. The bed requires a ⅜in. hole near each corner, for four bolts to fix it to the standards. The holes for the main spindle, through the bosses in the sides of the bed, may be located in the middle of the bosses, but must be quite in line and opposite, so that the spindle will stand square with the planed parts. With a boring bar on a horizontal machine, this is easily insured. But failing that, a hole about ⅜in. diam. should be made first, and the oppositeness of the holes tested by putting a straight rod through both. Either, or both holes, if slightly out, may be drawn a trifle by filing; or, if much out, may be plugged with a wrought-iron pin, and re-drilled. Having got these small holes in position, they may be enlarged by a pin-drill to very nearly full size; but a reamer should be used to finish the holes, and it should be used from the inside, with the opposite hole as a guide to the shank. It is usually necessary, and always well worth while, to make a special bar to lengthen the shank of the reamer, and a split collar to fit the holes and form a bearing for the bar. Without this, or some adequate contrivance, the holes will most likely be out of line, and so fail to form good bearings for the spindle. The horizontal holes in the bosses, at the upper parts of the standards, which form the bearings for the cross spindle carrying two mitre wheels, are marked as fairly as possible in the middle of their respective bosses, but they must be in line. The way to insure this is by using a reamer with a long shank, guided by the corresponding opposite hole. These holes, however, are not to be reamed till the standards are firmly bolted on their places. The vertical holes which form the bearings of the elevating screws are made quite large so as to leave play for the screws to adjust themselves to suit positions of the nuts. These screws merely require smooth surfaces for their collars to bear upon when supporting the cross-slide and its attachments. The four bolt-holes in the bases of the two standards are marked on the planed base in the positions shown in the drawings, and are bored through to clear ⅜in. For marking the holes in the brackets on the bed the standards are fixed together by the cross-bar, and also by the cross-slide, which is bolted on near the lower part, and stood in position. These four holes are bored ½in. diameter, and tapped with ⅝ threads. The remainder of the holes are small, and are more conveniently bored in the lathe.

The castings have now been planed and bored so as to allow the large parts of the machine to be got together. The remainder of the work to complete the machine is turning and fitting, and this point forms a convenient stage for concluding this article.

REVIEWS.

Modern Steam Engines. By JOSHUA ROSE, M.E. Philadelphia: Henry Carey Baird and Co. London: Sampson Low and Co.

THIS work is called an "elementary" treatise by its author; but in reality it gives full explanations of the construction of modern steam-engines, including diagrams showing their actual operation. It is elementary in the sense that it is written in the language of the workshop, and while intended for those who desire to acquire a knowledge of the construction of steam-engines, is of the greatest value to the practical engineer. Mr. Rose illustrates a considerable number of different engines, and to facilitate comparison of the action of different valve motions, has made the diagrams as nearly as possible of uniform size. The various slide-valve motions now in use have been treated very fully, for in them are found the distinguishing features of most engines, and this branch of the subject may be said to form the distinguishing feature of Mr. Rose's work; for the diagrams have been obtained by moving the engines throughout a revolution, and measuring the port openings at each inch of piston travel. These diagrams show the actual working of the valves, and the mind is enabled to grasp at once the effects produced. When a special form of engine is described the engravings show it as a whole, and its general action is explained. It is then treated in detail, separate engravings being given of the parts, which are shown in various positions. We need scarcely say that this is an admirable method, and a reader who cannot comprehend must be sadly wanting in the perceptive faculty. Commencing with a classification of the various kinds of steam-engines, Mr. Rose follows with a description of the common slide-valve example, and then we have lap and lead, the eccentric and its throw, cushioning and clearance fully explained. The distribution of the steam is shown by diagrams, with instructions for drawing them, and then we come to expansion and the Allen valve, which is chosen to show the effects of cutting off. Chapter II. is rather a long one, as it deals with the important subject of designing valve motions. Chapter III. treats of link motions and reversing gears, the so-called Stephenson link being the example chosen for general description. This subject runs over two chapters, and if all the different link motions are not illustrated, the principles are fully explained. As a matter of fact, nearly all the good valve-gears are described and illustrated in some portion of this work; for when they do not appear in the general explanation, they are described in connection with some one of the many engines which Mr. Rose has chosen as examples. The work is illustrated by 422 engravings, which include most of the modern steam-engines of American make, and sundry pumps and other machines which are intimately connected with engines. The student who makes himself master of the contents of this volume will have a fairly complete knowledge of the steam-engine in theory and practice, and will be fully prepared to take up any investigation or research connected with the utilisation of heat in the production of motive power.

The Life and Labours of John Mercer, F.R.S. By EDWARD A. PARNELL. London: Longmans.

TWENTY years have elapsed since the death of John Mercer, the "self-taught chemical philosopher," and his biography, which will be read with interest by calico printers, though delayed by the death of his two sons, has recently made a tardy appearance, the Misses Mercer having placed all the available information in the hands of Mr. Parnell. John Mercer was born at Dean, near Blackburn, in 1791, his father being the owner of a small spinning mill by the side of Dean Brook, who unfortunately died when his son had reached the age of nine years. John commenced life as a bobbin winder, and was ten years old before he learned the "rudiments," speedily developing, however, an "aptitude for figures," and also an aptitude for something else. Having determined to learn dyeing, he visited Blackburn and called on a druggist, from whom he purchased a small quantity of each of the dyestuffs then in use. Without any knowledge whatever he commenced experiments with his dyes, and naturally acquired a good deal of "rule-of-thumb" knowledge, his first important discovery being a means of dyeing with indigo. Whilst still a boy he started in business with a partner as dyers, and was so successful that the Messrs. Fort, of the Oakenshaw Print Works, offered him a post in their colour shop, stipulating that he should serve for a certain period as an apprentice. This arrangement did not last long, however; but in 1813 Mercer started again as a dyer, and succeeded in utilising with profit the imperfectly-spent materials of the printworks. Parkinson's "Chemical Pocket-book" was his first book on chemistry, and that he "devoured" with such success that he soon afterwards made his first important discovery—antimony orange, which was followed by the utilisation of chromate of potash. At this time Mercer had accepted a post at the Oakenshaw Works again, and his labours resulted in so much benefit to the proprietors that in 1825 he was admitted into partnership. Thenceforward a life of research in the laboratory and a study of books on chemistry resulted in the discovery or invention of numerous dyeing recipes, and Mercer, who was one of the original Fellows of the Chemical Society, was elected a Fellow of the Royal Society in 1852. A man who by investigation added largely to the number of dyestuffs, and in several respects revolutionised the calico-printing and dyeing industries, naturally went outside his special branches, and Mercer, we find, was an early worker in photography, and so far back as 1843 in a letter to Dr. Lyon Playfair hinted at the germ theory of disease. An appendix contains notes from Mercer's papers, and numerous recipes for colour preparations, some of which having never before been published may be found useful. A photographic portrait of this "worthy"—a worthy in more senses than one—forms a suitable frontispiece to a biography of another self-taught man.

Commercial Organic Analysis: a Treatise of the Properties, Modes of Assaying, and Proximate Analytical Examination of the Various Organic Chemicals and Products Employed in the Arts, Manufactures, Medicine, &c.; with Concise Methods for the Detection and Determination of their Impurities, Adulterations, and Products of Decomposition. By ALFRED H. ALLEN, F.I.C., F.C.S., Public Analyst for the West Riding of Yorkshire, Borough of Sheffield, &c. Second edition, revised and enlarged. Volume II. Fixed Oils and Fats, Hydrocarbons, Phenols, &c. London: J. and A. Churchill.

WHEN the first edition of this book was published it was duly reviewed in our columns, and we expressed our very high appreciation of the care, industry, and discretion shown by the author in the production of his work. On the appearance of the first instalment of the long-called-for second edition, we further congratulated Mr. Allen on the improved arrangement of the subject-matter. The volume now under notice shows no falling off in these respects. In his preface, the author apologises for the delay in the appearance of the book, which has been out of print for some years, and states that the subject-matter has been more than doubled in extent by the incorporation of the results of recent investigations by himself and others. He mentions as a further cause of delay the discovery of the maximum limit of his strength—a cause which we fancy may account for the rarity with which his name has of late appeared as a correspondent in our columns, where it was once seen so regularly. In the section of the volume treating of Fixed Oils and Fats, which now extends to 318

pages, Mr. Allen appears to have collected every scrap of reliable information, and with the aid of his own numerous and well-known investigations has transformed the subject of "oils" from one approaching chaos to a fairly orderly and systematic chapter of organic chemistry. Although much still remains to be done in this direction, Mr. Allen has shown that, by the industrious and intelligent use of the methods and facts now available, the difficulties formerly attending the investigation of oils are, in many cases, no longer insuperable. While giving general methods of analysing and examining oils, the author also devotes special sub-articles to each of the more important oils, fats, &c., employed in commerce, and in these a mass of valuable information is given respecting the adulterations and impurities peculiar to each oil, and the methods of detecting them. On page 113, the author remarks that "refined cottonseed oil is usually very free from acid, and when properly prepared is of pleasant taste and admirably adapted for edible and culinary purposes, for which it is now extensively employed, both with and without its nature being acknowledged. It is now substituted for olive oil in some of the liniments of the 'United States Pharmacopœia'; but its principal applications are in soap-making and the manufacture of factitious butter." In a valuable article on the Examination of Lubricating Oils, Mr. Allen remarks that "the presence or formation of free acid in an oil being the chief, if not the only, cause of its tendency to act on metals, the results published by various observers, showing the amounts of iron and copper dissolved in equal times by different oils, have no interest or meaning apart from the particular samples of oils examined, the action on the metals being simply a function of the free acid the oils happened to contain." The section on Oils proper concludes with articles on fatty acids, soaps, glycerin, and cholesterin, in all of which much valuable matter will be found. On page 249 the author states that "an admixture of glycerin in excess of that found in the process of saponification must be considered a valuable ingredient in certain classes of soaps. The same remark cannot be made of the large proportion of cane-sugar which replaces glycerin in some of the much-advertised transparent toilet soaps, as it simply dilutes the true soap material as so much water would do, without communicating any corresponding property of value." The section of the volume treating of Hydrocarbons exhibits many extensions from the first edition, some of the articles now appearing for the first time. Among these are the subsections treating of crude shale oil, coal-tar, asphalt, menthol, naphthalene oils, and naphthols. On pages 354, 355 there is an ingenious tabular view of the whole of the recognised constituents of coal-tar, so arranged that the fraction in which each one occurs is at once evident. The article on shale and petroleum products has been carefully written up to date, the author acknowledging his indebtedness to Mr. Boverton Redwood for a perusal and revision of this chapter. The section on Phenols, though shorter than those preceding, contains much information now for the first time brought together. It contains methods for examining crude carbolic acid, carbolic powders, creosote oils, wood-creosote, &c. Although the work requires some knowledge of chemistry on the part of those who use it, still the analytical tests and processes are so fully and lucidly described that no one possessed of a moderate experience in general chemical manipulation will find much difficulty in applying them. Mr. Allen has not contented himself by merely collecting a number of analytical methods, but has added such information respecting the origin, reactions, and properties of the substances described as will materially assist those who may require to examine them. The volume may be broadly described as a monograph on oils of all kinds, and we are confident that it will become a standard work.

Heroes of Science: Physicists. By WILLIAM GARNETT, M.A., D.C.L. London: Society for Promoting Christian Knowledge.

THIS volume forms one of a series, and its object is apparently to bring within the ken of school boys and girls material which is otherwise available only to those who have extensive libraries at command. In the lives of Robert Boyle, Benjamin Franklin, Henry Cavendish, Count Rumford, Thomas Young, Michael Faraday, and Clerk Maxwell, as depicted in this volume, we have also a history of the progress of physical science. Dr. Garnett modestly says his pages claim no originality, and although the stories of the lives of his heroes of science have been told before, they have never, we believe, been so told as to give, by way of an under-current, a connected account of the gradual development of such subjects as electricity, the mechanical theory of heat, the undulatory theory of light, &c. The "lives" themselves are epitomes of the biographies of the "heroes," and in an introduction and a conclusion Dr. Garnett gathers up the threads of the history of scientific discovery which run through them. In the lives of Franklin and Rumford there is much that has no connection, direct or remote, with science; but the volume altogether may be commended as an excellent reading-book for schools and for private students, as its contents cannot fail to be instructive and interesting.

We have also received *The Modern Practice of Shipbuilding in Iron and Steel*, by SAMUEL J. P. THEARLE (London: Collins, Sons, and Co.), comprised in an illustrated octavo volume of text and a quarto volume of plates. The author's "Practical Naval Architecture" is a well-known work; but wood and composite ships are rarely built nowadays, and examinations in naval architecture refer as a rule to iron and steel ships. Mr. Thearle's new treatise may take its place in the series issued by the Messrs. Collins as a work that can be trusted by the candidate for examination.——*Outlines of the Geology of Northumberland and Durham*, by G. A. LEBOUR, M.A., F.G.S. (Newcastle-on-Tyne: Lambert and Co.), is a little work originally prepared for the class of geological surveying which Prof. Lebour conducted in the Newcastle College of Physical Science. The present issue is a new edition in which matter has been inserted referring to Durham and Cleveland, and it is a useful little book, which will be welcomed by geologists, miners, and others interested in the northern counties of England. —— *The Century Almanack and Calendar*, by G. R. J. COMONT (Camberwell, 32, Parkhouse-street), is a useful "card" with a sliding slip and tables, by means of which we can set the calendar to any year between 1800 and 1906, and find the day of the month or the day of the week. It is a handy and useful device. ——*The Asclepiad*, by BENJAMIN WARD RICHARDSON, M.D. (London: Longmans), is, as usual, full of matter of more or less interest to medical readers, with papers which will be read by students of science—including one on "Ambrose Paré, and the Birth of French Surgery."

EARLY TELEPHONES.

WHATEVER may be the ultimate result of the suits now pending in the United States Courts in connection with the Bell telephone patent, it is certain that they have assisted in bringing to light many ingenious inventions which might otherwise have been altogether forgotten. A good deal of feeling has been imparted into the legal question on the other side of the Atlantic, because a suspicion exists that the American Patent Office authorities did not act altogether fairly in connection with rival claims (Gray's, for instance); while the courts have, so far, construed Bell's patent in a much wider and more liberal sense than they did Morse's important invention in connection with electric telegraphy. Bell's patent in the United States is, in fact, construed to cover the transmission of speech by an "undulatory current"; and in this country, any telephone with a diaphragm is an infringement of Bell's patent, with one exception—that known as the English Mechanic telephone, described in our columns August 11th, 1876. The question, "What is a diaphragm?" has not yet been answered within rigid legal limits, and probably will only be decided on the merits of specific cases. But whatever may be said by the friends of rival inventors, Bell and Edison both referred to the work of Reis, and tacitly acknowledged that he had taken some steps towards perfecting a telephone. A reference to Vol. XXV. p. 449, will show that so long ago as 1870 Mr. C. F. Varley had obtained a patent in which the use of rapid undulations, to produce audible signals, was clearly defined, although no mention of a speaking telephone was made. Mr. Varley, like other inventors, does not seem to have been aware of the potentialities of his musical telephone in 1870, nor was Mr. Royal E. House, in 1865 and 1868, when he patented in the United States what he termed improvements in "electro-phonetic telegraphs." Mr. House invented, in 1846, the printing telegraph, which has been widely used in America, and in 1868 he patented an "electro-phonetic receiver" for use in telegraphy, which, it is now known, is a very excellent telephone, superior to the early devices of Bell, and as good, it is stated, as the present Bell receiver and Blake transmitter. Mr. House is happily still alive, though nearly eighty years old; and it would be a curious termination to the Bell monopoly, as it is called, if his instruments should be employed to oust the more modern devices. We understand that large numbers of them are being manufactured, probably with some modification in constructive detail from the drawings deposited with the patent specification, but still accurate reproductions of the instrument described in 1868, eight years before Bell, Gray, and the others lodged their applications. If the House "electro-phonetic receiver" should prove to be an efficient telephone, there will be an end to the monopoly, and some curious results may follow in the law courts of the United States. The substance of the description extracted from the specifications, about which there can be no doubt whatever, shows that House's receiver, of 1868, consisted of a box—generally cubical in form—with one end closed by a diaphragm. Two slender bars of metal are attached to the diaphragm—one near the centre, the other below it. These bars the inventor terms "limiters." The upper "limiter" limits the motion of an armature working over a magnet, so that it cannot come in contact with the poles. The other limiter prevents the armature from receding too far from the poles. The armature is pivoted at one end: its inner and free end strikes the lower limiter; it is provided with an extension at the pivoted end that extends upwards at right angles to the armature. The end of this arm bears against the upper limiter. An electro-magnet operates this armature, and is situated below it in the bottom of the box, and is connected to binding posts. A tension spring is used to adjust the pull of the pivoted armature away from the magnet. Attached to the cubical box is an ear-trumpet, or receiver, and the directions specify that the interior surface of this receiver should be of such a form as to reflect the sound waves to a focus which is occupied by the ear of the listener. The model deposited by Mr. House, in accordance with United States law, was destroyed in the fire at the Patent Office; but the drawings accompanying the specification are still available, and render the evidence complete. Any suitable substance can be used as a diaphragm; but in the instruments now being constructed, metal is employed. The frame or body, indeed, is made of cast iron, and an ebonite ear or mouthpiece screws on the open end and clamps the diaphragm in position. In the original drawing both "limiters" have adjusting screws, by which their freedom of movement may be varied. They can be adjusted so that they will be in

contact one at a time only with the armature and arm. In this case a make and subsequent break, or corresponding and considerable changes in intensity of current, will produce two blows—the first on the upper limiter, and the second on the lower. However, by screwing out the limiter screws to a fuller extent, this oscillation is gradually reduced until no break is possible. Then makes and breaks of the current, or variations in intensity, will no longer produce blows, but a true telephonic sound from the diaphragm. If connected in circuit with a microphone transmitter, it will talk; and if two are connected having closed or ground circuit with battery, or if steel or cast-iron magnet cores are used without any battery, they will act as receivers or transmitters, and form a complete telephonic system. Probably, before long, instruments of this kind will be on sale in this country, and as they work well, both as transmitters and receivers, with four Leclanchés, will be found useful.

ELECTRICAL INSTRUMENT-MAKING FOR AMATEURS.—XII.*

By S. R. Bottone.

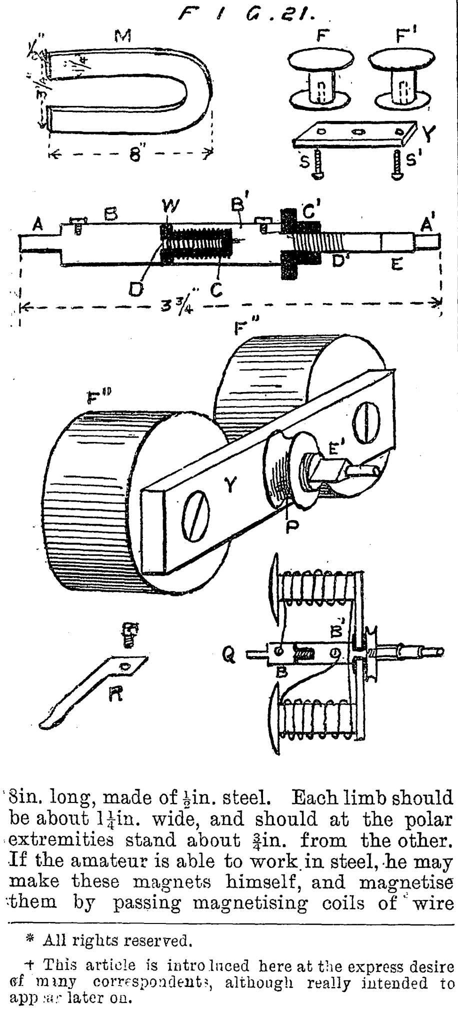
§ 42. **The Magneto-Electric Machine.**†

THIS is the first form of *dynamo* which the inventive genius of Faraday placed before the scientific world. It had its origin in the discovery "that a conductor moving before the poles of a magnet, in such a direction as to cut the lines of force of the said magnet, had its electrical condition upset, so that a flow of electricity was produced within it"; and this could be rendered evident by suitable means. Two forms of magneto-electric machines will be described: *firstly*, the ordinary "medical" or "shocking" machine; and, *secondly*, a rather more scientific instrument, which can be used for many experiments, for which the former would be totally useless.

§ 43. **The "Shocking" Machine.**

The amateur will need a pretty powerful horseshoe magnet, as shown at Fig. 21 M, about

FIG. 21.

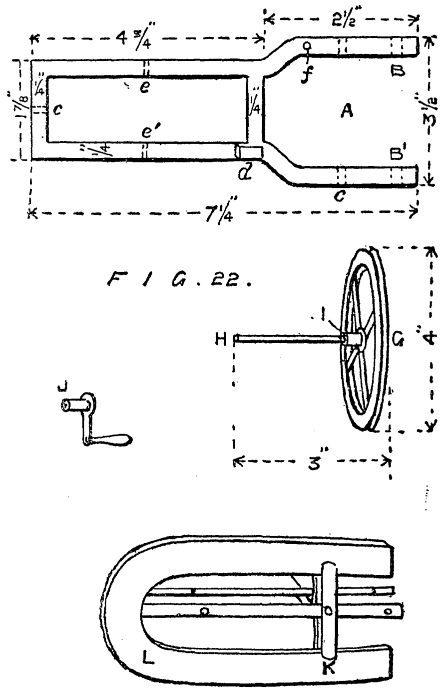


3in. long, made of $\frac{1}{2}$in. steel. Each limb should be about 1$\frac{1}{4}$in. wide, and should at the polar extremities stand about $\frac{3}{8}$in. from the other. If the amateur is able to work in steel, he may make these magnets himself, and magnetise them by passing magnetising coils of wire round each limb, and sending a powerful current of electricity through the coils, until the magnet is sufficiently strong. For the purpose required, the magnets should pull easily a weight of 10lb.; but it will, in most cases, be found cheaper to buy these magnets ready-made. The armature can be readily constructed at home. It consists in two iron bobbins, F F', screwed on to an iron yoke, or cross-piece Y; these bobbins should be turned up out of the very best soft iron circular rod, about 1$\frac{3}{4}$in. diameter. The centres, or cores, should be turned down to about $\frac{1}{2}$in. in diameter, a flange about $\frac{1}{16}$in. in thickness being left at both ends. A hole must be drilled up the centre of each bobbin, and this hole must be tapped to receive an iron screw about 1in. long, $\frac{3}{16}$in. diameter. These screws serve to clamp the bobbins to the yoke. Owing to the weight of the coiled bobbins, and the high speed at which they must be driven, it is needful that these screws should be strong to resist the centrifugal tendency. The length of the bobbins, including flanges, is 1$\frac{5}{8}$in. If the operator has not a lathe, he may make a fair substitute for the turned bobbins by putting a screw-thread on the top and bottom of two pieces of $\frac{1}{2}$in. iron rod, 1$\frac{5}{8}$in. in length, and screwing thereto discs of soft iron, $\frac{1}{16}$in. in thickness, 1$\frac{3}{4}$in. in diameter, having holes drilled and tapped in their centres to take the extremities of the rods. The yoke Y has in its centre a $\frac{3}{8}$in. hole, which must be carefully bushed with black ebonite, ivory, or boxwood soaked in paraffin wax, or some other good, hard insulator.

§ 44. The shaft or spindle on which the armature revolves constitutes the distinguishing feature of this particular form of magneto machine. It must be compact, easy to construct, strong, and well insulated in its two halves. It must also have some device whereby contact can be made and broken two or three times during each revolution. To this end an iron rod, about 5in. long and $\frac{1}{4}$in. in diameter, is turned down at both ends for a length of $\frac{1}{4}$in., to about $\frac{3}{32}$in. in diameter. This is to produce a shoulder at each end for the spindle to rest in its bearings. These thinner ends are shown at A and A'. Another, $\frac{1}{32}$in., is taken off at one end for about $\frac{1}{2}$in., say, at the end A'. Then a screw-thread of about $\frac{1}{2}$in. in length is run on at D'. The rod is then in cut in two at D, and a length of about $\frac{1}{2}$in. is turned down to about $\frac{1}{8}$in. in diameter. A screw must be formed on this thinner portion, as shown at D. The portion B' has then a hole about $\frac{3}{8}$in. in depth drilled in it, and about $\frac{3}{16}$in. in diameter. A female screw must be cut in this, and the hole bushed with ivory or ebonite, as shown at C. Great care must be taken in tapping this to receive the screwed end of D that the two halves of the divided rod are perfectly insulated from one another. To this end an ebonite washer is placed at W. It is well to test for insulation by inserting the spindle at this point, in the circuit between a galvanometer and a battery. If any current passes so as to produce a deflection, the hole C must be cleaned out and replugged, until perfect insulation has been effected. Two small holes, to take short screws about $\frac{1}{16}$in. diameter by $\frac{1}{8}$in. in length, must be drilled and tapped, near B and B'. These are intended to make connection with the two ends of the wire coming from the bobbins, as shown at Q. The next operation is to turn up a small brass pulley, about $\frac{3}{16}$in. in thickness, by about $\frac{1}{2}$in. in diameter, which must have a female screw put in it to fit over D', as illustrated at P. This pulley serves at one time to clamp the yoke Y in its place on the spindle, and to communicate the motion from the little driving-wheeel to the armature spindle. All that now remains to be done to the spindle is to file about $\frac{1}{2}$in. of its length, just beyond the screw-thread D', into a triangular form, like the Grecian letter Δ, as shown at E' and E. The length of the finished spindle should be 3$\frac{3}{4}$in.

§ 45. A brass frame, of the form and dimensions figured at Fig. 22 A, must now be provided. For substance it should be $\frac{1}{4}$in. wide by $\frac{1}{2}$in. deep. At the point *d* the frame expands both above and below so as to form a lug, projecting about $\frac{1}{2}$in. on either side, against which can be clamped the magnet M (Fig. 21). The amateur should construct a pattern of this frame in wood a trifle larger than it is intended to be (to allow for shrinkage), and after having carefully smoothed and bevelled the edges, send it to the brass founder's to get a similar one cast in brass. When cast, the frame will require careful cleaning and trueing up with a file. Holes to take $\frac{3}{16}$in. diameter screws must then be drilled and tapped at *c c*. These serve to fasten the frame into its box. At B and B' rather larger holes must be bored, the former being carefully bushed with ivory or hard ebonite, the latter fitted with a metal screw, through both of which a hole is put, sufficiently large to serve as bearings for the end A and A' of the spindle (see Fig. 21, A A'). At *e* and *e*, precisely opposite one another, are drilled two $\frac{3}{16}$ holes, which serve as bearings for the driving wheel. At *g*, a small hole about $\frac{1}{2}$in. and $\frac{1}{4}$in. deep, is drilled and tapped, to receive a small screw. This is intended to receive the small contact spring R (Fig. 21).

§ 46. The next thing needed is a small brass driving wheel about 4in. in diameter and $\frac{1}{4}$in. thick, with a groove cut in the periphery, to take a gut band. The tiro need not make a pattern for this, for nearly every toy-engine shop keeps brass flywheels of about this size. If it have not a groove when bought, one can easily be put in it on the lathe. This wheel is shown at Fig. 22, G, mounted on an iron

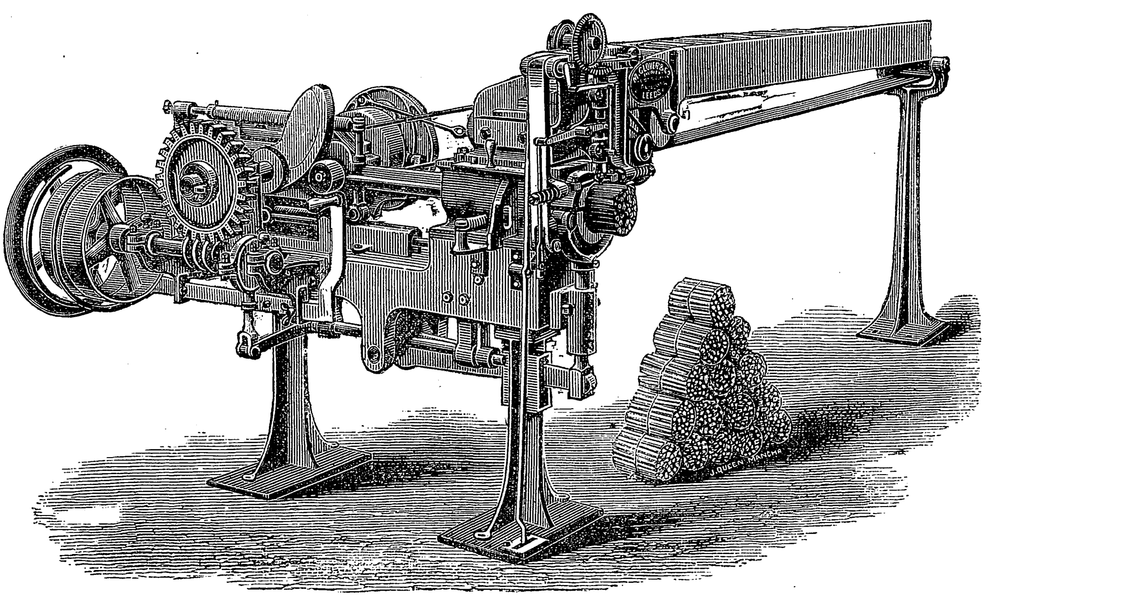


shaft 3in. long, H. This flywheel may be keyed or brazed to the shaft. Just beyond the flywheel at I the shaft is turned down so as just to enter freely into the holes at *e* and *e'*. At the extremity, G, a screw thread is put on the projecting end of the rod to take the female screw of the driving handle, shown at J. At the opposite extremity, H, the shaft is drilled and tapped to take a rather large-headed screw which serves to prevent the shaft from riding to and fro.

§ 47. The operator may now proceed to wind the bobbins. For this purpose he will need about 1lb. of No. 26 or 28 double silk-covered wire. Having ascertained by testing with a battery and galvanometer, that the wire is continuous, it will be well to soak the coil of wire for a few minutes in hot melted paraffin wax, allowing the paraffin afterwards to drain off, by suspending the coil for a few minutes in a rather warm place. The iron bobbins F F' are then wrapped round with one layer of brown paper, which is fastened down to the cores with good glue. Two semicircles, with hole cut in the interior to fit the iron cores, are also glued inside the flanges, so that the whole of the inside of the bobbins is entirely covered with brown paper. When the glue is *quite dry*, the bobbins may be warmed, and plunged for a few seconds in hot melted paraffin. Each bobbin is then to be wound, *in the same direction*, with the wire above specified, until the bobbin is filled to the top of the flange. To prevent unwinding the finishing ends may be tied down to the bobbin with a

† This article is introduced here at the express desire of many correspondents, although really intended to appear later on.

FIG. 1.



bit of silk, leaving, however, about 2in. of the wire *free* for attachment to the spindle. The commencing ends of the wire must also be allowed to protrude beyond the flange for 2in. or 3in. for connection. The two bobbins are then screwed firmly to the yoke, the yoke afterwards being put on the spindle. When this has been done, the four ends of the wires are joined, as shown at Q, Fig. 21; that is to say, the two lower ends (after their covering has been removed) are twisted together, soldered and rubbed over with Prout's elastic glue, to insure insulation; while the two top ends are screwed, each one down to the shaft, one at B and the other at B′, the covering having been previously removed from the wire at these points to insure perfect electric contact with the two halves of the shaft. In order that the machine may work, the relation between the winding and connections of the lower ends of the bobbin wires (as seen from the yoke end) must be like this— ∽. A thin ebonite washer is now placed over the yoke, and the little pulley P screwed tightly in its place. This must be screwed down very firmly, as upon this depends the stability of the armature. The armature is now *finished* as far as actual work goes, but the bobbins may be covered with any pretty-coloured silk velvet, if appearance be studied.

§ 48. The brass frame is now clamped by means of a stout brass cross-piece K (Fig. 22) to the magnet; and if necessary, a second cross-piece (also of brass) is screwed to the frame at L. The back end of the armature spindle (the end farthest from the pulley) is passed into the larger hole B′ of the frame A. This will allow the other end of the spindle being inserted into the opposite hole B, without strain. When the spindle is in its place, the hollow screw is placed in B′, and screwed home, until the armature spindle can just turn freely, without too much play, before the poles of the magnet. In like manner the driving-wheel I is put in its place by passing the long end of spindle through the holes *e* and *e*, and then fixing it in position by means of the larger headed screw already mentioned at the end of § 46.

The small spring R is then screwed down to the frame at *f*. It must *just rest* on the projecting corners of the triangle E′ during rotation, and *just clear* the flattened portions. On careful attention to this point a great deal of the efficiency of the machine depends. The shock is felt, not *while the current is continuous*, but at the instants of *breaking* and *making* contact. The instrument can now be placed in any suitable box, which must be sufficiently long to allow the armature to rotate without striking against the ends, and just a trifle—say, $\frac{1}{8}$in.—wider than the frame. The frame is attached to the box by means of screws which pass through the box into the holes *c* and *c′* of the frame. The screw at *c* should be hollow, so as to take a small pin, or screwed wood, which is intended to make connection with the metallic cords and handles, which are used for giving shocks. Another similar screw is put in the side of the box almost opposite the armature, and to this screw, in the inside of the box, is fastened a rather stiff brass spring about $\frac{1}{4}$in. wide, bent into the shape of L, the longer end of which must press firmly against the end of the armature spindle which projects through the bushed hole B (Fig. 22). This latter screw forms the other terminal of the machine, the other cord, &c., being affixed thereto. It is usual, though not essential, to place a soft iron keeper at the back of the magnets poles, which may be partially or wholly removed at will. This enables the operator to regulate somewhat the strength of the shocks by increasing the inductive effect of the magnet on the armature, consequent on the removal of keeper from near its poles. There must also be a hole in the box, to allow of the insertion of the driving-handle, J.

PATENT FIREWOOD CUTTING AND BUNDLING MACHINERY.

MESSRS. GLOVER AND CO., of Leeds, have patented machines, which we herewith illustrate, for the purpose of cutting-up waste timber and tying it in bundles ready for sale. These may be worked either separately or combined. The whole arrangements are so ingenious as to well merit the attention of all those who are interested.

The chopping portion consists of a knife, which is actuated in a manner similar to the chisel of a mortising machine. The timber to be chipped is cut into lengths of about 6in., and fed into the machine by rollers, the grain of the timber, of course, being vertical.

The blocks follow each other in close succession, and the cross head carrying the chisel being itself of some weight, the blocks are cleanly split, knots being readily cut through, which hand labour would probably have to throw on one side; and we notice that the splitting exactly resembles hand-work, the grain of the wood being followed, a spring side being fitted to the feed trough opposite the knife to allow the necessary small movement to take place in order to secure the above result.

A brake is applied to the wrist pin disc, which stops the machine when the strap is thrown off. Any required size of chips may be made by altering the rate of feed.

After leaving the knives the chips fall upon a set of revolving octagonal rollers, which thoroughly sift any dirt or dust out of them, and also carry them forward towards the bundling machine.

Here the chips fall into a box of a fixed size. In this box they are subjected first to a rapid agitation, which settles them into their least possible volume, their flat sides coming together, and they then are operated upon by four "formers," thus making the bundle round, after which they are firmly compressed. Previous to this, however, they are all set with their ends level by means of a plunger, which enters the back of the chamber, pushing the sticks up to a diaphragm, which then withdraws.

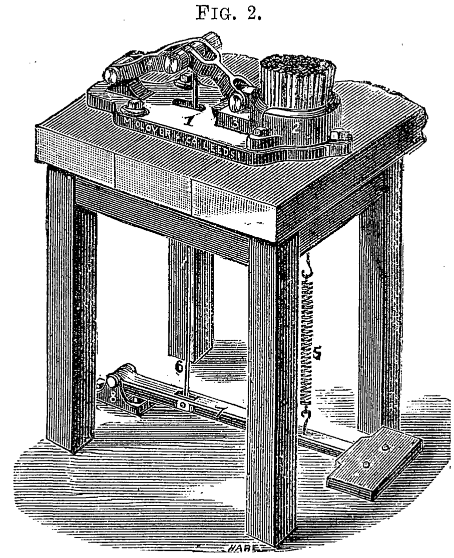
When compressed ready for bundling they are ejected from the chamber by the advance of a cam-driven plunger, and forced outwards through a slightly converging tube, having a movable spring top, into the position shown in the illustration Fig. 1.

In this position they are tightened up by means of an encircling belt of steel, which is drawn up by means of a powerful toggle-joint gear, and when thus held, a wire is passed round the bundle and held by means of a clip above, which can be released by a foot lever.

When the wire is fixed the clip is made to revolve by a peculiar engaging device, twisting the ends of the wire, and the bundle is then complete. The clip then releases the wire, and the operation goes on, the finished bundle being pushed out completely by the next comer.

Fig. 2 shows a bundling machine of a different

FIG. 2.



construction, for hand and foot work alone, being adapted to the smaller requirements of firewood dealers and public institutions. It is claimed that this very simple, yet extremely powerful and expeditious, machine effects a very great saving in time and wages, and turns out better work, though only requiring the most inexperienced hands. The illustration otherwise speaks for itself.

A THEORY OF VOLTAIC ACTION.*

THE experiments, as described below, lead to the conclusion that the difference of potential observed near two metals in contact is due to the chemical action of a film of condensed vapour or gas on their surfaces.

Such a pair of metals, with their liquid or quasi-liquid films are quite similar to a galvanic cell composed of the same metals, and a liquid similar to that of the films as electrolyte, said electrolyte being divided (in the ordinary static "contact" experiment) by the intervening diaphragm of air or other gas.

* Abstract of a paper by J. BROWN (Belfast), communicated to the Royal Society by Lord Rayleigh, Sec. R.S., Nov. 18th, 1886.

In making the experiments, a specially prepared quadrant electrometer was used, having opposite quadrants of the pairs of metals under examination. This instrument was gas-tight (in the ordinary sense), and means were provided for introducing any desired gas or vapour into it, so as to act on the metal quadrants while being tested electrically.

A copper-zinc Volta's condenser, having plates 8in. diameter, was also used. With both instruments the differences of potential near the metals were compared with that of a Daniell cell, represented by the symbol D in what follows.

A number of experiments were made to ascertain the rate of decrease of difference of potential of the films on copper and zinc in air, due to the gradual tarnishing of the metals, the object being to estimate the effect due to clean metals, and compare this with their heats of combustion with oxygen. Although with these metals the comparison holds fairly well, with some others it is only an approximation, which, however, is only what might be expected, seeing that so little is known of the nature of the film and the action taking place in it.

Similar measurements were made with copper and iron in an atmosphere containing hydrogen sulphide. The film on the copper becomes positive as soon as the gas is admitted, and in this particular experiment the difference of potential rose in 1h. 18m. afterwards to ·55D. It then fell gradually during eight days to zero, owing to the protecting action of the films of sulphide formed on the metals, the gas being still present. The following (quantitative) results were also obtained in this kind of experiment, where a change in the constituents of the atmosphere surrounding a pair of metals in contact reverses the difference of potential of their films, in correspondence with the reversal of electromotive force which takes place after a similar change in the corresponding liquid electolyte used with the same metals as a voltaic cell.

Such reversal takes place with pairs of copper-iron when hydrogen sulphide or ammonia gas is added to the air surrounding them; with silver-iron when hydrogen sulphide is added, or with copper-nickel when either ammonia or hydrochloric acid gas is added. The addition of neutral or inert gases has little or no effect, and no exceptional case has been found.

It was sought to annul all electrical effect by varnishing the condenser plates, as had been done by the earlier experimenters, or by filling the electrometer with naphtha till it covered the quadrants; but the difference of potential did not fall below ·29 D in the first case and ·23 D in the second.

Faraday's statement that electrolytic "decomposition, and the transference of a current, are so intimately connected that one cannot happen without the other" ("Experimental Researches," Vol. I. page 252), gives countenance to the idea that the film is of an electrolytic nature, and, therefore, probably, water condensed from the air. Two experiments were therefore made to test the effect of drying the air round the metals. With a pair of copper-zinc quadrants inclosed with phosphoric anhydride for 173 days the difference of potential gradually fell from ·659D. to ·5D. Then, on allowing the instrument to remain open for an hour, the value rose again to ·67D., a result quite as marked as might be hoped for with the unsuitable apparatus at command.

Touching more nearly on the nature of the film itself, it was found that when the copper and zinc quadrants were wet with distilled water, their difference was ·88D. (by calculation from thermo-chemical data it should be about ·9D.), and when the copper was wet with copper sulphate solution, and the zinc with zinc sulphate solution, thus forming a Daniell cell divided in its electrolytic circuit the value was almost exactly one Daniell.

The well-known experiment of Sir W. Thomson, where a water-drop was placed between the previously disconnected metal quadrants, is thus easily explained. The water-drop connection equalised sensibly the potentials of the films by altering those of the metals, which were previously at one potential.

This aspect of the Volta condenser as a copper-fluid zinc cell divided in its electrolyte, suggested the possibility of joining the films only on the two metals, without bringing the metals themselves into direct contact, and so producing a real galvanic current-producing cell from the apparently dry metals. After the expenditure of much time and care in bringing the copper and zinc plates to a true surface, cleaning and adjusting them, a current was observed which varied in different experiments from a few up to 130 divisions of the galvanometer used, but which immediately ceased when the plates were either drawn apart or placed in direct metallic contact.

It was found also that the "film cell" so produced could be polarised by connection with another battery.

In order to show that electrification is produced without any dissimilar contact of metals, an old experiment of Gassiot's was modified so as to avoid any such uncompensated contacts. The zinc plate of the condenser was joined to the zinc quadrant of the electrometer, and the copper of condenser to copper of electrometer. Now, on altering the capacity of the condenser, a very decided alteration of the difference of potential near the quadrants of the electrometer was observed. It is evident there were electrical charges present, although there was no actual metallic contact at which any electromotive force could (according to a commonly accepted theory) have existed to produce them.

The paper concludes with a series of diagrams representing the distribution of potential in a zinc-water-copper element, under different conditions, according to the theory adopted.

In an appendix, Mr. J. Larmor, Fellow of St. John's College, Cambridge, points out the difficulty of explaining the production of a variation of potential at the quadrants in the above modification of Gassiot's experiment by any hypotheses other than that of some kind of chemical action at the surface of the metals.

A METHOD OF FINDING OUT THE GENERAL CHARACTER OF THE COMPONENTS OF A CEMENTED COMBINATION.*

By EDWARD M. NELSON.

SOME microscopists take no special interest in their lenses beyond occasionally wiping the front, and with a camel's-hair pencil brushing the dust from the back when it gets too thick. Others unscrew the combinations to clean them, and like to know whether they are composed of two, three, or four sets of lenses. Some, again, know all about the components of each combination, and some wish they did. It is to this last class of inquirers that this paper is directed. Let me first say that there is only one way of finding out the exact composition of a lens, and that is by taking down every combination, uncementing every lens, measuring the exact curvature, and the refractive and dispersive power of the glass of which it is made. It will be admitted, however, that it is very useful to know whether a combination consists of two or three lenses, and if those are biconvex, plano-convex, meniscus, &c. To find such information without uncementing a combination is the scope of this paper. The method I employ is simply the consideration of the reflected images from the surfaces of the glass. Take the plane mirror of your microscope in your hand, and examine the reflection of a window. Notice that it is an erect image, and that when you move the mirror in a certain way the image appears to come towards you. Now look at the concave side, the image is inverted, and when the mirror is moved in the same direction as before the image goes away from you. A convex mirror behaves as a plain mirror, there being only this difference—that the greater the convexity the smaller is the image, which difference is also true of a concave mirror—viz., the greater the concavity the smaller the image. If you now examine a single biconvex lens, you will see a large erect image from the surface next the window, and a small inverted image from the surface on the other side. It acts precisely as if it were a convex and a concave mirror. In a single biconcave lens you have a large inverted and a small erect image. In a plano-convex, with the convex side towards the window, you will find a small erect image from the convex side, and a large inverted image from the plane side. With the plane side towards the window, you will have a large erect image from the plane side, and a small inverted one from the other side. With the concave side of a plano-concave towards the window, the concave side will give an inverted image, and the plane side an erect image; but with the plane side to the window, you will get two erect images. Converging and diverging menisci have for their convex sides two erect images, and for their concave sides two inverted. I find, however, that in a converging meniscus, if the concave surface is of very large radius, the reflection from it when viewed from the convex side will be inverted instead of erect; in other words, it will take the form of a plano-convex. I imagine that in a diverging meniscus, which closely approximates the form of a plano-concave, the same result would be found—viz., that the image from the flat side, when seen through the more concave side, would be erect instead of inverted, as one would expect; but of this I have no practical experience, not having a single lens of that form to experiment on. Now, if we take a cemented doublet, consisting of a biconvex and a plano-concave, we shall very easily see the two bright reflections from the two exterior surfaces—viz., the plane and the convex. The image from the cemented surfaces, however, will not be so readily apparent. With a little attention it will be discovered as a faint image, with most probably a bluish tinge, though occasionally it may have a reddish tinge. When once seen, it will be easily recognised again. A triple combination will have two faint images as well as two bright ones. I find the following the best method of procedure. First find out by the number of faint reflections if the lens is a doublet or a triplet. Next find out the nature of the external surfaces, and write them down—e.g., plano-convex doublet. This means that the combination is composed of two lenses, and that one of the external surfaces is convex and the other plane. Now write down the reflections as they come, beginning at the side next the window, underlining the reflection from the first surface, and putting the reflection from the cemented surface in (). In writing these down, I use the following abbreviations: *e* for erect, *i* for inverted, *s* for small, *l* for large, and L for very large. It is a good plan to draw the lens by representing, first, the external surfaces only, and then filling in the cemented surfaces, according to the reflections you obtain. It is absolutely necessary that the reflections from both sides of the combinations should be ascertained, as it is impossible to discover the construction of the combination from one set of reflections. When the images are large it is as well to look at the reflection of the bar across a window; the knob of the hasp showing if the image is erect or inverted. The images from small lenses require to be examined by a magnifying glass. One word of caution, and that is, until one is practised in picking up these faint images, the very large faint ones are apt to be overlooked. Until one is familiar with the manner of holding a lens, only a faint blue tinge will be seen over the glass; but after a little practice, a distinct image of the window bar will be obtained. The following are a few examples:—

A plano-convex doublet—

Convex side .... *se* (si) li.
Plane side .... *le* (se) si.

It therefore consists of a biconvex and a plano-concave. The next two form an interesting pair, as both have the same external form.

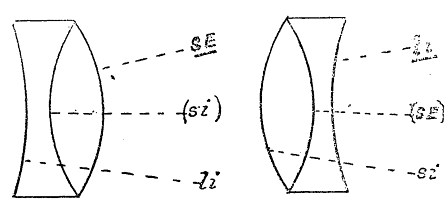


FIG. 1.

Converging meniscus doublet—

Convex side .... *se* (si) li.
Concave side .... *li* (se) si.

This consists of a biconvex and a biconcave. The other has—

Convex side .... *se* (se) li.
Concave side .... *li* (si) si.

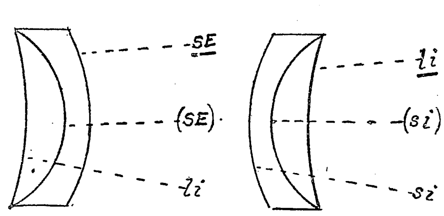

FIG. 2.

This consists of a converging and diverging meniscus. The difference between these two last combinations is at once shown by the different characters of the reflections from their cemented surfaces. The intelligent observer will note that the concave external surface, when seen through the convex surface, has its sign changed from *e* to *i*; of this I spoke above.

An unequal biconcave doublet—

Most concave side .... *li* (se) si.
Least concave side .... *Li* (si) se.

This is, therefore, a biconcave and a converging meniscus. The s i in the most concave side is not what one would have expected. The internal curves of the meniscus must have a short radius, so that it overpowers the external concave surface of the biconcave. The least concave side is very flat as shown by L. A biconvex triple will take the form of *e* (i) (e) i on both sides. In consists of a biconvex, biconcave, and a biconvex. A plano-convex triple consisting of a biconvex, biconcave, plano-convex will have the same form, only the plane side will give *Le* instead of *se*, and li instead

* Read before Quekett Microscopical Club, Nov. 26, 1886

of si. An unequal biconvex triple, as a properly constructed opera-glass objective, will give:—

Most convex side ...... *le* (si) (Li) li
Least convex side ...... *le* (Le) (se) si

The lenses therefore are biconvex, diverging, and converging menisci. A biconcave triple, as in a properly-constructed opera-glass eyepiece, gives:—

From the thickest lens side...... *li* (se) (le) se
From the thinnest lens side ... *li* (Le) (li) se

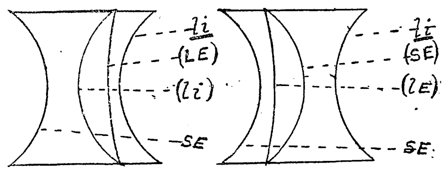

FIG. 3.

Its form is biconcave, converging meniscus and diverging meniscus. If the middle were a piece of plain glass, which is sometimes fraudulently put, its form would be—*i* (e) (e) e alike on both sides. But if it had a thin converging meniscus in the middle, it would read:—

From one side .... *li* (le) (le) se
From the other ...... *li* (Le) (Le) se

You will have probably noticed that the diverging meniscus turns the (i) into an (e), following a plano-concave, as I hinted above, only making the s into an L. These examples will be sufficient to make anyone acquainted with the method I employ. I have for long thought it was possible to find out the character of a combination by means of the reflections; but having only received negative replies to my repeated inquiries from those who ought to know, I have been deterred from investigating the matter for myself until this summer.

USEFUL AND SCIENTIFIC NOTES.

Orthochromatic Photo. Plates.—According to the *Photographische Mitarbeiter*, the following is the recipe for orthochromatic gelatine plates, as given by Dr. Mallmann and Ch. Scolik. The plates are first dusted with a soft camel's hair brush, and placed in a bath containing water, 200c.cm.; ammonia, 2c.cm.; in which they are allowed to remain for two minutes. They are then taken out, and after draining are immersed in the following solution:—Erythrosin solution (1 to 1,000), 25c.cm.; ammonia, 4c.cm.; water, 175c.cm.; for 1 to 1¼ minutes, the dish to be kept covered and in motion. Both baths can be used for a dozen plates, but after the seventh or eighth 1c.c.m. ammonia should be added to both solutions. The plates are then taken out, and allowed to dry in a perfectly dark room. This is accomplished in about three hours. Care should be taken against overheating. With these plates the alkaline pyrogallic developer should be used. If the oxalate of iron developer be employed, veiling is the result.

Detection of Leaks in Water Mains.—The microphone is now being used in Germany for the purpose of detecting loss of water through leakage in town mains. The apparatus consists of a steel rod, which is placed upon the cock in the neighbourhood of which the leak is suspected, and a microphone attached to the upper end of the rod. A dry battery and a telephone complete the equipment. No sound is heard in the telephone if the cocks are closed and no leak occurs; but a leak of even a few drops through a badly fitting cock causes sufficient vibration in the pipe to affect the microphone, and to give audible sounds in the telephone. At a recent meeting of gas and water engineers in Eisenach, it was stated that the apparatus is so simple to handle that, with a little practice, ordinary workmen are able to detect and localise any leak.

A CORRESPONDENT of the *American Machinist* gives the following as his method of straightening a shaft: "It was 16ft. long, 2$\frac{15}{16}$in. diameter, and had a 44in. pulley, 8in. face upon each end, one tight and one loose pulley, 8in. face upon the middle of shaft. Without taking it out of its bearings I took a piece of timber 8in. by 8in., 10ft. long, and hung it to the shaft by a ⅝in. chain, at each end of the timber, the timber being 24in. inches below the shaft, then chalked the shaft at the high point, then turned that point down, then set a jack screw upon the timber with top of jack at the chalked point, turned up the screw a little, took out jack, chalked again, and repeated the operation until I had the shaft straight. The whole operation did not take over one hour. This shaft was ½in. crooked, and I once straightened a 3in. shaft the same way that was bent 6in.

SCIENTIFIC NEWS.

IN the course of his anniversary address before the Royal Society, Prof. G. G. Stokes, the president, said that the balance-sheet showed a considerable excess of income over expenditure, and that what has been called the "Scientific Relief Fund," thanks to the munificence of Sir W. Armstrong and the subscriptions of Fellows and others, will shortly amount to £20,000. Referring to the late eclipse expedition, Prof. Stokes said that, although there has not been time to discuss the observations in full, two points appear to have come out clearly—that the brightness of the corona was much less than had been expected, and that it is doubtful whether it is possible to photograph the corona unless the sun is eclipsed. Speaking of the advance which has been made in celestial photography, Prof. Stokes said he had received an invitation to be present, with another delegate from the Royal Society, at the Conference which is to be held at Paris on April 16, and would take an early opportunity of consulting the new council about it. The Royal and other medals were awarded, as specified on p. 282, and Prof. Michael Foster was elected one of the treasurers, and Prof. D. Ferrier and A. Gamgee, M.D., members of the council.

The death is announced of Mr. Arthur Grote, on the 4th inst. He was born in 1814. He was a Fellow of the Royal Society and also of the Linnæan Society. Mr. Grote wrote a number of papers on subjects connected with botany and natural history, and contributed an introduction to Hewitson's "Description of New Indian Lepidopterous Insects in the Atkinson Collection."

Prof. Rücker, F.R.S., has been appointed to the post so ably filled by the late Prof. Guthrie, F.R.S. The professorship of Physics in the Normal School of Science at South Kensington is worth £800 a year.

In the *Journal* of the Liverpool Astronomical Society for December, Mr. T. G. Elger continues his article on "The Moon surveyed in Common Telescopes," Mr. Denning has some useful hints on "Telescopes and Telescopic Work," and there are a number of papers on interesting subjects connected with astronomy.

Messrs. Macmillan will publish almost immediately "The Chemistry of the Sun," by J. N. Lockyer, F.R.S., in which will be a full statement of the hypothesis put before the Royal Society by the author some years ago—viz., that the so-called elementary bodies are in reality compound.

In the course of one of the Rosebery lectures at the University of Edinburgh, Mr. G. J. Romanes said that the cell remains the unit, for protoplasm could not yet, so far as the microscope could show, be said to justify the name of structure. At the same time, the difference of cell pointed to difference of protoplasm, and it must be concluded there were as many kinds of protoplasm as there were species in the vegetable and animal world.

The Potato Tercentenary held at St. Stephen's Hall, Westminster, produced a splendid show of the famous esculent vegetable, and at the conference several papers were read. Mr. W. S. Mitchell said in his paper that he believed Drake introduced the potato to England in 1586. Mr. Clements Markham read a paper in which he stated that the original home of the potato was in the Cordilleras of the Andes, and that it had been cultivated from time immemorial over an extent of 3,000 miles. Mr. J. G. Baker of Kew, read a paper on the "Wild Germs of Tuberous Solanums," in which he stated that there are five thoroughly distinct species of tuber-bearing solanums, all natives of America. S. tuberosum (the common potato), in one form or another, extends down the western side of the American continent from the Rocky Mountains to the Chonos Archipelago, a range of 75 degrees of latitude, and within that area no fewer than sixteen forms are found, so different that even some botanical writers have regarded them as different species. Mr. Murray, of the British Museum, read a paper on the "Potato Disease," in which he said that microscopic investigation showed that the complete fungus could be produced in three hours—a fact which sufficiently accounts for the sudden and disastrous spread of the disease, too familiar to all potato growers. Dr. Maxwell Masters read a paper on the "Production of Varieties by Cultivation," and several well-known cultivators took part in the "conference," which will certainly result in the wider dissemination of more accurate knowledge concerning the history and character of the favourite vegetable.

According to Dr. C. W. C. Fuchs's twenty-first annual report, the number of earthquakes recorded during the year 1885 was 230, of which 40 occurred in January, 30 in February, 27 in March, 23 in April, 11 in May, 18 in June, 10 in July, 12 in August, 15 in September, 14 in October, 10 in November, and 20 in December. It appears that the volcanic eruptions during 1885 were few and insignificant. Vesuvius remained in its usual Stromboli-like condition, except in May, when a feeble eruption occurred. Etna was also generally quiet; but in March the instruments at the observatory indicated subterranean disturbances, and in August ashes were ejected.

At an inquest held last week in Clerkenwell relative to the death of a man aged 77, it was stated that the deceased "was inventing a valuable improvement in steam navigation," giving "four times the ordinary speed with a quarter the present consumption of fuel"—at least, so said a witness, who also stated that the deceased expected £40,000 from the Government; but was somewhat stubborn, as he wanted the cash before divulging his invention. The deceased probably had a sufficient reason for his reticence.

With reference to the submarine boat which has attracted some attention in the daily papers, it may be as well to point out that the idea is certainly more than 250 years old, for in the reign of James I. a Dutchman, named Drebbel, constructed a boat which travelled under the surface of the Thames. Since then many submarine vessels have been designed, but none of them have yet accomplished what has been done by Prof. Tuck's *Peacemaker* (see p. 82) in the Hudson River, New York. That vessel apparently dives with ease, and returns to the surface as desired. A very powerful submarine vessel is being built to the designs of Mr. Nordenfelt, with engines of 1,300 horse-power, and it will probably be ready for trial in Southampton Water in the spring.

The Paris Academy of Medicine, expressing an opinion on the adulteration of wine, declares that the addition of pure alcohol to wine to the extent of 2° may be permitted, because that quantity is necessary for the preservation of wines of low strength. Some of the wines sold in New York have been recently analysed by Dr. Cyrus Edson, who says that one firm of "extensive growers" manufacture wine from dried fruits and a solution of sugar, the liquid being preserved by the addition of salicylic acid. Dr. Edson has recently succeeded in getting an order for the destruction of upwards of 5,000 gallons of this stuff.

On Friday last a conversazione in connection with the King's College Engineering Society was held at the College, when all the departments in which there are evening classes were exhibited in full work. The advantages offered by these classes to those desirous of obtaining technical instruction are evidently appreciated, and the number of students is rapidly increasing.

We do not often draw attention to advertisements in this page, but we make an exception for once, for which not a few readers may thank us, with regard to the sale next Friday at Manchester of the scientific and mechanical instruments of the late William Hartley, the inventor of the geometric chuck. His machine for geometric turning included in this sale is the most perfect ever made for this purpose, and is absolutely correct in all its movements.

The general meeting of the Aëronautical Society of Great Britain will be held in the hall of the Society of Arts next Saturday, commencing at 3.30 p.m.

THE production of copper in the United States in 1885, including 5,086,841lb. made from imported pyrites, was 170,962,607lb., valued in New York at 18,292,999dols. at the average price of 10·7 cents. per pound. The increase in pounds over 1884 was 25,740,667; in value, 503,312dols.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the EDITOR *of he* ENGLISH MECHANIC, *332, Strand, W.C.*

All Cheques and Post-office Orders to be made payable to J. PASSMORE EDWARDS.

⁂ In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks, a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

THE BINARY STAR η CASSIOPEIÆ.

[26566.]—I SHOULD be glad to know of any very recent measures of η Cassiopeiæ, Σ 60. Engelmann gives, for 1882·87, 165·70° : 5·155″ (six nights); Seabroke, for 1883·10, 166·2° : 5·11″ (five nights); Doberck's elements give, for 1883·0, 164·6° : 5·51″; L. Struve's, 168·1° : 5·40″. Evidently the semi-axis major obtained by both Doberck and Struve, though much smaller than Dunér's, is still too large. The "Star Guide" gives, for 1886·0, 175° : 4·9″. Probably a does not much exceed 8·5″. I have drawn attention to the remarkable similarity between the binaries 70 Ophiuchi and η Cassiopeiæ in the ENGLISH MECHANIC for July 10th, 1885 (letter 24441.) **H. Sadler.**

DOUBLE STARS—U CYGNI.

[26567.]—I HAVE noted Mr. S. M. B. Gemmill's query *re* U Cygni in letter 26492, page 260; but after a prolonged search I regret to say I can find no mention of it as a double star in any books I have consulted. This may perhaps be accounted for by the fact that it is almost too wide a pair to be considered a double star at all in the strict sense of the term, and is certainly not a case where any considerable orbital motion would be expected. I have placed the star on my working list, and have measured it on four nights, with the following result:—

P.A.	Dist.		
51·7°	62·72″	1886.90	4 nights

The definition on two occasions was rather unsteady, but the colours were noted in brilliant contrast, and with a low power the pair is unquestionably a very fine one of its class. I omitted to mention that a power of 180 was employed, and both methods of illumination used in making the measures. **Kenneth J. Tarrant.**

Letchford House, Pinner, Dec. 3.

SIRIUS.

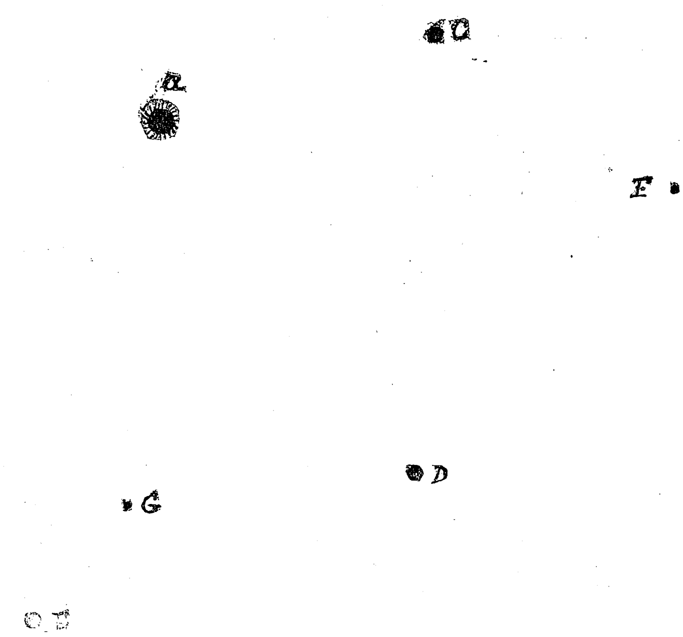
[26568.]—IF Mr. Sadler will read my paper in the *Journal* of the L.A.S., and compute by the formula there given the sum of the masses of the Sirius system, for a parallax of 0·150″, he will find, I think, that my figures are substantially correct. As the *cube* of the parallax enters the formula as a divisor, a small difference in the assumed parallax will make a considerable difference in the resulting mass. I fail to see, however, how Auwers arrived at so small a mass as $13\frac{3}{4}$ for Sirius and $6\frac{3}{4}$ for the companion, with his assumed parallax of 0·193″. This parallax would give, for a mean distance of 13 times the radius of the earth's orbit, semi-axis major a = 0·193″ × 13 = 2·509, and the semi-axis major of the Sirius system is certainly more than this. Colbert found a = 8·41″. There is a misprint in the formula given in my paper. On page 48, $\left(\frac{a}{p}\right)$ should, of course, read $\left(\frac{a}{p}\right)^3$. **J. E. Gore.**

ASTRONOMICAL—α ARIETIS—δ EQUULEI.

[26569.]—AS this star has come to the front of late in the "E. M.," I send you the result of two observations I have made lately. If the sketch inclosed is compared with the one given on p. 222, it will be seen that the stars have changed their places considerably since the time of Ad. Smyth. Their magnitude also has varied. I estimated—

α C P. = 108° dist. 260″
α F = 80°
α D = 50°
α G = 350°
α E = 340°

D is half a mag. smaller than G; F is, at least, two mags. fainter than D; G is very faint, and does not seem to have been observed before. It is, at present, the nearest *comes* to α visible; E is



given only as a point of reference to find G. I looked for the close *comes* S. of α. During my first observation I thought there was something like it at position 230°; but this was not verified during the next.

δ Equulei is now position 180° ±, and enters that portion of its orbit where it has never been observed. Double-star observers will doubtless watch its movements with the greatest interest, as this seems to be the most rapid movement known.

Nov. 25. **C. M. Gaudibert.**

THE VARIABLE STAR V CYGNI.

[26570.]—THE non-success of Mr. Gemmill in not seeing this variable on Oct. 31 (letter 26492, p. 260), probably arose from the aperture of his telescope being too small. However, if he is familiar with the place of the object, he should have glimpsed it with a $3\frac{1}{4}$in. o.g.; but if he is not certain of its identity, he will find a description of its position in letter 24964, page 199, for Nov. 6, 1885.

Mr. E. W. Maunder (letter 26546, p. 301) states that this star has not often been observed, and that its period has not been satisfactorily determined. I think it will probably be found to be an irregular variable with *two* unequal maxima.

I have not seen Mr. Baxendell's observations, to which he refers; but great weight will be attached to this accurate observer's data. The Rev. T. E. Espin stated that he has kept this variable on his list for regular observation, and possibly he could now add particulars. Some Continental astronomers noted in 1882 and 1883 several variations in the physical appearance of this beautiful star, as it presented sometimes a nebulous aspect with a sensible diameter.

The late Mr. J. Birmingham, its discoverer, gave the following estimates of its magnitudes:—1881, May 22, 9 mag.; June 9, 8 mag.; July 30, 9 mag.; Dec. 21, 12 mag. 1882: April 28, 8 mag.; May 6 and 16, 8·3 mag.

The following are the dates of my own observations, with the respective rough eye-estimates of magnitudes, which I hope may be of some service, in connection with others, to enable its light curve to be tabulated for future reference by observers of variable stars:—

	Mag.		Mag.
1881, May 31	$9\frac{3}{4}$	1885, Oct. 3 and 15	$10\frac{3}{4}$
1882, May 13	$9\frac{3}{4}$	" " 26	$10\frac{1}{2}$
" Sept. 3	9	" Nov. 12.........	$9\frac{3}{4}$
" Oct. 19	$9\frac{1}{2}$	" " 14.........	$9\frac{1}{2}$
" Nov. 7	$9\frac{1}{2}$	" " 16.........	$9\frac{1}{4}$
1883, May 5	$12\frac{1}{2}$	" " 18.........	9
" May 27	12	" " 21.........	8
" June 2	$11\frac{1}{2}$	" Dec. 2	$8\frac{1}{4}$
" July 26	$8\frac{1}{2}$	" " 5 and 7	8
" July 28	$8\frac{3}{4}$	" " 10.........	$8\frac{1}{4}$
1885, Sept. 19	$11\frac{1}{2}$	1886, Jan. 2	8
" " 26	11	" Oct. 31	12
" " 29	11	" Nov. 25.........	$11\frac{1}{2}$

Belfast, Dec. 6. **I. W. Ward.**

BARNARD'S COMET.

[26571.]—I FIRST saw this object on Nov. 11th in strong twilight. I noted it as a "pearly-white nebulosity, with strong central condensation as bright and larger than Messier 13 Herculis."

Cloudy weather prevented further observations until December 2nd, 17h. 40m. G.M.T., when I picked it up when sweeping. A great change has occurred. The comet, which before had no trace of a tail, has now *two* tails, the longest, which expands as it recedes from the nucleus, being 8° long; the short one, which tapers to a point, is about 1° in length. The tails inclose an angle of about 40°. The edges of the long tail, and that of the short tail which is farthest from the long tail, are perfectly straight and sharply defined; but the other edge of the short tail seems to shade off indefinitely except just near the nucleus, where it is sharp.

The head of the comet is about equal to a star of the third magnitude in brightness, and its position is, roughly, 15h. 10m. N. Dec. 16°, about 3° west of τ^1 Serpentis (Proctor), while the tail can be traced to 45 Boötis with an opera-glass, and about two-thirds this distance with the naked eye. **C. L. Tweedale.**

[It is impossible satisfactorily to reproduce the sketch sent with this.—ED.]

COMET f 1886.

[26572.]—SEEING from the letter of B. J. Hopkins (26545, page 301, Dec. 3rd, 1886) that this comet was developing into a rather interesting object, I persuaded myself to rise at the rather unusually early hour (for me) of 5 o'clock this morning, and, the sky being clear, I was amply rewarded for my trouble by a splendid view of the comet, both naked eye and telescopic; so with your permission I will just describe its appearance, and, taking the naked eye aspect first, I may say the head was as bright as a large third magnitude star, and was situated in the eastern sky about half a degree north of κ Herculis—in fact, exactly at the point of the elbow of Hercules' left arm as he is placed amongst the old constellation figures. The tail, though faint, I could see stretching upwards almost perpendicular above the head to a distance of about 9°, passing exactly over the star π Serpentis, and almost reaching ϵ Coronæ. Now, turning my 3in. achromatic on the comet, with a low power, I found it a beautiful object, with two tails, the long one and a short one at an angle of about 40° with the other, as mentioned by B. J. Hopkins; but he describes the short one as on the preceding side which I think must be a mistake on his part, as I found the short one on the following side, and I hardly think it likely they can have changed places. The nucleus was very bright, and situated about in the centre of the head as far as I could judge, and the long tail (here again I differ from B. J. Hopkins) widened out a little gradually as it receded from the head, the short tail, on the contrary, tapering almost to a point at its end, and being widest near the head—in fact, curving there towards the long tail, and, in my opinion, actually joining it, though at a short distance from the head the division was quite distinct, and this distinctness increased with distance from the head, though the inner edges of both tails were nowhere so clearly defined as their outer edges, which were comparatively sharp, especially the preceding edge of the long tail. The latter stretches over several small stars, which did not appear in the least dimmed by it; in fact, the tail as it crossed the field of the telescope resembled, as much as anything, a ray of sunlight shining through a chink in a shutter into a dark room, and seemed to make objects which it crossed more distinctly visible rather than less so. It was a very interesting sight altogether, and I shall certainly

not neglect any opportunity I may have of renewing my acquaintance with it, and I am sure it will repay anyone for any trouble he may be put to in getting up early to see it; but, by the by, if it continues straight forward in the apparent path it is now travelling across the sky, it will soon be visible in the evening, as it, in fact, does not pass below the western horizon now till after 6 o'clock in the evening, and each evening it is a little higher; so let us hope it will continue in that course, and then we can view it at our leisure, at reasonable hours, when weather permits.

Huddersfield, Dec. 6. **Excelsior.**

EGYPTOLOGY.

[26573.]—IT may be quite true, as "Memnon" says, page 283, that the Pentateuch nowhere promises or threatens anything in another world; but it constantly implies that blessings or curses on the posterity of those addressed are to affect themselves. Unlike the Sadducees, it takes for granted a "resurrection," being in fact pervaded, as well as the later books, by the Buddhist or Pythagorean idea of retribution in future lives here, in this same world. Eli was threatened in prophecy, before Samuel's time (probably before his birth) that the misery and short lives of his distant posterity should "consume his eyes and grieve his heart." On the contrary, Abraham and Isaac had been promised not only "to thy seed will I give this land," but to "thee and thy seed after thee," though in that life, under those names, they possessed none of it but a purchased burial plot. Each and his seed were yet to enjoy it together. Accordingly, Christ told the Sadducees that, at the time of His own birth, Abraham had been among them. "Your father Abraham longed to see my day, and he saw it and was glad." They were promised too, ages after David's time, that they should be gathered with David their king, "whom I will raise up to them." And Christ promised His apostles that they should sit on twelve thrones; which for aught we know they have. Such kings as our Alfred and St. Louis may have been of them.

Though it was predicted to Noah, "Whoso sheddeth man's blood, by man shall his blood be shed," the two most treacherous murderers in the very same book, Simeon and Leir, died peaceably, one at a greater age (Ex. vi. 16) than any Jew recorded since, or any Gentile, till old Parr and older Jenkins; as if to hammer into the brains of us European minority (for the Asiatic majority have always held it) that the threat need not be realised in the same life and death, for bloodshedders (and others) may have more than are dreamt of in our philosophy.

The people under Moses were so repeatedly reminded by him that they were fewer than any single nation of the seven they were to conquer, that the language of Canaan must have soon become the only one of all that were not grown up at the Exodus. Four centuries later, when Samuel wrote the Heptateuch, there was not a particle more reason for Israelites to retain Egyptian words than for the Moabites or Philistines to do so.

I said, and repeat, it is not written at the end of any other life than Abraham's, that "God had blessed him in all things." One more text compared with "Memnon's" speech of Eve will dispose of his accusation that translators ever used "the Lord" to disguise a difficulty. If Eve's speech be inconsistent with aught after it, why not with ch. iv. 26. "Then began men to call upon the name of JHVH"?

Why does he not object that if men only began to use this name after Seth was 205 years old (or in our corrupt dates 105), and Seth had not been born till Cain was grown up, and a murderer, Cain's mother could not have used it at his birth. Translators had but to leave "Jehovah" in one of these verses, no matter which; but by putting "the Lord" in both alike, they supply "Memnon" with a stiffer contradiction than he thinks he gets out of Exodus. The later neither says nor implies that the name *began* to be used only then. I said that anyone believing this (Moses, or any later), would still have applied it to God in translating the oldest documents. But there is no sign that this was ever believed by any. The Lord merely told Moses (Ex. vi. 3) that to three particular forefathers, He had not been known by this name; but the previous oracle (iii. 15) rather implies that to others He had been. "This is My name for ever, and this is My memorial to all generations," rather looks as if even antediluvians had known at least its meaning. All the Genesis names, we must note, by having meanings in Canaanite, show that they were translated into that from older tongues, not merely transliterated by sound, as they are into English. We might have had them Englished, as Hanahash, the liar who deceived Eve, and was doomed to become "the crawler," has been made for us a "serpent"; though a king of Ammon with the same name is not called so.

If there were fifty more Egypts on earth, all with histories going back before Menes, and all consistent, and every other Gentile legend not only ignored the Flood (which they all remember), but contradicted it, and pointed to monuments alleged older (as Lyell's invention of the cinder cones, that the "Speaker's Commentary" swallowed without inquiry), the facts of geology would outweigh all that as feathers. Even those certain 40 years ago sufficed. What are "great Egyptologists" to what is stamped physically on the globe? What "Memnon" can or can't "imagine" has even less to do with it. God's universe contains several more things than "Memnon" has imagined.

Joshua, according to the text, never spoke to either "the sun" or "the moon," but only to a "sun of Gibeon" and "moon of Ajalon Valley." And if "the sun stood still in the midst of heaven," no such thing had been predicted. Why could he not have said, Sun in heaven, stay; instead of "Sun of Gibeon, be silent"?

It is a small point, but "Ramases," "Dens," and "Memnon" all will have Samuel the "high priest"; I. Samuel i. shows he was of the tribe of Ephraim, and therefore could never be a priest; though as a prophet he had higher privileges. He could build altars and offer sacrifice anywhere; which no priest could do away from the sanctuary, and one who was neither a priest nor prophet, even if king, could do nowhere. Samuel's anti-royalist politics were nowise inconsistent with his editing the old prophecies about kingship. He believed himself ordered by God to accede to the popular clamour; and for aught that appears, he was the sole dissentient. I prefer Sir Isaac Newton (to whom I am indebted for all these views except Jacob Bryant's explanation of Joshua), who found no inconsistency here, to "Memnon" after all. **E. L. G.**

[26574.]—"MEMNON," in his reply (26526), says "'Dens' would find it hard to prove that Samuel wrote Deuteronomy." In that he is quite right; but as I never said so in my letter (26514), of course I do not need to prove it. If "Memnon" will refer back, he will see that I mentioned Samuel as the arranger of the Pentateuch, and that the whole possibility of his reformation depended upon its being in existence as the basis upon which he had to work. But as in this discussion the original information asked for has been overlooked—viz., as to who was the Pharaoh of the Exodus—the general opinion of authorities seems to be that it was Thotmes II. of Manetho's eighteenth dynasty, and Joseph's Pharaoh was Osirtasen I. of the Tanite (Zoan) dynasty, also styled the "Beloved of Set," "Set the Golden" being the Baal or sun-god of the Phœnician branch of the Shepherd kings; and when Aahmes, the king who knew not Joseph, drove out the Hyksos he captured Tanis or Anaris, their capital city, made it his principal residence, as did also his successors —hence the ease with which Moses and Aaron (living in Goschen) could have an interview with the king.

In the able letter of "E. L. G." (26527), he says of the hailstorm that it took place in the night. Well, it may be so; but if "E. L. G." will look at the 26th verse, he will find it says that Joshua hanged the kings upon trees *till the evening*, and in verse 27 it says, "And it came to pass at the time of the *going down of the sun* Joshua commanded and they took them down off the trees." As the hailstorm had done its work before this time, I don't see how it could have been in the night. **Dens.**

[26575.]—WITH regard to "E. L. G.'s" idea (26527) that no place now above sea-level has ever been submerged, and that the English and Irish Channels, much of the Mediterranean, &c., have become sea-beds, "not by sinking, but by the addition of so much water to our globe as to raise the ocean level about 100 fathoms," I would simply advise him to calculate the quantity of water necessary to raise the ocean level this height (even supposing it possible), and then ask himself where the water came from?

"E. L. G." also tells us that he now thinks "all our strata kept their form unmoved." There can be no doubt in any reasoning mind that the stratified rocks were deposited under water; if this is not sufficiently proved by their construction, it is by the existence of marine shells. The strata would therefore be horizontal when deposited, but now it is in many places folded into huge ridges and valleys, while marine fossils are carried in these upheavals and contortions to all habitable heights, and have been found in the Himalaya Mountains at 18,000ft. above sea-level. And in a lesser degree, if "E. L. G." would only take the trouble to notice cliffs and escarpments, or even railway cuttings, he could see that his statement of the strata being originally deposited in their present positions is erroneous.

If there are no traces of aqueous action in the "hills under the whole heaven" more than may be attributed to the "actual downpour" of the rain, I would ask "E. L. G." how the fossils of marine organisms came to be imbedded in the stratified rocks, or how the pebbles obtained their rounded form.

"E. L. G.'s" quotation from Darwin, which he says, "Poor Darwin, the most famed—Evolution Darwin—contrived so well to forget," does not in any way justify the sneer implied, for there is not a word in it that is anywhere in Darwin's works recanted. Darwin is not alone responsible for the statement to which "E. L. G." objects, for it is a well-understood geological fact that there have been in the long history of the world wide and repeated exterminations of its inhabitants. There is, however, a vast difference between wide and total extinctions, and the very widest extermination as yet suggested would not necessarily have any material effect upon the evolution of species. **Silex Seadrift.**

[26576.]—I AM really sorry for "E. L. G.'s" position about the Flood. His former position, from which he was routed by Prof. Challis, was at least an intelligible and consistent one. On the one side was the Bible with its clear assertion that the Flood covered the whole earth; on the other science, with its equally clear assertion that no such flood could have occurred by natural means, and that all the evidence available is dead against any such Flood having ever occurred. I can understand and sympathise to some extent with those who give up common sense and accept the miracle. I heard a remarkable sermon on the subject by Müller, the founder of the great orphanages at Bristol. He insisted on the absolutely literal interpretation of the words of Genesis, and threatened unbelievers with various pains. He was perfectly logical—the Bible said so—and, therefore, it was true.

But "E. L. G." now gives up both the Bible and common sense. The Bible, because I defy any candid person to read that chapter and infer from the words of the text that the author meant his readers to believe that the hills were not covered by the flood, but by torrents. If he did mean that, all I can say is he expresses himself so badly that I should hesitate to accept his account of any occurrence whatever. The world, anyway, for 3,000 years has taken the passage the other way.

But "E. L. G." gives up common sense and science as well, for I challenge him to find a single geologist of established position who will date the birth of Mount Ararat from the time of this flood.

I cannot see the good of these attempts to twist the words of the Bible and twist science till they fit in a wholly distorted state. In the long run I am quite sure they do more harm than good to the cause they are intended to advance, for they make men treat the more important parts of the Bible with the same carelessness. Why not accept the fact that these old legends are the ones which Moses (if "E. L. G." likes) found preserved amongst his people and accepted? We know that the story of Chedorlaomer in the 14th chapter is such an old legend. **F. G. S.**

[26577.]—"MEMNON" (26526) says:—"I have asked 'Ramases' for particulars often, and do not get them." This is unfair. "Memnon" asked for particulars of Gesenius's opinion, and he got them. In the connection now referred to regarding the two writers (so-called) of Genesis, I gave my authority, and where to be found. If the ENGLISH MECHANIC will print the particulars in full from the "Speaker's Commentary," I will send them.

"Memnon" ought to have known that the apparent motion of the moon, equally with the sun, is due to the rotation of the earth. So this point tells in favour of the Bible record; and as to its using the language of appearance, so also does the *Nautical Almanac*. Again, "Memnon" considers the miracle as "singularly improbable," since it had the extermination of the Canaanites in view. The very opposite is the case, because it is alleged that the same God, who is the Author of that law which in Nature exterminates the unfit, gave the command to exterminate these very unfit and corrupted nations. And had Israel been obedient, they would have been able to have completed the extermination, and the world to-day would have been better on that account.

Nov. 26th. **Ramases.**

[26578.]—I AM afraid "Ramases" and I can never agree either as to facts or theories. He insists (26528) on supposing all the great Egyptologists rely absolutely on Manetho, which is a perfect delusion on his part. Manetho's lists are useful, and must be considered by all Egyptologists, but are only to be absolutely relied on when corroborated as they have been largely by the monuments. Is it possible "Ramases" thinks that Mariette absolutely relies on Manetho? If he does, he can believe anything. Everyone knows that in Rameses II.'s time the name of Menes heads the lists of kings on a public monument. The Turin papyrus of the same age is a valuable historical document, and as a matter of fact all the

eminent Egyptologists believe in the great age of Egyptian civilisation. As this great age is considered to clash with Genesis, all proofs go for nothing to thousands of small people, who can see nothing when it interferes with their theories.

I do not rely on Menes or any particular king. I rely on the well-founded knowledge of the extreme antiquity and peculiar character of the civilisation of Egypt.

Certainly, the early king (probably Menes) who turned the course of the Nile at Memphis to protect his capital must have had many subjects and many enemies—so could not be Noah, or any of his immediate descendants. From the time of Moses (Maneptha) to the expulsion of the Shepherds can hardly be asserted even by "Ramases" to be less than 200 years (it probably was much more); to this add 500 for the time of the Shepherds, that leaves about 160 years for the fourteen previous dynasties reaching to Noah, during which many of the most wonderful works in Egypt were produced, many of them early in that time, yet, according to "Ramases," at the end of the 160 years we come upon Noah and Shem, Ham, and Japhet, with a boatful of animals.

"Ramases" may object to the 500 years, as he objects to everything not telling on his side, though all the best authorities accept it. Still, as clericals cut it down I suppose I may as well do so, just to show it will do "Ramases" really no good. So let us divide it in two, so as to make the period from Noah and his Ark to the arrival of the shepherds 410 years—about as much as the Jews are said to have spent in Egypt. Into this length of time, according to "Ramases" I suppose, we must crowd, the Great Pyramids, and about 70 others, the Tomb of Ti, the Great Sphinx, the Labyrinth, the Great Dyke at Memphis, Lake Moeris, the obelisk at On, the Proto-doric tombs at Beni Hassan, the marvellous statue of the School Master, the statue of Chephron, &c. The idea is so ludicrously absurd that none but a thick-and-thin theologian could imagine it.

At what rate could the population have increased in the first years of that time, and why should Egypt have at once such a peculiar style of art-religion and written language? I fully agree that art and science produced these masterpieces in rapid succession very generally, but must point out that we find such flowering always preceded by a long slow period of dull preparation. In Egypt this early period can hardly be seen, it is so far off, but all analogy requires us to admit it; indeed, the peculiar character of the art, as distinguished from Assyrian, Hindoo, Chinese, &c., necessarily obliges us to consider it took a long time to attain such a character. Your London readers can see a specimen of the early style in the far end of the large Egyptian room in the British Museum, where two complete fronts of tombs of the time of the Pyramids are on view. Our notion of evolution in anything requires long periods before marked outbursts, and all evolution theories require all notions of a flood 4,000 years ago to be discarded, so Darwin's views won't help "Ramases," and he certainly did not share "Ramases'" views. Neither will Champollion's date of 2200 B.C. for the oldest existing Egyptian monument prove useful to him, as that date only leaves 147 years to Noah and his Ark—a ridiculously short time—especially when we remember that no record exists of the making of such a big thing as the Sphinx—it was mended in the time of Chepron. Who made it, or when it was made, no one knows—it was certainly not later than the Pyramids. But since Champollion's time immense strides have been made in Egyptology, and all in the direction of lengthening the monarchy.

To show that all orthodox people don't share "Ramases'" views, let me refer to a lecture delivered by the late Sir Erasmus Wilson, vice-president of the Biblical Archæological Society, and president of the Egyptian Exploration Fund, to the Young Men's Christian Association at Margate in 1883, published by Kegan Paul and Trench, on "The Recent Discovery of Ancient Egyptian Mummies," in which he says: "Now, the first Pharaoh of Egypt, King Mena, lived nearly 6,000 years ago—4,000 years before the birth of our Lord Jesus Christ."

That the writer of Genesis was not aware of this, or of the history of ancient Egypt is clear, so that if Moses was learned in their learning, he could not have placed Noah and his Ark where it is placed in Genesis; therefore, I consider I have clearly established that point.

The question of language I think I have also made clear—namely, that the ancient Jews could not have written and spoken Egyptian for either 250 or 400 years without its leaving deeper marks on their language than exist. Also that the ignorance of immortality displayed is decidedly anti-Egyptian. Also that the book Genesis is largely written by one person, who said that at an early date—the time of Enos (Gen. iv. 26)—"then began men to call upon the name of Jehovah." While another part of the same book is written by another person, who also writes in Exodus, and states that the name Jehovah was not known till God told it to Moses. It is impossible to suppose we have perfectly reliable or contemporary documents or writings by any one man, though they appear to have been edited by Ezra, or somebody about his time. What they were originally we cannot know with certainty, so that the clash of dates and the flourishing of marvellous miracles in extreme antiquity go for very little. Indeed, the date 400 or 430 is probably a simple round number, adding an 0 to the favourite number of 40; or is a reminiscence of the 511 years of the Shepherds in Egypt, or of a part of it.

"Ramases" complains of my saying "I suppose," &c., about Deuteronomy; but really it is impossible for me to enter fully into every point raised, and I wish to use the mildest language possible. In such short letters as I can write I cannot attempt to prove everything. I only referred incidentally to its *very* late date. All I need prove is that it was not written by Moses, and that I think I did. Anyone who reads it without prejudice must see that it cannot have been written throughout by Moses, either as to the beginning or end, while its matter also proves it. It is quite clear that the passage as to the death of Moses was not written by one of Moses' scribes, as asserted by "Ramases," as a long period after his time is implied necessarily by the words, "And there rose not a prophet since in Israel like unto Moses." "Ramases" has met all my definite statements on this point by *unproved denials and assertions*, all of which are against the facts.

"E. L. G." is an astonishing writer, and I hope "Dens" will answer his oddities. He actually says of the Flood, "We have no warranty, I now think, for supposing any submergence of places now above sea-level." Does he not consider the remarkably plain words of Gen. vii. 19 warranty enough when it says: "And the waters prevailed exceedingly upon the earth, and *all* the *high hills* under the *whole* heavens were covered"? If this full and clear statement is not a warranty for the assertion, why should I, or any one else, rely on either or both of the conflicting dates of the time Israel was in Egypt or the date of the Flood, or any other particular?

That the present arrangement of continents, islands, and sea level was not made by the addition of water is shown by the fact that the dove could find no rest for her feet (Gen. viii.), though when she was sent out was long after the forty days rain, when Noah thought he could come out soon. Also in verse 11, where it is asserted that "the waters were abated from off the earth," clearly, they were supposed to have gone somewhere. Where did they go to? "E. L. G." says "Nowhere—they remained"; but this is flatly against the text, as is also his other extraordinary assertion that there was no time when "our hills were covered with standing water."

"E. L. G.'s" opinion on texts is so interesting that I am anxious to know why, if miraculous hail showers, &c., were so common, that they were not more efficacious? The curious reason given for Judah's failure has nothing to do with faith or morality, but is simply ascribed (Judges i. 19) to the fact that he "could not drive out the inhabitants of the valley because they had chariots of iron." The rest of the chapter shows many other failures. Why did not the hail affect the horses of the chariots, and the men also?

His arguments from Darwin are quite comic. Darwin, who knew all that was known, when in his prime, had not an atom of belief in a universal flood 4,000 years ago, and yet is now considered to be one of the very greatest men of the 19th century.

The disappearance of the horse from America required no universal flood, and is a fact well known to all palæontologists; but what about the presence of animals peculiar to America—such as the sloth, tapir, llama, pecari, jaguar, condor, &c.? These are not found elsewhere, so I suppose Noah sent them in a supplemental Ark to America, where also we find the fossils of their particular ancestors.

Prof. Agassiz says: "Ever since New Holland was discovered it has been known as the land of Zoological marvels—all its animals differ so completely from those of other parts of our globe that it may be said to constitute a world in itself, as isolated in that respect from the other Continents as it truly is in its physical relations.

In Australia fossil and living kangaroos occur, and various other sets of peculiar animals. Did Noah send an Ark there?

Prof. Owen says, in "British Fossil Mammalia," speaking of South America: "Most of the fossil mammalia from these formations are as distinct from the European-Asiatic forms as they are closely allied to the peculiarly South American existing genera of mammalia."

This would not be so if a universal flood occurred about 4,000 years ago; yet Genesis says, "All flesh died," which I respectfully deny, and maintain that the facts of history, geology, and palæontology all go to prove that no recommencement of human, animal, or vegetable life dates from that time. Can "E. L. G." find any eminent naturalist or scientist who denies what I say? Huxley, our most eminent naturalist, I know, thinks as I do.

I recommend "E. L. G." to admit it is possible that other things may be true besides those enshrined in his philosophy, which, though I must suppose he is old, has a very juvenile flavour. It seems to consist largely in arranging the facts or statements as he pleases, and vigorously asserting that expresses the true meaning of the text, while "Ramases," working with caution, asks his opponents to prove to his judgment every minute point, never thinks it has been done, and eagerly accepts everything apparently telling on his own side.

These gentlemen start with a false assumption; namely, that everything is really true in Genesis, Exodus, &c., so must make them square with what else is proved, or deny what contradicts them. For, at least, the present, I must bid them good-bye.

Memnon.

[This must end the discussion.—ED.]

IS VIOLET A PRIMARY COLOUR?

[26579.]—THE question raised in the first paragraph of Mr. Hardie's letter (26452) will bear only one interpretation. It clearly implies a belief that, if the violet of the spectrum is a secondary colour, it can be decomposed by the prism into its blue and red constituents. No one having a clear conception of Young's theory of colour-vision would have raised such a question; and not until I had carefully re-read the passage did I feel satisfied that I had not misunderstood it.

Mr. Hardie professes to doubt that continued exposure of the eye to any one colour tires the colour nerves, and so renders them temporarily less sensitive to that colour. There is no lack of evidence to support the belief. If a piece of stained glass be held for a minute or two before one eye, it will be noticed that the intensity of the colour gradually diminishes, and if the glass be then transferred to the other eye, there will be no further room for doubt that the eye before which the glass was first held has lost its power to perceive the full depth and richness of the colour. The proof obtained by placing a small square of black paper on a white or coloured ground, gazing at it for some time, and then removing it, is too well-known to require a detailed description.

Let the possibility of fatiguing the colour nerves be once securely established, then the changes of tint, observable in all secondary colours when the eye has been rendered partially insensitive to one or other of their components, follow, as a necessary consequence, from Young's theory, and furnish the best possible proofs of the truth of that theory. But if Mr. Hardie's explanation of the changes of tint is correct, then the two following conclusions are unavoidable:—First, that all colours, primaries or secondaries, can, with equal readiness, be altered in tint; secondly, that no colour can be modified in exactly the same way by exposing the eye to either of two such different colours as red and green, or blue and green. Neither of these conclusions can be established by an appeal to facts. No decided change of tint can be produced in the red or blue of the spectrum, though their intensity may be much reduced. The green appears slightly bluer when the eye has been exposed to red light, and a little more yellow after exposure of the eye to blue light, which is just what Young's theory would lead us to expect, since green is supposed to affect both the red and blue, or violet (?) nerves to a moderate extent, as well as its own special set of nerves. The modifications, however, which can be effected in the secondary colours of the spectrum are most striking. The boundary between blue and green, which ordinarily appears nearly coincident with the dark line F of the solar spectrum, will seem to have been shifted to a position midway between lines E and F—that is, much nearer the red end of the spectrum, after the eye has been fatigued by long gazing through green glass. When the eye has, by similar means, been rendered partially insensitive to blue, the opposite effect is produced, and green then appears on both sides of line F. Again, long exposure of the eye to light passing through red glass causes the green of the spectrum to extend quite up to the sodium line, and yellow is found on the red side of that line. I need not again describe the changes of tint produced in the violet of the spectrum by similar means.

The second conclusion which ought to follow from Mr. Hardie's explanation of these facts is refuted by the additional fact that exposure of the eye to red light produces exactly the same change in the blue-greens of the spectrum as that produced by exposing the eye to green light. This also is quite in accordance with Young's theory, according to which the red rays excite the red nerves powerfully, the green nerves moderately, and the third set only slightly. Therefore long gazing through ruby-stained glass, which transmits no green or yellow rays, and not much orange, will fatigue the green nerves to some extent as well as the red, but can have little or no effect on the blue nerves. In like manner, gazing through violet-blue glass,

which transmits no green rays, fatigues the green nerves sufficiently to cause the green yellow of the spectrum to look more yellow, and the yellow slightly more orange. Again, using a common prism, it will be observed that, after prolonged exposure of the eye to green light, the violet seen through the prism will appear bluer. This effect is doubtless due to fatigue of the red nerves of the eye; but since I was unable to find for this experiment a green glass which entirely cuts off the red rays, it would be too hasty to assume that the fatigue of the red nerves was principally due to the action of the green light. But, whatever the cause, there is no doubt about the effect, which is the direct reverse of that which Mr. Hardie's hypothesis requires. The complementary to green being rose-purple, the violet ought to have looked much redder.

In the face of these facts it would be useles to discuss at length Mr. Hardie's experiments; but a few brief remarks upon them will not be out of place. Granted the visibility of coloured ghosts on a black background, then they should be just as plainly visible with closed eyes, if daylight has nothing to do with the continuance of the impressions on the retina, as Mr. Hardie insists. Now, three or four seconds' gazing at small bits of bright-coloured paper suffices to render coloured impressions distinctly visible on a white ground; but a much longer interval is insufficient to form an impression which will remain visible after the eyes are closed. Likewise, if green glass be held before the eyes for half a minute or more, as soon as it is removed the light from the sky appears strongly tinged with a rose colour; but if the eyes be closed and covered by the hand, the rose colour is not seen.

Several of the effects described by Mr. Hardie must be in great measure, if not entirely, due to contrast. At all events, the bare possibility of such being the case suffices to render the experiments inconclusive. Whoever doubts the influence of contrast in such cases should place a small square of darkish grey paper on a coloured ground, and cover the whole with tissue paper. The bit of grey paper immediately appears strongly tinted with the colour which is complementary to that of the ground upon which it lies. The effect of contrast is also admirably illustrated by shadows falling upon a white ground which is illuminated by sunlight shining through stained glass; and another beautiful illustration is furnished by the purple patches often seen on a bright green sea. The purple patches are the shadows of small detached clouds, and owe their colour entirely to contrast with the surrounding green.

Before closing this letter I must refer to an experiment described in my last, having modified it in a manner which throws additional light upon the result. I pointed out that staring at a small piece of violet paper will cause a green ghost to be visible on a blue ground; a fact which, accepting the usual explanation, appears at first sight to countenance the hypothesis that blue is a secondary colour composed of green and violet. Believing this green ghost to be due to the reflection of white light from the surface of the blue ground, I screened off all direct daylight from the blue paper by placing it within the shadow of a piece of deep blue glass. This does not interfere with the blueness of the ground, but, on the contrary, greatly improves it. The ghost, however, seen upon this ground no longer appeared green, but became so as soon as the blue glass was removed. This result brings the experiment into harmony with the evidence obtained from the blue of the spectrum.

I certainly made no "unconscious slip" in my suggested explanation of the violet ghost seen on a blue ground after staring at green, and I have nothing to retract from that explanation. Since I attribute the violet ghost to the presence of white light and to fatigue of the colour nerves (both of which causes Mr. Hardie repudiates), what ground has he for saying that I explain the ghost in his way?

It is not my intention to continue this controversy; this letter will therefore be my last contribution on the subject.*

Nov. 10th. **F. W. Reynolds, B.A.**

[*And the last we can admit.—ED.]

HOW A BOY MAY RAISE A SOLID TON WEIGHT WITHOUT MACHINERY.

[26580.]—IT is surprising how this question can be made a subject of controversy and denial. It is a well-known fact that the native Hindoos raise heavy logs by numerous ropes hauled taut from the elastic branches of trees above them, the operation being repeated seriatim till the desired height is attained. I have on more than one occasion seen a stone raised off the ground by a spider, the stone weighing, perhaps, a hundred times more than the insect; this was accomplished without intention, as the tie from the lower framework of the web was first attached to the stone, and every night on repairing the web the spider added another strand to the tie, and hauled it taut, till at last the stone was lifted.

Some years ago one of our indiarubber companies (I forget which) advertised and sold what they termed "accumulators," consisting of an elastic cord, with a loop or eye at each end. By attaching a number of these to the body to be raised or otherwise moved, and hauling them in succession, and fixing them at the available stretch, any desired power may be obtained, according to the number used. On a smaller scale these appliances are sold by most ironmongers for door-springs. **F. H. Wenham.**

HEATING WATER RAPIDLY.

[26581.]—THERE exists an apparatus capable, as is asserted for it, of heating by gas 36 klgs. (83·61b.) of water, for bathing purposes, from 12·7 deg. C. to 35 deg. C. (55 deg. F. to 95 deg. F.) in *one minute*, or a full bath of 35 gallons of water in about five minutes. The consumption of gas is about 0·533 klgs. (1·167lb. or 26 cub. feet) for the 35 gal., or 160 klgs. of water, so heated.

The calorific effect is, therefore, 160 klgs. of water raised 22·3 deg. C. with 0·533 klgs. of gas. Assuming gas to develop about the same number of calories as coal, weight by weight, the *useful effect* is, in this case—

$160 \times 22{\cdot}3 \times 425 = 1{,}516{,}400$ kilogramme meter

and—

$0{\cdot}533 \times 7{,}000 \times 425 = 1{,}585{,}675$ „ „

or ·956 of the *theoretic heat value* of the gas.

Marienberg.

THE "STRONGEST MOTIVE" IN OBEDIENCE.

[26582.]—HAS your correspondent, Wm. John Grey, F.C.S. (29288, p. 86), ever asked himself what he means by the "strongest motive" in obedience to which he takes it as axiomatic that a man always acts? What test does he propose of strength? That the motive in question gets the better of the other motives which compete with it? But, surely, that only amounts to saying that the prevailing motive is that which prevails—a truism which "Garrison Gunner" will scarcely concern himself, I imagine, either to assert or deny.

I can conceive of no other test of the *strength* of a motive unless it be the extent to which it affects or disturbs the nervous system; but if the strongest motive equals the motive which most strongly affects our nerves and brain, we certainly do not always obey it—e.g., a man will stand fire, though he is trembling all over with fear. Here the desire to run away affects him most strongly, yet his habit of courage will prevail over it.

May I add that if "motive" means the desire of whatever kind which I adopt as my good for time being and principle of my action, then "motives" as such never compete? Desires *may* compete, but all competition is over and selection made before one in particular becomes the *motive*.

Lastly, I think Mr. Grey should class along with inherited constitution and training not merely the agent's environment at the instant of action, but the agent's *view* of that environment, the environment as focussed in his self-consciousness. Except so far as the agent takes into consideration some of his circumstances more than others, environment has little to do with his action. I think the problem of free will is more complicated than Mr. Grey suspects. **F. C. Conybeare.**

RANGE OF BAROMETER.

[26583.]—WILL some of the many scientific readers of the ENGLISH MECHANIC give me the ordinary rise and fall of the mercury column, or the sweep of the index-hand of an aneroid barometer? I am told that in England the column varies several inches during the course of an unsettled spell of weather.

Here, in California, I have never seen the hand of my own, or any other aneroid barometer fall lower than 29·65, or rise higher than 30·25, and these extremes would indicate very fine weather or an unusual storm.

This query may prove interesting to many, if your many subscribers in all parts of the world will give it their attention.

I should also like to ask some of your astronomical correspondents a question. I know "A Fellow of the Royal Astronomical Society" will help me out, for he is as a beacon light to the benighted amateur. If an observer at the earth's Equator in a perfectly clear atmosphere should look for a star to rise in the east, he would see the star by refraction before it was actually above the horizon, and when setting he could still observe the star after (theoretically) it had set, thereby he would be enabled to see the star over twelve hours.

Now, then, suppose another observer at the exact opposite point of the earth's surface were to be watching the same star, he would, in practice, see the same star at the same time; while, in theory, one should lose sight of it just as it rose to the other—in fact, each would be able to see it over twelve hours. I know this is a simple, and, perhaps, foolish question, but the answers may be interesting.

Again, any object—say, a building—at the North or South Pole would turn once upon its axis every twenty-four hours, while a building at the Equator would not. The first would have the motion of the hub of a wheel, while the other would have the motion of the spoke. Will someone tell me at just what latitude both buildings would have the same amount of axial motion, and what that motion would be?

M. C. B., San Francisco, Cal. U.S.A.

CUTTER-BAR.

[26584.]—I HAVE for twenty years had your magazine, and have received many a good wrinkle through its Query and Answer to Queries Columns. But I have one good thing I would like to communicate for the benefit of your readers and for the encouragement of "J. L."

In looking over the number for March 26th, 1880, I found a sketch of Haydon's cutter-bar, and further on there was a correspondence, one of those correspondents being "D. H. G.," this gentleman asserting that he had banished every solid tool from his bench for 10 years; he also very truly styled this bar his slave-of-all-work. At this time I was seeking some easier method of grinding turning tools, and lo! here to my hands, in a forgotten mine of turning lore, is the very thing. Being an adept at the anvil of 32 years' experience, I quickly forged a bar and sling out of shear steel, the shank of bar $\frac{11}{16}$ths square, the sling and screw of proportionate strength. I broke some old square files $\frac{3}{8}$in. thick into pieces $3\frac{1}{4}$in. long, and ground the faces to have 5° clearance, and the top face to 55° with the two front faces. I have also tried round cutters; but hexagon is the form that comes nearest to 120° front angle.

The result is a great surprise to me. I have cut out square corners right and left, cut V-threads right up to a deep shoulder; can do any surface work;—in fact, there is no outside piece of turning but for which a cutter is most readily fashioned at a trifling cost. I would suggest to you, Mr. Editor, the desirability of giving another sketch of "Haydon's Cutter-Bar" from the hands of our old friend.

I am purposing to buy Mushet's steel to make the cutters from, and would thank any fellow reader to record his experience of its cutting power.

Evod.

RHEA FIBRE.

[26585.]—I NOTICED in your issue of, I think, the 12th ult., a remark relative to the fibre of the Urtica nivea (Ramie or China grass). You appear to think that this fibre could not be compared to flax either for strength, durability, or cheapness. For the benefit of the readers of your journal, I would call your attention to the fact that for many years the Government of India have had before them statistics concerning the value of this fibre, and offered £5,000 for the best method of treatment on account of its wonderful properties, being the strongest, longest, and lightest fibre known. It will work up to compare with silk, and for coarser fabrics is of more value than flax, as, for instance, I had two lengths of hose constructed on the same principle and the same counts of threads; on testing, the Ramie hose stood a test of over 600lb. to the square inch, a pressure of about double that of the flax. A machine-belt of the Ramie fibre was tested to a strain of over 3,900lb. per square inch, against 2,100lb. for leather belting.

The fibre is used largely in France instead of silk, as it is capable of receiving a fine gloss which makes it almost impossible to tell it from silk. A company was formed some nine months since to work this fibre in England, and have erected works near Old Ford, where they are preparing the fibre for spinning.

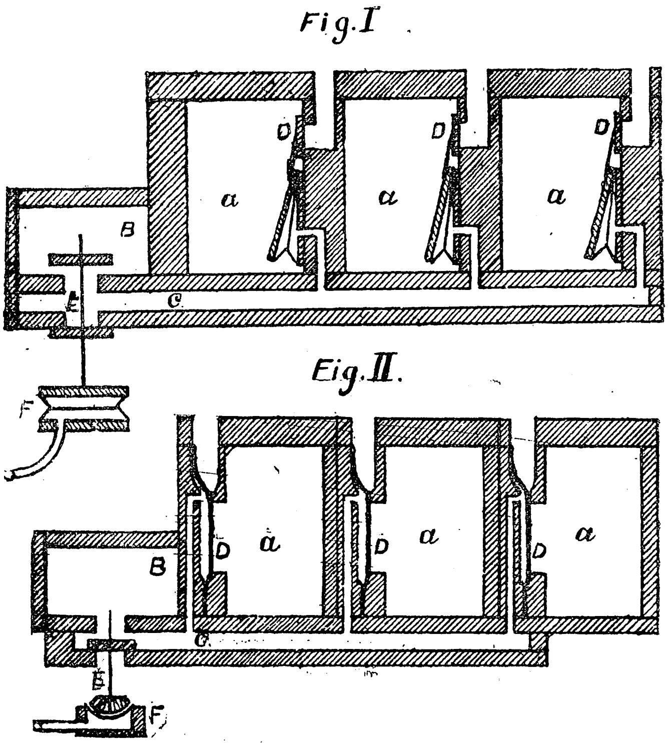
At the late Colonial and Indian Exhibition the Glenrock Company (Limited) were requested by the India Office to exhibit products from the fibre which is being cultivated to a large extent on their Indian estates, and the samples shown were greatly admired by all experts.

Dec. 4. **Urtica.**

ORGAN WINDCHESTS.

[26586.]—AS Mr. Audsley has been writing about Mr. Roosevelt's patent windchest, I beg to say that there is another pneumatic windchest, simpler than Mr. Roosevelt's, and, I think, in several parts better. I give the two sketches to show the difference.

No. 1 is Mr. Roosevelt's patent, and No. 2 is Mr. Drechsler's patent (Askew-crescent, Uxbridge-road, W.) Both have the same principle, only Mr. Drechsler has done away with those little bellows (wanted one to each pipe), and is using a piece of leather for the pipe valve. Mr. Roosevelt has the higher pressure of wind permanent in those little



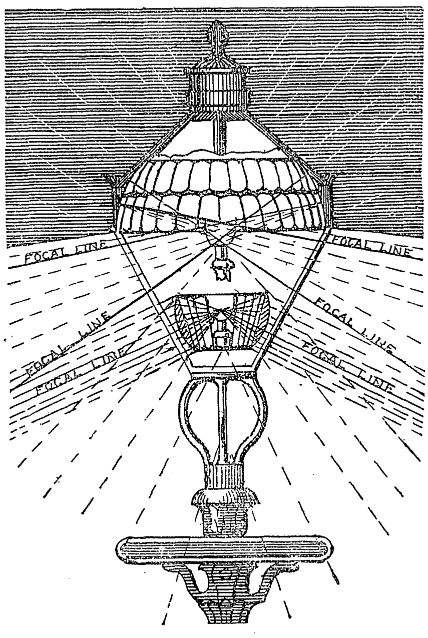
bellows F, Fig. 1, and in all tubes, running from the keys to the windchest, while in Mr. Drechsler's the wind is only required when touching the keys. This system prevents a good deal of leakage. Box B, Fig. 1, contains wind of a higher pressure than the pipes are wanting, and keeps through C the pneumatic bellows open, the pipe valves D closed. By exhausting the high pressure through C E by touching the key, the pipe wind in A presses the bellows together and opens the pallet D. In Fig. 2 the higher pressure in B keeps the leather valve against D, and when exhausting through C E the pipe wind in A forces the leather to the left and enters the pipe. This system seems to me very simple and good, is not liable to go out of order at all, and the use of action wind is not worth mentioning. I should advise "C. H. D." and "W. H. H.," before doing anything else, to see Mr. Drechsler's windchest and action. It is the quietest and quickest action I ever have seen in tubular pneumatics. **N. H.**

STREET LIGHTING.

[26587.]—To increase the lighting power of street lamps by means of refraction and reflection has more or less occupied our mind for some time past. We commenced our experiments with the "druggist's bottle"—placed six lights around a globe of glass filled with water, refracting the rays from the one light through that of the opposite one, which gave off right and left a powerful refractive light. Were the globe totally surrounded with jets of gas, we would have a ball giving off refraction light (at a certain angle below the horizontal axis of the ball) all round the horizon. We adjusted the ball by means of a cupped elongated nut, by this means placing the horizontal axis more or less below the white of the flame, thereby altering the rays deflected downwards. We consider, however, that the druggist's bottle, even although carried out with a ball of solid glass, must be rejected for street lamps.

Our next step consisted in placing two convex lenses closely together at the bottom, and inclining the convex surfaces downwards, one jet being placed before each convex surface; the rays were refracted through the convex surface, caught up by the other lens, and refracted down at a certain angle, or, in other words, the rays from the one light are refracted through that of the other light, or vice versâ. The lenses should be 6in. diameter and upwards, and for narrow streets they throw beams of soft light right and left along the pavement; the lamp must be perfectly air-tight, with wire gauze at the bottom and ventilator at the top, so as to burn the gas steadily in all weathers.

All-round refraction now claims our attention: this is effected by subdivision, as shown in the *Multum in Parvo* design for a street lamp, as per engraving, and which is delineated merely for the sake of illustration at the bottom of the lamps. It is obvious that the light of itself is not visible to the eye; but the focal centre of the lenses being brought close together, the refraction from the one is amalgamated with that of the other, giving off a powerful all-round increase of light from a single jet of gas. We will now draw the reader's attention to the reflective system of increasing the lighting power of street lamps. The most powerful reflectors are made of concave glass, silverised, or otherwise coated to form a concave mirror, and which are greatly used in lamps on our various railway systems. A number of those mirrors may be placed around a single light, deflecting the rays downwards, or when we take an odd number of reflectors and place them around a single light, leaving open spaces opposite each reflector, beams of light will be cast all round the horizon in rays according to the number of reflectors used.



To obtain an all-round light as nearly as practicable recourse must be had to subdivision, thus bringing the focal centres closely together, amalgamating the reflection from the one in that of the other.

We should not advise any experimentalist to try and subdivide a concave mirror, as they must be manufactured; but by placing paper gummed on to the part we wish to reject, we retain the focal portion to experiment with. The engraving shows two rings of subdivided concave reflectors, and unlike plain mirror glass, the two rings become flooded with reflection.

For an ordinary height of lamp-post we should only use one subdivided ring; but when a central lamp is preferred to light up a large area, such as a railway station, &c., the lamps should be placed at a greater elevation, and then two rings are preferable, the focal lines adjusted to meet the requirements. Of course we have no desire to place the refraction or reflection method in a lamp, but merely do so for sake of illustrating our subject.

Portobello, N.B. **John G. Winton.**

JOY'S VALVE GEAR—GREAT EASTERN LOCOMOTIVES.

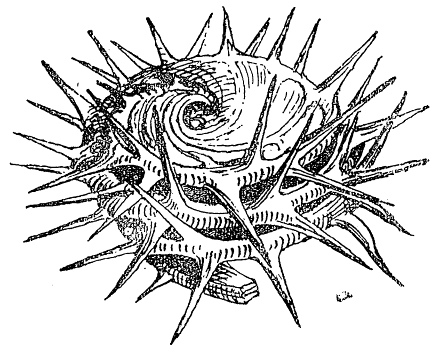
[26588.]—Joy's valve-gear, as used on the G. E. R., does not seem to have been an unqualified success. The goods engine (No. 696) fitted with it has been reported in the English Mechanic to be a failure, and recently it has been removed from one of Mr. Worsdell's four-coupled express engines (No. 562), its place being filled by the link-motion, with the valves between the cylinders instead of on the top as formerly, and a powerful spring is used to take the place of the ordinary balance weights. This engine, so altered, has been out since the middle of October, and is, I believe, considered an improvement. It would be interesting to know how the Joy valve-gear has fared on other lines.

A new type of express engine has recently come out on the G. E. R., the first of this class, No. 710 having been out about three weeks. This engine has 18in. cylinders and 7ft. four-coupled driving wheels, and was built at Stratford. The leading wheels, 4ft. diam., have outside bearings, and the valve-gear is similar to that of No. 562, except that the valves are beneath the cylinders. A noteworthy feature of this engine is the unusually large blast pipe, its diameter being 5¾in. I have not full dimensions at present. **East Anglian.**

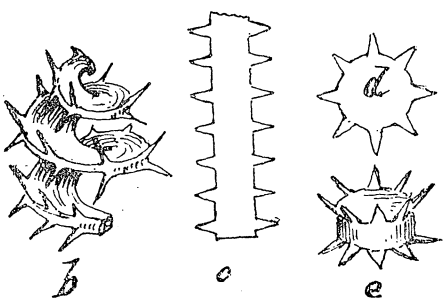
ERODIUM CYGNARUM.

[26589.]—Amongst the objects of interest imported with our fleeces of Australian wool is the seed vessel of the above plant.

It is about ¼in. in diameter, of a helicoid form, and consists of about three whorls. In the woollen manufacturing districts it is known as the "burr," and is greatly detested by all who have to deal in wool on account of the way in which it entangles the fibres of wool amongst its spines.



a.. Seed vessel. x .6.



Reference to Fig. *a* will show how troublesome a thing it can be.

Fig. *b*, drawn on a smaller scale than *a*, shows the screw-like form. On being steeped in warm water it separates into three parts—the top, bottom, and a narrow strip that forms the side.

Figs. *c*, *d*, and *e* show this; and also that each spine is composed of two halves, one attached to the top or bottom of the chamber, and the other coming away with the side-wall.

Description of model:—The plan of construction can be demonstrated by means of a paper model, thus: Cut a strip of paper about ⅛in. wide and 4in. long, with a few spine-like processes projecting from each side. Fasten the ends with strong gum, so forming a ring, and bend the spines at right angles; fasten the spines to a flat piece of paper, and cut away the surplus paper as shown at *d*. Do the same with the other side. This shows the mode of construction; but, of course, gives no idea of the beauty of the seed-vessel itself.

T. Prince.

DIATOMS—VEGETABLE OR NOT?

[26590.]—I am very much obliged for W. H. Shrubsole's kind answer (26562, p. 304) to my query. I was not surprised at the motion only of a navicula, but at its *backing out* of the "rock" and *going round*,

which seemed to display sense. I believe it is not yet definitely settled what is the source of motion of diatoms. Could Mr. Shrubsole tell me what he holds to be the best theory?

Londiniensis.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[60700.]—**To Draughtsmen, &c.**—The method given on p. 306 for dividing a straight line into any number of parts is very simple; but it occurs to me that those divisions which are farthest away from E must be longer than those nearer to E. Is not this so? If so, do you know of another equally simple but more correct way of dividing? I should much like to have your method of division of circles, if you would kindly send it.—G. M. S.

[60766.]—**Wheel Tire Furnace.**—This querist should look in Vol. XXIV. pp. 275, 296, 320, 365, 414, and 437 for a great deal of information about heating and bending wheel-tires. He should also read the articles on Cart and Wheelmaking, especially one which appeared in XXXVI. p. 375. —NUN. DOR.

[60768.]—**Glass Taps.**—Small taps are made out of glass rod; but "G. W. A." can purchase them cheaply ready to attach to any tube he wants. If he must make, he must thicken up the tube at the spot wanted, and when a hole is made, grind the tap in that with the finest emery and oil, finishing with rottenstone.—SAML. RAY.

[60782.]—**The Mustel Organ.**—The querist can obtain the drawings and specifications to which he refers from MM. Mustel et Fils, Rue de Malte, 42, Paris; probably also from Messrs. Metzler, Great Marlborough-street, London, W.—ORGANON.

[60788.]—**Botany and Geology.**—Surely any one who has obtained an advanced certificate from the S. and A. Dept. in these subjects ought to know what books to study for honours. Geikie's "Geology" and Lindley's works on "Botany" ought to give all information; but, for honours, some amount of field practice is necessary.—JURASSIC.

[60795.]—**Studio.**—One should really see the place before offering an opinion; but it is safe to have glass wherever light can be obtained, and to fit every part which has any effect in lighting the sitter with blinds in working order.—COL.-CLO.

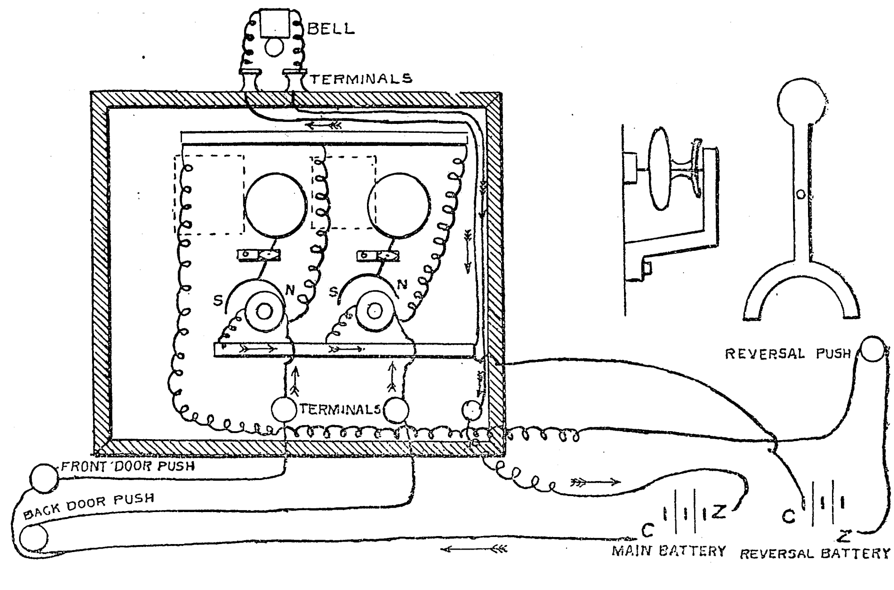
[60800.]—**Ratepayers' Association.** — The only way is to call a meeting, and if there are public grievances, no doubt a sufficient number of ratepayers will attend, and perhaps a sufficient number will subscribe to the requisite fund. The association will have no "power" at all; but it may be able to influence the whole body of ratepayers to such an extent that the local board, or the guardians, or the vestry will pay some attention to the resolutions and amendments duly passed by the association. It is "votes" only that the members of these bodies care about. A change of men is desirable, and an association can often effect that when good reason is shown.—THE BEADLE.

[60807.]—**Mersey and Severn Tunnels.**—The top of the Severn tunnel is about 145ft. under the level of high-water spring-tide, and about 50ft. under the bed of the river at the deepest point. I have not any figures of the Mersey tunnel; but they might be found in any of the engineering papers, or the *Building News*, for instance.—NUN. DOR.

[60808.]—**Small Gas-Engine.** — Read the letters on the gas-engine which appeared in Vol. XXXIX., and procure a set of castings.—T. P. M.

[60812.]—**Paper Making.**—The chloride of zinc is clearly stated to be added to the pulp; but as to the quantity, probably those who use it do not know yet what are the best proportions. It is a matter for experiment.—SELIM.

[60839.]—**Mounting Plates of Wimshurst Machine.**—I beg to thank the correspondents who have so kindly answered my question. With respect to Mr. Wimshurst's suggestion of employing a bobbin of hard fibre, it so happened that I hit on a similar device in the interval between putting my query and obtaining the replies. My method differs slightly from that recommended. I turn the end of the boss quite flat, leaving only the end of the brass tube projecting; then turn a disc of either hard fibre or wood the same size as the boss, with a suitable projection to fit the 1in. hole in the plate. This is fixed in its place with tricycle-tire cement, and a hard fibre washer cemented to the inner side of the plate in the ordinary way. A central hole is then made in the



bobbin thus formed to receive the projecting end of the brass bushing tube. This method affords a solid centre, and the plate can safely be attached to the boss with screws and, if necessary, be taken off again without difficulty. If also the boss is out of truth, the error can be corrected by inserting thicknesses of paper or other thin material between the bobbin and the boss. With reference to the method of mounting described by "A., Liverpool," I venture to think he ascribes undue importance to the alleged weakening of the plates by making a central hole. It may be true if the centres are broken out; but I always bore mine with a copper tube and emery powder. There is no difficulty in doing this after a little practice. I have only had one instance in which plates thus pierced have come to grief after being mounted. This was last winter, when having left a 16in. machine in a wooden outbuilding used as a workshop one frosty night, both the plates were found badly cracked from the centres next morning. In reply to "G. M. S.," I always turn the bosses on a steel rod the same diameter as the spindle. This practically embodies his idea, and requires no keying. I think he will also see that the advantage to be gained by employing boxwood washers is included in the bobbin method described above.—SODIUM.

[60862.]—**Parallel Motion.**—Find the exact length of stroke, and cut two pieces of timber of such a length that when stood on cylinder cover and steam gently turned on, the main links will come down on them to exactly half-stroke. If not quite correct at first trial, you can see what is wanted and alter accordingly. Now see that the bearings are all in line and horizontal, and radius rod of correct length. Level top of cover first. Of course it should be perfectly level, and if not, the line of bearings of motion must be same amount out of level.—T. C., Bristol.

[60911.]—**Steam-Engine.**—In reference to my question on page 248 to "T. C., Bristol," and others, the ports are 1$\frac{3}{4}$in., travel of valve 5in., with $\frac{3}{8}$ clearance top and bottom of valve-chest. It is a D slide. To bring eccentric forward and put lap on steam edge of valve, would not the other port open before the crank got to the centre, and so cause a reaction on the piston?—SLIDES.

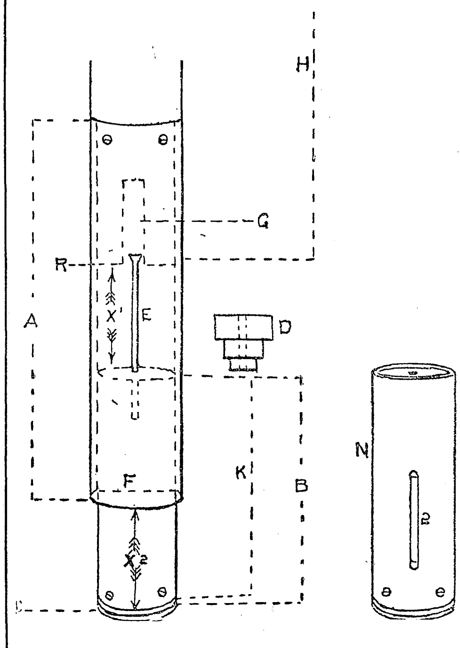
[60936.]—**Oxygen.**—Mr. Allen is quite right, I believe (p. 302), as to chlorate being practically the only source of oxygen for theatres and other exhibitions, during at least these last 20 years; but he should know, and all querists should, that it is always to be mixed with either black oxide of manganese or red-lead, or some other oxide. When heated alone, it is liable either to explode or to send off nearly all its oxygen in one violent rush. Great care is necessary that the matters you mix with it contain nothing combustible, as carbon, starch, &c.—E. L. G.

[60948.]—**Electric Indicator.**—The diagram herewith represents one of the best and simplest forms I know of. It is for two rooms; but the connections are the same for any number. I have had to put in some of the parts of the indicator to make the drawing intelligible. Two batteries are required; but only one electro-magnet for each hole, and the reversal battery may be a very small one; probably one cell would do. The flat bands are strips of thin metal, the arches, pieces of steel or hard cast-iron, as sections of a split gas-pipe. Remember that for successful working of electric reversal indicators, thoroughly soft iron for magnet cores is requisite. The dotted squares represent the holes in the face of the indicator; the principle of the whole is the reversal of polarity of an electro-magnet in conjunction with the magnetic law that, like magnetisms repel, and vice versâ, and Ampère's rule for winding to produce N. or S. poles. The arches should be so adjusted as to touch at the outer ends of the coils (with left to right winding), and are permanently magnetic with poles arranged as shown, which you can test by the working before fixing, or by a compass.—E. CONRY.

[60953.]—**New Electric Machine.**—In reply to "L. H. R.," it may possibly be of some benefit to himself as well as of others of "ours" to state that until quite recently I held the opinion inculcated in my youthful days—that electricity was an entity present always and everywhere. But the unexpected outcome of my experiments not agreeing with such a doctrine, forced me to look for a better, because I found that electricity is not always in a state of existence any more than is the sound of my violin, or the light of my box of matches, or the heat of the coals I am at present toasting my shins at. I know that if I bend a spring that every particle of material included in that bend must shift its relative position to its neighbouring particles, and that this may be repeated indefinitely, but I do not know how to explain these phenomena. Likewise, then, if we bring suitable bodies into certain relations with each other, these similar vibrations are set up and constitute what is termed electricity. And as regards this molecular theory, one cannot do better than to master its doctrines as enunciated in Mr. Sprague's work. It appears to me that as a rule, 'tis the "try, try, and try again" men who make most of the new discoveries, leaving it to those more mathematically inclined to do the theorising. I belong to the former, and only deal in actual experiment. Thus, I made a rubber, say, 2ft. square. On rubbing this upon a sheet of glass, if it be removed there is a certain amount of electricity upon the opposite side of said glass. Now, if, whilst rubbing, or just after, a finger be applied and removed, upon removing the rubber it will be found that there is a considerable increase in the quantity, but a lowering of the tension; if a section of foil of same area as the rubber is laid upon the glass the action is much improved, as it gathers the electricity of the whole surface at once, and if the aforesaid rubber be raised straight at one end from the glass and the operator puts himself in the circuit from said foil to the rubber, he will experience a shock more enlightening than pleasant (Memo., try it upon something a good deal smaller than 2ft. square). Another lesson to be learned from these experiments is that the glass will not part as freely with the electricity so long as a rubber is in contact with it, as is the case if it is removed; so will it be found that the circuit of the current when electricity is carried away from its place opposite to the rubber, is back again to that position equally as it is to the opposite face of the glass. Now as to your questions anent the arrangement of the machine. I have tried four rubbers upon it, and find that it does not produce the desired quantity, nor even reasonably increase the quantity produced by one only, and the only reason for using two rubbers is to balance the strain upon the glass, as a better effect may be obtained with one only, from the above-mentioned reasons, and a rubber can be employed as large as one half of the area of said disc, the foil on face being divided into two sectors, the result being what we term shocks instead of sparks, if the little brush marked A be removed, as the effect of this upon either this machine or a Wimshurst is to convert tensional into what is termed normal electricity, or in other words, to cause it to expand

into quantity at the expense of its energy. It does not improve the machine to add the second brush, as in a Wimshurst machine. But it would do so, if the rubber were so arranged as to lift off the glass whilst the charge is being delivered; but if the object be to collect a quantity under tension, (or would it be better to term it compression?) as when in a Leyden jar, for instance; on the rubber coming into contact with the glass again, the electricity so stored would leak back in large quantity to it: this may be well observed by arranging a Wimshurst machine of, say, 19in. plates, with a large number of sectors, only divided from each other by, say, ⅛th of an inch of glass, in a dark room. The electricity may be seen flowing back in a regular torrent in the direction of the brushes, whence it has been carried by the revolution of the discs. In "all" these machines, increasing the number and area of the sectors means quantity with proportionate loss of tension. The question thus resolves itself into, "What is it you want to do, Mr. Wimshurst?" I opine he is actuated by the same motive impelling myself—viz., an improved method to the clumsy dynamo for producing electricity. Mechanically speaking, a dynamo is a rude contrivance, and must sooner or later give up the palm to something much lighter and far more efficient. To the engineering mind, heavy weights, requiring extreme accuracy and running at tremendous velocities, are evils to be ameliorated, if not entirely got rid of. The best arrangement for producing a light with a Wimshurst machine is to take a piece of glass tube, say, ⅜in. bore, place a cork, say, 2in. from one end in the tube, which may be 12in. long; fill up the inside to, say, 2in. of top with shreds of tinfoil waste, and push in a section of cork to keep same in place. The bottom cork is provided with a wire with an eye on it, so as to connect with earth; the other end is in contact with the inside foil. Similarly, there is a short piece inserted in the before-mentioned section—one end in connection with the inside foil; next, we must put another cork in this end, having also a wire through same, capable of adjustment by sliding to within any distance, say, a quarter of the inner wire, and a hook to hang it upon the conductor on the other end. Now, then, if we coat the outside with corresponding foil an inverted Leyden jar is the result, and a constant flow of shocks can be obtained with very little jumping, and the objectionable noise is "corked up." If a fine wire be fastened to the end, instead of hanging it to conductor, we may hold it in the hand directly to one of the discs without feeling any inconveniences; so also can same be worked by bringing it into contact with the outside of an insulated Leyden jar, which is in process of charge and discharge. One important advantage of my arrangement is, that although it does not give the quantity a Wimshurst does, it will give it at a greater tension, and is capable of doing so in states of the atmosphere in which a Wimshurst will not work at all. By the way, I have one of these with no shellac upon it, and by leaving 1in. of the circumference of the disc free of the sectors it can be started in almost any weather in a cold room by the application of a rubber, gently. This does away with the permanent application which I have described heretofore. I cannot suggest any gain in altering the connections from that shown in the diagram. Lining paper is a strong paper possessing the same property as drawing paper, that of shrinking as it dries, after being damped, and is used by paperhangers for cracked ceilings and walls, and costs from 9d. the piece. I have not as yet arranged any conductor to this machine, and for the afore-mentioned reasons cannot state size of spark, being engaged in the interesting problem of "how to thicken the same." I may at a future period give some details of the machine I am at present experimenting with, which is a disc of 3ft. diameter, inclosed in a case 4ft. square, one side of which is of glass. —A., Liverpool.

[60958.]—**Crutch Slipping.**—The following appliance screwed on to the end of "Magnet's" crutches will probably give satisfaction:—A, piece of strong brass tubing, outside diameter same as crutch stick, end of stick being pared round for about 3in. to fit on to it that amount a good tight fit, secured with three screws countersunk; B, turned boxwood plug, with hole for screw carefully drilled in centre, with a piece of brass tubing (K) fitted tightly on to it, secured with three screws countersunk, the tube K to move in A easily, when oiled, but without any shake; C, leather to prevent slipping (soak leather for half an hour in water, hammer it on flesh side on smooth iron or stone, to get moisture out, leave for half-hour, and then hammer again a little, and then whilst it is damp nail it on B with smallest wrought-iron boot rivets); E, iron screw, its threads being entirely buried in B, leaving smooth part of screw only above it; smooth edge of head with fine file; F, pin to keep B in position, made of a long thin screw, cut in half where the thread joins the smooth part, the smooth part only being used, and a fine thread screwed on it for ½in. to screw into a hole drilled and screwed for it on one side of A, the other side being drilled and countersunk to take the head of screw (after all is done, and amount of spring arranged to satisfaction, this threaded end of pin should be slightly riveted to prevent any chance of its working loose); G, hole drilled in centre of crutch stick to allow free motion of screw head; H, crutch-stick; D, three indiarubber rings of varying diameters, as shown, the holes through centre of each being about half again as large as screw E, so that the holes, when the rings are compressed by becoming smaller, will not bind on screw, and also for a similar reason the outside diameter of largest ring should be less than inside diameter of A. The thickness of three



rings will of course be according to amount of spring that "Magnet" would like the plug to have, and in the same proportion of course, the distance between the points of arrows X 1 and X 2 will be respectively, X 2 being in all cases ¼in. longer than X 1. But I advise, to make tubes, &c., to have more spring than might be at first thought advisable, and then if spring be found too much, a wooden ring could be put in place of an indiarubber one. Of course the rings D are only shown detached for clearness of sketch, their proper place is slipped on to screw E. (A steel spiral spring could be used instead of indiarubber if "Magnet" so prefers.) N, side view of plug, showing slot W to allow plug to move up and down on pin F; the amount of spring must be so arranged as to cause the top of W to slightly press against pin F, when crutch is off the ground, by means of the indiarubber and wooden rings, as before stated, and length of slot W downwards must be such that when the maximum pressure is put on crutch, then there will be still a space of ¼in. between pin and bottom of slot, because the pin is not intended to take any pressure, and would break; the cushion of rubber must take it all. You will perceive that the slot in tube K is rather longer than slot in boxwood plug, this is so that K will not touch pin F, and thus tend to wear it through; oil K and slot W occasionally, but do not get oil on indiarubber rings, as it might soften them.—G. M. S.

[60975.]—**Paraffin Oil or Coal-Gas.**—Thanks to "B.Sc., Plymouth," for his reply. I have a pamphlet by the patentee or manufacturer of the apparatus, but that does not give the information asked for in my query. Can any of "ours" give further information, and oblige?—JIMBO.

[60982.]—**Chronic Inflammation of Nostrils.**—Probably due to inspiration of cold air while body warm. To avoid the effects of this, place small plugs of cotton wool in each nostril. Discontinue iodine and Ol. eucalyptus, as both are irritating or stimulating. Use instead nasal douche of sodæ bicarb. sol. (½ per cent.) night and morning. Nothing will cure if cold baths are used.—A DUNLOP STEWART, M.B.

[60983.]—**Chloride Battery.**—Thanks to the friends who have so kindly given their opinions of this form of cell. Would they now please go a step further and suggest a battery having some of the qualities of the Leclanché, but about three times its strength per cell, and much oblige?—M.M.I.SC.S.

[60976.]—**Arithmetical Question.**—Although this question is correctly answered by Mr. S. M. Cox in issue of 26th inst., I offer a few notes for the further information of "Puzzled" which I hope may not be thought superfluous. If "Puzzled" is to perform the whole calculation himself without reference to Inwood's tables (which only deal in whole numbers in percentage), it may not be amiss to jot down the formula, which is—

$$x = \frac{P}{\dfrac{R^n - 1}{R^n (R - 1)}}$$

In which x = required annuity,
P = the principal,
R = £1, plus its interest for one year (the interest in this case, after deducting tax, is 4·375 per cent.),
n = number of years.

So the formula becomes—

$$x = \frac{1000}{\dfrac{1{\cdot}04875^{10} - 1}{1{\cdot}04875^{10}\,(1{\cdot}04875 - 1)}}$$
$$= 128{\cdot}7.$$

If he has Inwood's tables he can find by one reference, without any computation or division, in the fifth table (p. 118, ed. 1884), the annuity that £1 will purchase at 5 per cent. for ten years, and by moving the decimal point three places, the annuity that £1,000 will purchase for the same time—viz., £129·5. The income-tax can be then taken off the gross interest of £295, leaving £287 nett, and a correspondent annuity of £128·7. If, however, the mortgage is only to bear simple interest, and at the same time to be paid off in instalments, the calculation is not so readily performed.

Let r = the rate, or the interest on £1 per annum.
n = the number of years.
p = present value of the annuity.
x = the annuity.

Then it is evident that the present value of the first annual payment is $\frac{x}{1+r}$, and of the second $\frac{x}{1+2r}$, and so on to $\frac{x}{1+nr}$. Therefore the statement is—

$$P = x\left(\frac{1}{1+r} + \frac{1}{1+2r} \dots\dots\dots + \frac{1}{1+nr}\right)$$

and in the case in question—

$$100 = x\left(\frac{1}{1{\cdot}04875} + \frac{1}{1{\cdot}09750} \dots\dots\dots \frac{1}{1{\cdot}4875}\right)$$

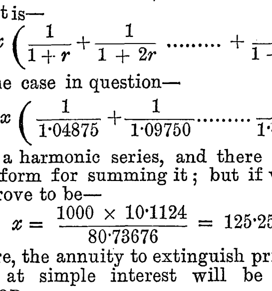
This is a harmonic series, and there is no convenient form for summing it; but if worked out it will prove to be—

$$x = \frac{1000 \times 10{\cdot}1124}{80{\cdot}73676} = 125{\cdot}25.$$

Therefore, the annuity to extinguish principal and interest at simple interest will be £125 5s.—SURVIVOR.

[60984.]—**Boat Propulsion.**—If Mr. Harrison will communicate with the inventor of a "Velocipede Boat" (patented 1884), he can have a boat made to order which can be propelled either by hand or feet, which will exactly answer his purpose.—Address: A. BIVER, Norfolk Villa, Norfolk-road, N.W., London.

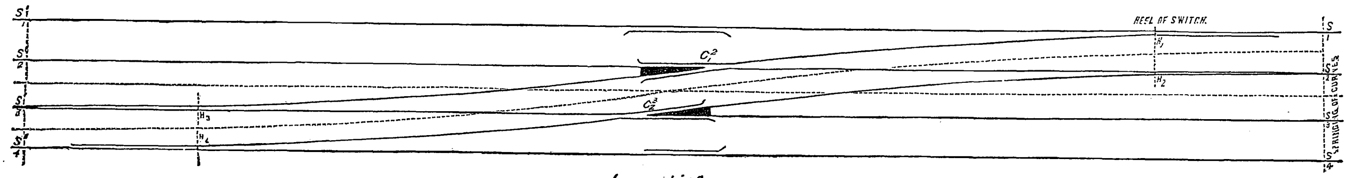
[60989.]—**To Mr. Wimshurst and Others.**—As this query is not addressed to Mr. Wimshurst exclusively, permit me to point out that if you had strictly adhered to the instructions referred to, you would have used tricycle-tire cement and not the disastrous "diamond" variety. If your machine has not less than 14 sectors on each plate, it ought to be freely self-exciting and not require the somewhat novel application of a dry duster. Did you clean the plates well before applying the shellac varnish? It has often occurred to me that many of the machines reported in these columns as faulty are defective through inattention to this



point. I always clean my plates first with turpentine to remove any traces of grease, then with methylated spirit. If this is done properly, the leaves of the charged gold leaf electroscope will not collapse when the glass plate and the knob of the electroscope are brought into contact—an experiment which at once demonstrates the electrical quality and cleanliness of the glass. I find small plates, say, from 12in. to 16in., can be mounted with very considerable accuracy, by using

the following expedient:—Out of a piece of hard wood turn a disc of about 4in. diameter, with a projecting pin or spindle about 4in. long. (See sectional sketch.) This pin must be of such a thickness as accurately to fit the spindle-hole of the boss. If now the plate be placed on the disc with the pin projecting through its central hole, and the boss, with its cement heated to the proper degree of liquidity, be passed down the pin and gently pressed into position, it must evidently be held truly perpendicular to the plate while the cement sets. It is better to turn this bit of apparatus out of brass or iron, as the wooden pin is apt to warp. Don't destroy your cracked plates. They can be repaired with "coaguline," as Mr. Wimshurst has pointed out. One of mine has been thus repaired, and works excellently. I will not undertake to say where the electricity comes from. Theories differ.—SODIUM.

[60993.]—**Permanent Way.**—In answer to your question in ENGLISH MECHANIC, the book I have quoted from in the following rules is Donaldson's "Switches and Crossings," which is, with the exception of these simple rules, purely theoretical, and would not be any use to anyone who had not a fair knowledge of mathematics. It is published by Messrs. Spon, Strand, London, at 10s. 6d. I inclose tracing of a cross-over road for example, one in eight, hoping it will be clear enough for you. I must explain, the lines on the plan represent the centre of the rails, so the point of crossing would not therefore be at the position marked, but some little distance in front; a string, or straight-edge, placed along the centre of rails would give you the required point, or a line run along the inner side of rails would give two points B B, so that you could line on the centre point A. Also the rules only apply in the case of when the clearance at the heels of the switch is 2in. and the thickness of rail $2\frac{1}{2}$in., and the gauge is 4ft. $8\frac{1}{2}$in. Any other information that I can give you are welcome to. Rule I.—When the main line is straight the radius of branch line in feet is equal to ten times the square of the lead:



LEAD OF 1 IN 8

1 in 7 radius of branch line =
$10 \times 7^2 = 10 \times 49 = 490$ft.
1 in 8 radius of branch line =
$10 \times 8^2 = 10 \times 64 = 640$ft.
1 in 9 radius of branch line =
$10 \times 9^2 = 10 \times 81 = 810$ft.
1 in 10 radius of branch line =
$10 \times 10^2 = 10 \times 100 = 1{,}000$ft.

Rule II.—The lead of one crossing is equal to that of the other, and to the interval between the heels of the switches expressed in feet, divided by fifteen and a half:—H_1H_3 and H_2H_4.

Interval $108\frac{1}{2}$ft. lead of crossing =
$$\frac{108\frac{1}{2}}{15\frac{1}{2}} = 108{\cdot}5 \div 15{\cdot}5 = 7$$
Interval 124ft. lead of crossing =
$$\frac{124}{15\frac{1}{2}} = 124 \div 15{\cdot}5 = 8$$
Interval $138\frac{1}{2}$ft. lead of crossing =
$$\frac{138\frac{1}{2}}{15\frac{1}{2}} = 138{\cdot}5 \div 15{\cdot}5 = 9$$
Interval 155ft. lead of crossing =
$$\frac{155}{15\frac{1}{2}} = 155 \div 15{\cdot}5 = 10$$

Reverse the above rule, you have the interval between the heels of the switches is equal to fifteen and one half times the lead. Rule III.—The distance in feet of either crossing from heel of the switch on the same rail as the crossing is equal to seven and one quarter times the lead of the crossing, and the interval between the points of the crossings is equal to the lead of either crossing: $H_2C_1{}^2$ and $H_3O_2{}^3$. Distance of either crossing from the heel nearest switch lead of—

1 in $7 = 7 \times 7\frac{1}{4} = 50$ft. 9in.
1 in $8 = 8 \times 7\frac{1}{4} = 58$ft.
1 in $9 = 9 \times 7\frac{1}{4} = 65$ft. 3in.
1 in $10 = 10 \times 7\frac{1}{4} = 72$ft. 6in.

Interval between the points of crossings measured parallel to main line =
1 in 7 = 7ft. 1 in 8 = 8ft. 1 in 9 = 9ft. 1 in 10 = 10ft.
—T. ATKINS.

[60995.]—**Brighton Engines.**—1st. The engines coupled in front run very smoothly, owing to a special arrangement of the valve gear, by which, at high speeds, the temperature of the cylinder is maintained, and as much steam is locked up in the cylinders as raises the pressure at the end of the stroke to near that in the steam-chest. 2nd. The front-coupled engines, when running at high speeds, only have a slight rolling motion due to the irregularities of the road, and are not subject to the violent lateral oscillations peculiar to engines with a low centre of gravity. 3rd. The advantages claimed for front coupling are that a shorter coupling rod can be used for fast-running engines, and a larger boiler and fire-box obtained than when the coupled wheels are at the back, and it also allows the use of small lightly-weighted trailing wheels. The above statements are taken from a paper read by Mr. Stroudley before the Institution of Civil Engineers, on March 3rd, 1885.—A. W. B.

[60996.]—**Points and Crossings.**—For an ordinary crossing, narrow gauge, the length from point to crossing should be 75ft., the angle of crossing 1 in 10, the total length from point to point 165ft., and the radius of curves 9 chains. Almost any elementary engineering work will give instructions respecting the laying down of points and crossings.—HENRY W. WEBB.

[61001.]—**Landscape Painting in Oil-Colours.**—In my reply to this query will "Welsh Hog Hair" read, "along with a badger hair softener No. 8 or 9," as there is an error which makes the information foolish.—DENS.

[61001.]—**Landscape &c., Painting in Oil Colours.**—The following colours will be sufficient to commence with:—White, yellow ochre, vermilion, crimson lake, brown-red, burnt sienna, bitumen, cobalt blue, and black. A few hog-hair and sable brushes. Medium-strong drying oil and turpentine, equal quantities. The shadows may be thinly painted with brown-red and black mixed to a bistre tint, and, when dry, wet the shadows again with the same tint, and commence painting. Strong colour is not in the high light or in the deep shadow, but will unite both, greying down when required; the shadows to be a little cooler than the lights. Practice is the only way to find out your own style of colouring. Some prefer warm and others cool pictures. For my own part, I like the old-fashioned way of glazing and scumbling with all the warmth that can be got.—J. C., Southport.

[61002.]—**Dynamo and Storage Battery.**—TO E. CONRY.—Thanks for your reply and offer. I shall be greatly obliged for full details of above, as I can bring in play gas or water, and probably steam by the time I shall be ready for it. I thought, perhaps, I might have driven with lathe, as I can drive 3in. emery wheel 4,000 revs. per minute; but will lay it aside now.—LUMSIE.

[61004.]—**The Italian Language.**—In reply to "A Student," the letter *s* in Italian is *impure* before a consonant, as in scena (scene), strumento (instrument). The present and past participles are formed from the infinitive of the three conjugations as follows:—

Infinitive.	Present.	Past. Sin. m.	f.	Plu. m.	f.
1st Am-are	ante	ato	ata	ati	ate
2nd Cred-ere	ente	uto	uta	uti	ute
3rd Sent-ire	ente	ito	ita	iti	ita

There is no rule for the placing of the adjectives in Italian; the correct placing of them can only be learned by practice. The placing of certain adjectives before or after the noun greatly alter its signification, as—*un uomo buono*, a good man; *un buon uomo*, a simple fellow. The personal pronouns are usually omitted before the verbs; *coloro* and *eglino* are both the proper words to use for the third person plural. In translating "I go to the friends of the lawyer," "to the" must be expressed by *dagli*, and not *agli*, as the preposition *da* corresponds to the *chez* of the French, signifying *in the house of*: *da* also signifies *from.* It would be too long to give a list of the best books to read; but I should not omit De Amicis as one of the best modern writers.—NELIGEL.

[61008.] — **Belting.** — CORRECTION.—I added 2c. instead of cos. ϕ of 2c.; the length would consequently be $19{\cdot}9 + 22 = 41{\cdot}9$ft., not 44ft. as given by me.—T. C., Bristol.

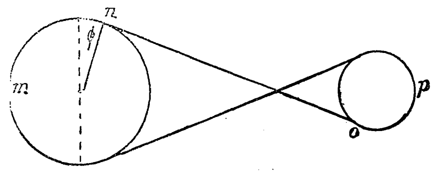
[61012.]—**Annealed Zinc.**—Zinc cannot be annealed. When cast, it is just as hard or soft as it is, and remains so; if heated, it will be brittle while hot, and if then cooled, it is just as before. Lead and tin are the same.—DENS.

[61015.] — **Magnets.** — To "MECHANIC."—I think I have slightly misread your query. My reply refers to the inherent capacities of the magnets rather than to what I see you desired to know.—EDWARD CONRY.

[61008.]—**Length of Belting.**—In this question the given quantities being $D = 6{\cdot}7$, $d = 3{\cdot}5$, and $c = 12{\cdot}1$, the third formula becomes—

$$\text{Sin. } \phi = \frac{D + d}{2c} = \frac{10{\cdot}2}{24{\cdot}2} = {\cdot}4214876.$$

Now, in the table of natural sines, the nearest



lower value to this number is ${\cdot}4212996$ = sin. 24° 55'. Correcting for the difference, we have ${\cdot}4214876$ = sin. 24° 55·71'; hence $\phi° = 24{\cdot}928°$.

Multiplying this by ·0175, which is the sine of 1°, we have the circular measure of—

$$\phi = 24{\cdot}928 \times {\cdot}0175$$
$$= {\cdot}43624$$
$$\therefore \left(\frac{\pi}{2} + \phi\right) = \frac{3{\cdot}1416}{2} + {\cdot}43624$$
$$= 2{\cdot}00704.$$

Hence—
$$\left(\frac{\pi}{2} + \phi\right)(D + d) = 2{\cdot}00704 \times 10{\cdot}2$$
$$2\,(m\,n + o\,p) = 20{\cdot}4718.$$

Again, from the table of natural sines we find—
Cos. ϕ or Cos. 24° 55·71 = ·9068325.

Hence— $2\,c$ cos. $\phi = 24{\cdot}2 \times {\cdot}9068325$
$\therefore 2\,n\,o = 21{\cdot}9453465.$

But, from formula (1), the length of the belt—
$$L = 2\,(m\,n + o\,p + n\,o)$$
$$= 20{\cdot}4718 + 21{\cdot}9453465$$
$$= 22{\cdot}4171465.$$

It will be observed that this does not take into account the thickness of the belt or band, unless the diameters of the drums or pulleys D and d are each supposed to include the thickness of the belt.—MILVERTON.

[61046.]—**Logarithms.**—Napier used e as the base of his system of logarithms, where—

$$e = 1 + \frac{1}{1} + \frac{1}{1\cdot 2} + \frac{1}{1\cdot 2\cdot 3} + \frac{1}{1\cdot 2\cdot 3} + \ldots\text{ad.inf.}$$

Calculation of a few terms of this series shows $e = 2{\cdot}71828\ldots$ From the expansion of a^x in terms of x—

$$\log._e a = a - 1 - \tfrac{1}{2}(a-1)^2 + \tfrac{1}{3}(a-1)^3 - \tfrac{1}{4}(a-1)^4 + \tfrac{1}{5}(a-1)^5 - \ldots\ldots\ldots$$

For a write $1 + z$, then—
$$\log._e (1 + z) = z - \frac{z^2}{2} + \frac{z^3}{3} - \frac{z^4}{4} + \frac{z^5}{5} - \ldots\ldots\ldots$$
also—
$$\log._e (1 - z) = -z - \frac{z^2}{2} - \frac{z^3}{3} - \frac{z^4}{4} - \frac{z^5}{5} - \ldots\ldots\ldots$$
By subtraction—
$$\log._e\left(\frac{1+z}{1-z}\right) = 2\left\{z + \frac{z^3}{3} + \frac{z^5}{5} + \ldots\ldots\ldots\right\}$$
Multiplying both sides by $\frac{1}{\log._e 10}$ (= M)
$$\log._e\left(\frac{1+z}{1-z}\right) = 2\,M\left\{z + \frac{z^3}{3} + \frac{z^5}{5} + \ldots\ldots\ldots\right\}$$

Putting in the value of z from the query, and applying (1)—
$$2\log.(n-1) - 2\log.(n+1) + \log.(n+2) - \log.(n-2)$$
$$= 2\,M\left\{\frac{2}{n^3-3n} + \tfrac{1}{3}\left(\frac{2}{n^3-3n}\right)^3 + \tfrac{1}{5}\left(\frac{2}{n^3-3n}\right)^5 + \right\}$$
—F. T. B.

[61046.] — **Logarithms.** — When Napier, or Neper, published his table of logarithms, it does not appear that he gave any account of his methods of computation; but it is probable that these, as also other methods of his time, had their origin in the quadrature of the hyperbola—hence the name given to them of hyperbolic logarithms. The

early methods of computing logarithms were very operose, and have been long abandoned for the more expeditious methods of converging series. One of the best and most rapid series that have been invented for this purpose is the one under the present number, for which an explanation is required; it was first given by Borda, it is known as *Borda's Formula*, it was used by him in the computation of his table; it is as here—

$$2 \log. (n-1) + \log. (n+2) - 2 \log. (n+1) - \log. (n-2) = 2M \left\{ \frac{2}{n^3-3n} + \tfrac{1}{3}\left(\frac{2}{n^3-3n}\right)^3 + \tfrac{1}{5}\left(\frac{2}{n^3-3n}\right)^5 \times \&c. \right\} \quad\ldots\ldots\ldots\ldots\ldots\ldots \quad (1)$$

It is obtained from the well-known formula—

$$\text{Log.} \frac{1+z}{1-z} + 2M\left\{ z + \tfrac{1}{3}z^3 + \tfrac{1}{5}z^5 + \&c. \right\} \quad (2)$$

by an artifice, for if we make—

$$z = \frac{2}{n^3-3n}$$

we have evidently—

$$\frac{1+z}{1-z} = \frac{1 + \frac{2}{n^3-3n}}{1 - \frac{2}{n^3-3n}} = \frac{n^3-3n+2}{n^3-3n-2}$$

$$= \frac{n^3 - 2n^2 + n + 2(n^2 - 2n + 1)}{n^3 + 2n^2 + n - 2(n^2 + 2n + 1)}$$

$$= \frac{(n-1)^2(n+2)}{(n+1)^2(n-2)}$$

∴ Taking the logarithms we have—

$\text{Log.} \frac{1+z}{1-z} = 2 \log. (n-1) + \log. (n+2) - 2 \log. (n+1) - \log. (n-2)$. Substituting these values of z and $\log. \frac{1+z}{1-z}$ in equation (2) we have equation (1) as required.—MILVERTON.

[61046.]—**Logarithms.**—It would take up too much space fully to discuss the question of logarithms; but if "Equivolt" wishes thoroughly to understand them, he should read the chapter on Logarithms in Todhunter's larger Algebra or Trigonometry. He will there see that logarithms to the base 2·71828, &c., or e, as it is generally called, are those which occur naturally in theoretical investigations. As to the last part of the question—

$$\log._{10} \frac{(n-1)^2(n+2)}{(n+1)^2(n-2)} = 2\log._{10}(n-1) - 2\log._{10}(n+1) + \log._{10}(n+2) - \log._{10}(n-2)$$

Let M be the modulus for transforming from base 10 to base e. We have also—

$$\log._{10} \frac{(n-1)^2(n+2)}{(n+1)^2(n-2)} = \log._{10} \frac{n^3-3n+2}{n^3-3n-2}$$

$$= \log._{10}(n^3-3n+2) - \log._{10}(n^3-3n-2)$$

$$= \log._{10}(n^3-3n)\left(1 + \frac{2}{n^3-3n}\right) - \log._{10}(n^3-3n\left(1 - \frac{2}{n^3-3n}\right)$$

$$= \log._{10}(n^3-3n) + \log._{10}\left(1 + \frac{2}{n^3-3n}\right) - \log._{10} - (n^3-3n) - \log._{10}\left(1 - \frac{2}{n^3-3n}\right)$$

$$= \log._{10}\left(1 + \frac{2}{n^3-3n}\right) - \log._{10}\left(1 - \frac{2}{n^3-3n}\right)$$

$$= M\left\{ \log._e\left(1 + \frac{2}{n^3-3n}\right) - \log._e\left(1 - \frac{2}{n^3-3n}\right) \right\}$$

$$= M\left\{ \frac{2}{n^3-3n} - \tfrac{1}{2}\left(\frac{2}{n^3-3n}\right)^2 + \tfrac{1}{3}\left(\frac{2}{n^3-3n}\right)^3 - \tfrac{1}{4}\left(\frac{2}{n^3-3n}\right)^4 + \tfrac{1}{5}\left(\frac{2}{n^3-3n}\right)^5 + \&c. \right\}$$

$$- M\left\{ -\frac{2}{n^3-3n} - \tfrac{1}{2}\left(\frac{2}{n^3-3n}\right)^2 - \tfrac{1}{3}\left(\frac{2}{n^3-3n}\right)^3 - \tfrac{1}{4}\left(\frac{2}{n^3-3n}\right)^4 - \tfrac{1}{5}\left(\frac{2}{n^3-3n}\right)^5 + \&c. \right\}$$

$$= 2M\left\{ \frac{2}{n^3-3n} + \tfrac{1}{3}\left(\frac{2}{n^3-3n}\right)^3 + \tfrac{1}{5}\left(\frac{2}{n^3-3n}\right)^5 + \&c. \right\}$$

Hence $2\log._{10}(n-1) - 2\log._{10}(n+1) + \log._{10}(n+2) - \log._{10}(n-2) = 2M\left\{ \frac{2}{n^3-3n} + \tfrac{1}{3}\left(\frac{2}{n^3-3n}\right)^3 + \tfrac{1}{5}\left(\frac{2}{n^3-3n}\right)^5 + \&c. \right\}$

The proof of the expansions is too long to give here; but will be found in the works mentioned above.—IGNOTUS.

[61047.]—**Multiplex Copying Ink.**—Make the following into a warm solution, pour into your dish, and when set it is ready for use:—Water 4oz., sulphate of barium 2½oz., sugar 1oz., gelatine 1oz., glycerine 6oz. A very good ink is made by triturating aniline violet (which can be procured at most chemists) with glycerine quant. suf. The writing should be done with a quill pen. As I have tried the above, I can answer for its efficiency.—W. C. HALL, Newport, Mon.

[61050.]—**Pigs.**—The first thing to be considered is whether there is any by-law affecting the keeping of pigs within a certain distance of a public road or dwellinghouse. If not, I do not think your neighbour has any remedy against you unless they are kept in such a state or manner as to be a nuisance to him, in which case he can take proceedings for the removal of such nuisance.—W. C. HALL, Newport, Mon.

[61052.]—**Accumulators.**—I do not think there is any such rule, though there ought to be one elaborated by somebody, considering the amount of time and money that has been spent on accumulators. I know that even in the works of one of the largest accumulator-making establishments in the United Kingdom, the formation is simply done by "rule of thumb," derived from experience—i.e., that size x takes about so long at so many ampères to form; size y so long, &c.; and there is often an immense and unaccounted for variation even in these quantities. In regard to the latter part of your query, the following results, deduced from my own experience, may perhaps be of some little guidance. They are for accumulators formed from the plain lead, but are very rough, and depend greatly, if not altogether, upon the treatment during formation, a matter upon which the electrical literature is almost absolutely silent, and upon which, even in actual practice, there is no rule, each electrician doing what is right in his own eyes. These figures assume the cells to be well constructed and properly cared for, so as to avoid any internal short-circuiting or external leakage. The dimensions may to some seem large for the given storage capacity, but any reduction of the size would only risk disappointment:—To give about—

25	ampère hours.	520	sq.	ins.	of	peroxide	plate
35	"	"	700	"	"	"	
75	"	"	1,560	"	"	"	
150	"	"	2,856	"	"	"	
250	"	"	7,514	"	"	"	

General percentage of efficiency, about 65 per cent. —i.e., about 100 amp. hours would have to be put in to get 65 out. If the cells were well placed, well made, and well handled, perhaps as high as 75 per cent. might be got, and this percentage for accumulators would be, in actual practice, very fair. You will observe the storage capacity does not increase in absolutely direct ratio with the size—i.e., a cell double the size does not mean quite double the power.—EDWARD CONRY.

[61054.]—**Magnets and the North Pole.**—The least unsatisfactory explanation is that thermo-electric currents are caused in the earth by the sun "travelling round" from east to west, causing the currents to circulate in the same direction, and thus magnetising the earth (or at least the iron in the earth). Currents from east to west would make the North (properly the South) Pole of the earth in the north.—LONDINIENSIS.

[61054.]—**Magnets and the North Pole.**—I presume you mean "why does the 'so-called' north pole of a magnet turn towards the north, &c.?" The earth itself is a great magnet whose poles coincide nearly, but not quite, with the geographical north and south poles, and therefore it causes a freely-suspended magnet to turn into a north and south direction. But it should be remembered (having regard to one of the first laws of magnetism), viz., "like poles repel, unlike attract." That is the south pole of a magnet that points to the north (although called the north pole) and *vice versâ*.—W. C. HALL, Newport, Mon.

[61054.]—**Magnets and the N. Pole**—It is one of the natural laws of magnetism that permanent magnets tend to place themselves due N. and S., the "north-seeking" pole, or, as it is generally, though perhaps erroneously, termed the N. Pole, turning northwards. Various conflicting reasons have been assigned for this, one being that a strong current of electricity is continually flowing round the centre of the earth, about the equator, with other currents in other parts flowing parallel to the parallels of latitude at right angles, to which currents the needle tends to set itself, according to a well-known electrical law.—EDWARD CONRY.

[61054.]—**Magnets and the North Pole.**—Magnets do not always turn to the north in preference to any other point. When free to move, they place themselves in the magnetic meridian, i.e., the south-seeking end pointing to the S. pole, and the north-seeking end pointing to the N. pole. The reason of this tendency is because there are electric currents circulating round the earth from east to west, while there are also currents circulating round the magnets at right-angles to their poles. Since currents travelling in the same direction attract, while those travelling in opposite directions repel one another, it follows that the currents in the earth and in the magnets will tend to move these bodies until the currents are parallel in direction.—S. BOTTONE.

[61055.]—**Varnish for the Bright Parts of Bicycles.**—See information under "Answers to Correspondents," in last week's number, p. 313.—EDWARD CONRY.

[61055.]—**Varnish for the Bright Parts of Bicycles.**—As a practical cyclist, I can say that I have found a thin coat of vaseline smeared over the bright or plated parts of a cycle with a rag, quite as efficient and much more easily removed than any of the so-called invisible enamels in the market. Of course, this is assuming that you are putting the machine by for the off-season. If you wish to ride the machine you would have to wipe the vaseline off the handle bar and brake, or it would spoil your clothes. If you still decide on using a varnish, you must be careful to choose one that will not affect the nickel (if any).—SEVERN TUNNEL.

[61058.]—**Glass Embossing.**—I would advise "Perseverance" to slightly warm his glass plate, and apply Brunswick black, which I always use for the purpose, and find little difficulty from the lifting he mentions, and which I think is owing to the glass not being perfectly dry. Don't breathe on it.—ALBO CARBON.

[61058.]—**Glass Embossing.**—Let "Perseverance" try a varnish of bees'-wax dissolved in turps. When cold it is solid. Heat it, and apply with a brush a thin coating; the glass being warmed slightly all the better. Then, when cool, remove the wax, taking care to press the pointer on to the glass, and remove all the wax where he wants the hydrofluoric to bite—i.e., eat the glass. I have never seen the wax lifted bodily off the glass. As to the cause of "lifting" of any varnish, it would probably be the want of making the glass clean.—R. S. T.

[61060.]—**Gut v. Leather Bands.**—As it is for a slow motion, decidedly the two ⅜in. gut bands will transmit more power than the 1in. flat one. I think the best kind of fastening for leather belts as regards facility in joining up is "Greene's patent," which can be obtained of most engineer's furnishers.—F. R. DAVIS.

[61060.]—**Gut v. Leather Bands.**—I have had lathes with both gut and band, and much prefer gut. It does not slip nearly so much as 1in. belting. A single gut not over $\frac{5}{16}$ is better than the belt in my experience. The plan I adopt for fastening of 1in. belt is to remove the pin from a hinge and rivet one half of the hinge to each end of belt, and then have a pin to slip in rather loosely. I do not find it have any tendency to work out. In practice I do not buy hinges, but fold two pieces of sheet brass and cut them to form a hinge and rivet them on with three rivets in each, the rivets being the brass nails used for escutcheons on doors.—T. C., Bristol.

[61061.]—**Engine and Boiler.**—Boiler will safely work at 35lb., but you should test at 60lb. Connect your small boiler to the other when steam is down, so that the pressure will gradually rise to 60lb., when you can disconnect it. Your engine is only about half large enough all ways to do what you want, unless you are willing to stand and freeze at the job this weather.—T. C., Bristol.

[61061.]—**Engine and Boiler.**—Steam is not a suitable thing to test a boiler with, and rather a funny thing to turn on gently; something like the old joke about letting a gun off gently! It should of course be done with cold water, and the boiler you speak of might then stand 50lb., but do not get more than 25lb. of steam into it. It will not supply the engine you describe, and you do not say if you intend it to. Do not exceed a 20in. saw for so small an engine.—F. R. DAVIS.

[61061.]—**Engine and Boiler.**—Most locomotives carry a pressure of 140lb. to the square inch, and your wrought-iron boiler, if only ⅛in. thick, will only carry the following pressure. If single-riveted, lap-jointed, the cylindrical part will only stand safely a pressure of about 80lb. to the square inch; if doubly riveted it will safely stand about 100lb. to the square inch. These figures are from a factor of safety of six. Supposing the ends to be well flanged in or well riveted to the shell, there will be almost as great a tensive stress on the stay as the absolute tensive strength of the material, so that you see the cylindrical part of your boiler is much too weak and the ends are worse off still. Even supposing your ends were strong enough (say, ¼in. with one 1in. stay), the cylindrical part should be at least $\frac{3}{32}$nd (if single riveted) or about $\frac{7}{16}$ths (if double riveted). On the whole, I should not feel safe near your boiler if the pressure exceeded 30lb. to the square inch. As regards the second part of your query, it is obvious that the diameter of your saw would have to be about 15 or 16in. in order that the spindle might clear; but even supposing your cylinder ends stopped on, if you proposed to use the boiler at the locomotive pressure, I don't suppose you would be able to run a 15in. saw through beech.—SEVERN TUNNEL.

[61062.]—**Cheap Dynamo.**—TO MR. BOTTONE.—I cannot advise you better than tell you to double the dimensions of the dynamo described in my book, using a laminated armature and wire of double the diameter. You may charge accumulators, if you prefer it, from this same dynamo; but, of course, you will lose about one-third the power. —S. BOTTONE.

[61064.]—**Vertical Engine.**—You are radically wrong somewhere; you should have 40lb. in the cylinder at the commencement of stroke. The top diagram is of good form; but the vacuum is decidedly low; and as it seems good by gauge—viz., 12lb., and only about 7lb. in diagrams, I should think, perhaps, your indicator was out of order—the shape of diagrams generally being good. What are the size of ports? They should be, say, 9in. by $1\frac{1}{2}$in.—T. C., Bristol.

[61066.]—**Electric Lighting.**—Use a stranded lead composed of seven strands of No. 20, for the main. For the branch circuits use No. 16. You will use the same wires whether you are lighting 10's or 20's. It is well to take the mains to a central point, and then divide into branch circuit of nearly the same length. By this means the lights are fairly equal.—S. BOTTONE.

[61067.]—**Casting Name Plates.**—Brass name plates are moulded like other work, the face being rammed and turned over. The mould is faced with charcoal and with flour or meal, the castings washed in water with a scratchbrush, and dipped for a few minutes in dilute nitric acid.—J. H.

[61070.]—**Lathe.**—Reversing gear to alter the direction of the travel of the slide-rest is merely an arrangement of a simple train of three wheels, which we will call A, B, and C. One of these (A) is geared into B, and its axis forms the stud on which the "mandrel" wheel of the screw-cutting train is placed. The other two wheels B and C, geared together, rotate freely on studs fixed in a plate that is centred on the axis of A. A slight angular motion to the plate sets either of the two wheels B and C in gear with the actual mandrel wheel. When the mandrel drives the wheel A through one intermediate wheel B, the rotations are in the same direction; but when it drives through two intermediate wheels, B and C, the rotations are in different directions. Give particulars of how the left-hand end of your mandrel headstock is constructed, and I will sketch reversing gear to suit.—GOOLWA.

[61071.]—**Lathe.**— The reversing motion is effected on the same principle as that for self-acting lathes, and is essentially as follows:—There are in addition to the change-wheel train, sundry idle wheels whose function is the changing of the direction of motion without affecting the velocity ratios. In a lathe of this class the first driver is on a stud attached to the back of the headstock; and, of course, the other succeeding wheels are on the stud or studs on the quadrant plate, and on the end of the leading-screw. The wheel on the headstock mandrel, which we will call A, remains of constant size. On the stud which carries the first driver is another idle wheel which we will call D. Between A and D the reversal is effected. Two equal wheels, B and C, run loose on studs on a rocking plate, like that which reverses the motion of the back shaft in any common self-acting lathe. The radii of these wheels, B and C, are such that while B always remains in gear with D, C is always clear of D. When the rocking plate is in one position B has its centre in line with the mandrel wheel A and the stud wheel D, and gearing with *both* becomes the direct medium through which the former drives the latter. By turning the rocking plate through an arc of a circle, wheel B is thrown out of gear with the mandrel wheel A, remaining, however, engaged with the stud wheel D, and also with its fellow C on the rocking plate. But the latter having its centre placed slightly farther out than that of its fellow, enters now into gear with the mandrel wheel A to one side of the line of centres of A and D. Hence the gear is driven in the second case *through both wheels* B and C in the rocking plate: thus A, C, B, D, C, being in gear with A and B, and B as always being engaged with D, and the introduction of the extra wheel C reverses the motion. The advantage of this mode of reversal is that the quadrant plate does not need to be moved in order to bring another wheel into the train, as is the case with common lathes, when cutting left-handed screws. Set the tool-box over at an angle of 10° or 15° from the perpendicular, leaning the upper portion away from the work, and the tool will not hitch.—J. H.

[61071.]—**Planing-Machine Tools.**—By reference to the illustration on page 273, where the tool-box of a planing machine is shown, the querist may see a curved slot just above the tool-box. This slot allows the tool-box to be set out of upright, and is for the purpose of allowing the swing of the tool to be altered so as to relieve the tools used on side cuts during the back stroke. The text explaining the construction of the planing machine refers to the subject of this query: see last five lines page 273. Further information if wanted; but probably the above will suffice.—GOOLWA.

[61073.]—**Electric Boat.**—I am very glad you called my attention to the observation in question, as by a piece of ill-fortune I had omitted to read the No. of Oct. 8th, and had not seen it. I have not the least idea what the correspondent meant, and he has never offered any explanation. He promised at the same time to give a description of a motor after his own plan, but, so far as I can find, has not yet done so. I can only say I have nothing to alter in the dimensions, &c., I then gave. They were specially designed to meet the requirements of amateurs, who, according to my experience, almost always more or less short-circuit their field-magnets, and sometimes their armature too, in winding. Amateurs, especially in hand-winding, never keep the steady tension of the professional winder; they (perhaps unconsciously) lay a strand and then pull on it, thus bruising and disturbing the insulation. Out of eight small motors and dynamos that I once tested, there was only one that was not more or less short-circuited in the F.Ms. I advised a little extra length of coils on the F.Ms. in view of this, and if you care to refer to Urquhart on "Electromotors," p. 105, and "E.M." Vol. XLII. pp. 128, 227, 348, and 386, to say nothing of others I could give, and compare quantities and resistances with those I gave on Oct. 1st, you will be able to form an opinion for yourself of how little warrant there is for the remark you have referred to. I have made several motors exactly of the pattern of my description Oct. 1st, and all are now working, and with every satisfaction. Connect the F.Ms. in parallel, and you will thus be able to run with fewer cells in series. I wound the motor with an eye to its use in parallel, which I prefer myself, as current is easier got than E.M.F., though a little more costly. I know the motor and its performance sufficiently well to enable me to promise you that if you make it exactly according to directions, I will take it off your hands at a fair price if I do not show you that it will do what I claimed for it.—EDWARD CONRY.

[61075.]—**Magneto-Electric Machine.**—TO MR. BOTTONE.—If an "Amateur" will kindly turn to p. 20 of my book, "The Dynamo: How Made and How Used" (see "Sixpenny Sale Column"), he will find a full description of what he requires; or, if he will wait till the next article but one on "Electrical Instrument-Making for Amateurs," he will be able to make a commutator on the principle therein described.—S. BOTTONE.

[61078.]—**Red Rust from Sheet Tin.**—"Sheet tin," as you call it, is neither more nor less than iron tinned over to prevent its oxidation. When this coating wears off the iron rusts, and it is this rust that troubles you. It can be removed by immersion in sulphuric acid and subsequent polishing with bran or sawdust; but as it is always liable to reappear, it is better to discard the sheet, or have it re-tinned.—W. C. HALL, Newport, Mon.

[61079.]—**Lathe.**—Evidently either slackness in lathe somewhere, or tool or work springs. Perhaps tool is rather too high, and also rather light. —T. C., Bristol.

[61079.]—**Lathe.**—There are various causes for the fault that you name—viz., the tool being below the centre, insufficient rake on tool, having the tool-rest too slack, or not having the tool sharp enough.—WALLACE NEWLAND.

[61084.]—**Fireclay.**—I give two good kinds of fireclay for brick:—98·0 per cent. silica, 0·72 per cent. alumina, 0·22 per cent. lime, 0·18 per cent. iron oxide, 0·14 per cent. potash, 0·40 per cent. water. This would do for reverberatory furnaces, and stand very high temperature, but not when in connection with lime or acid matters. The other is—

Silica	50·0	per cent.
Alumina	32·6	"
Ferric oxide	3·5	"
Potash	2·3	"
Lime	0·4	"
Magnesia	0·4	"
Water	9·7	"
	100·0	

—H. B.

[61085.] — **Flameless Combustion.** — Your correspondent is probably aware that flameless combustion in some form is as familiar as combustion itself, and has been known for ages. My object in taking this matter up was not to discover an old thing, but to study the question from a practical point of view. It has been thought by many that the presence of a large flame was an indication of great heating power, until my experiments showed conclusively that, with a given fuel consumption, the larger the flame the lower its temperature, and the smaller the efficient duty obtained. With any specified heating surface and fuel consumption, perfect combustion being insured, I found that as the flame was reduced in size the available fuel duty increased until a point was reached when the flame disappeared entirely, the disappearance of the flame being accompanied by a sudden and great rise in the duty obtained. Perfect combustion without flame can only be obtained under certain peculiar conditions which are not always available, and its application is therefore limited. It is practically applied in the well-known injector furnace in a small gas forge, and also in a furnace for making Siemens-Martin steel; but the most important part of the experiments is the conclusive proof of the fact that not only is flame not necessary for combustion, but that the reduction in the size of a flame is, other things being equal, always accompanied by an increased duty and a higher temperature in the furnace. My experiments, although called flameless combustion, were really a series of researches into the internal conditions and the general properties of flames. In the original paper on this subject the internal temperatures of various flames were given, and the inefficiency of some large volumes of flame was conclusively proved on the lecture table by putting my hand inside them, and by placing in them with my hand balls of gun-cotton and parcels of gunpowder, which remained unburnt for any length of time. The more recent experiments on the action of flame on cold surfaces are a continuation of the same series of experiments, and the fact that it is quite impossible to force any flame, however powerful, into contact with a cold surface, is as unexpected as it is important from a commercial point of view. Flames are curious things, and the more they are studied the more unsatisfactory and disappointing they are; the less we have of them the better the results: they are simply signs of incomplete and imperfect combustion, and this being the case, it is better, as far as possible, to do without them altogether. If your correspondent will bear in mind the fact that I have not attempted to discover a new thing, but have simply been studying an old one from a new standpoint, he may possibly find my results of some practical use.—THOS. FLETCHER, F.C.S., Warrington.

[61086.]—**Wimshurst Machine.**—The following is from King, Mendham, and Co.'s catalogue:—"For taking the current oneself, medicinally or otherwise, the Leyden jars should be placed on the table without the tinfoil between them, and their knobs connected one to each conductor of the machine. A handle or sponge holder should then be connected to the outside of each jar and held in each hand. By altering the distance between the discharging knobs of the machine the current can be regulated to a nicety."—LONDINIENSIS.

[61086.]—**Wimshurst Electric Machine.**—In my former reply it did not seem to me to be necessary to state how shocks could be obtained, for I thought that in the common order of things "Electric" would have tasted more shocks than he cared for, and also have made fifty other experiments before he read my reply. However, he can "obtain shocks similar to the shocking coil" by connecting the top of one Leyden jar to one collecting comb, and the top of a second Leyden jar to the other collecting comb; then let him place the terminal balls a little way open, say, $1\frac{1}{2}$in., and place himself in the circuit by holding the outer coating of the jars, one in each hand; all that has then to be done is to get someone to turn the machine. "Electric" will be quite satisfied that the shocks are strong enough; they may be made stronger by using larger jars, and be made lighter by leaving less space between the terminal balls.—J. W.

[61087.]—**Metallic Fire Alarms.**—I believe iron and zinc strips are generally used for the most sensitive forms. Have had no personal experience. —S. BOTTONE.

[61089.]—**Coils.**—The second would probably be the strongest.—S. BOTTONE.

[61090.]—**Electric Scarf Pin.**—TO MR. BOTTONE AND OTHERS.—No, it is simply because polarisation takes place. Give the battery ten minutes or a quarter of an hour's rest, and you will find it work again all right.—S. BOTTONE.

[61091.]—**Curious Phosphorescent Insect.** —This is a centipede.—S. BOTTONE.

[61093.] — **Hexagonal Nuts.**—You can see them "from 3in. to 6in." in Calvert's *Almanac* for 1885, p. 54, and for particulars for smaller sizes, see Calvert's *Almanac* for 1884, p. 48.—WALLACE NEWLAND.

[61093.]—**Hexagonal Nuts.** — As engineers generally work by Molesworth's book, I give the list from that work, diameter first, and size over flats next—$\frac{1}{4}$ and $\frac{3}{8}$, $\frac{5}{16}$ and $\frac{9}{16}$, $\frac{3}{8}$ and $\frac{9}{16}$, $\frac{7}{16}$ and $\frac{3}{4}$, $\frac{1}{2}$ and $\frac{3}{4}$, $\frac{9}{16}$ and $\frac{7}{8}$, $\frac{5}{8}$ and 1in., $\frac{3}{4}$ and $1\frac{3}{16}$, $\frac{7}{8}$ and $1\frac{5}{16}$, 1 and $1\frac{1}{2}$. The list runs up to 3in. bolts.—T. C., Bristol

[61093.] — **Hexagonal Nuts.** — "Ben Bolt" will find an absolutely correct list of Whitworth's standard sizes for the above in a table in "Molesworth's Pocket-Book," p. 418 (21st edition). This

table ranges from a $\frac{1}{4}$in. bolt to a 3in. bolt, and gives to four decimal places the width across flats, thickness of nuts, thickness of bolt-heads, and diameter of bolt at bottom of thread. I believe these are also given in Templeton's "Workshop Companion," but am not sure.—SUDBROOK.

[61093.]—**Hexagonal Nuts.**—This being my first attempt at answering any questions in the ENGLISH MECHANIC, I hope it will be of some value to "Ben Bolt." This is a full table of the sizes of the Whitworth standard of hexagonal nuts.

Diameter across flats.			Dia. across angles.	
Dia. in inches.	(*d*) in decimals.	nearest $\frac{1}{32}$in.	(*c*) in decimals.	nearest $\frac{1}{32}$in.
$\frac{1}{2}$	·9191	$\frac{29}{32}$	1·0612	$1\frac{1}{16}$
$\frac{5}{8}$	1·101	$1\frac{3}{32}$	1·2713	$1\frac{5}{32}$
$\frac{3}{4}$	1·3012	$1\frac{5}{16}$	1·5024	$1\frac{1}{2}$
$\frac{7}{8}$	1·4788	$1\frac{1}{2}$	1·7075	$1\frac{23}{32}$
1	1·6707	$1\frac{11}{16}$	1·9291	$1\frac{15}{16}$
$1\frac{1}{8}$	1·8605	$1\frac{7}{8}$	2·1483	$2\frac{5}{32}$
$1\frac{1}{4}$	2·0483	$2\frac{1}{16}$	2·3651	$2\frac{3}{8}$
$1\frac{1}{2}$	2·4134	$2\frac{13}{32}$	2·7867	$2\frac{25}{32}$
$1\frac{3}{4}$	2·7578	$2\frac{3}{4}$	3·1844	$3\frac{3}{16}$
2	3·1491	$3\frac{5}{32}$	3·6362	$3\frac{5}{8}$
$2\frac{1}{4}$	3·546	$3\frac{17}{32}$	4·0945	$4\frac{3}{32}$
$2\frac{1}{2}$	3·894	$3\frac{29}{32}$	4·4964	$4\frac{1}{2}$
$2\frac{3}{4}$	4·181	$4\frac{3}{16}$	4·8278	$4\frac{13}{16}$
3	4·531	$4\frac{17}{32}$	5·2319	$5\frac{7}{32}$

I hope this will suit. This is the standard given in the advanced science series of "Machine Construction and Drawing."—JOHN G. BELL, W. Nook.

[61095.]—**Incandescent Light.**—If you employed 5c.p. lamps, then for each set of three such lamps you would require 15 cells of a chloride of zinc battery. Hence, 30 cells would be ample for your purpose. To make the battery: Place rod of zinc in porous cell; surround the porous cell with broken carbon and one or more carbon plates connected together. Charge the zinc cell with solution of chloride of zinc (2oz. to the pint), the outer cell with chromic acid, 1 part; water, 1 part; hydrochloric acid, 1 part.—S. BOTTONE.

[61097.]—**Coil.**—The addition of condenser will not improve matters. Add another 4oz. of wire on the secondary.—S. BOTTONE.

[61097.]—**Coil.**—With two cells in series the shock should be irresistible enough, if the coil is well made, and does not leak anywhere. A condenser will certainly make a great difference; but it should be remembered that coils with condensers are never used to give shocks, unless we wish to half-kill someone. Try an extra cell first; but of course if there is a leak, this will not mend matters. I presume there is a soft iron core.—BOBADIL.

[61098.]—**Invalid Carriages.**—There are two methods by which the cycles now in the market for those who have not the use of their legs are steered. As a general rule, these are rear-steerers, because of the ease of mounting. The first is to steer by means of a back-rest connected to the rudder-wheel; this seems to me to be clumsy (though mechanically simple), and dangerous on a declivity. The second is as follows: The right-hand lever has a rotating handle, actuating an internal rack and pulling a rod, which is connected by a bell-crank to the steering-rod. This is apt to get loose and shaky; still, it must be a much more natural method of steering than moving your back from side to side.—SUDBROOK.

[61099.]—**A Rule of Grammar.**—"Doctor Med." should reflect on German idiom, "Es ist mich (not "Es ist ich"), meaning "It is me." On the other hand, "It is I" has authority of auth. vers. of Bible. "Me" is not necessarily accusative, or any objective case at all, though narrow-minded scholars may fancy so. Possibly "It is I" is merely the product of an erroneous grammatical conscience springing up in the English people. French personal pronouns have a special form or case distinct from the nominative form (or that used as the subject of the verb), which is at once the independent ungoverned form, the form after "to be," and the form to be used with prepositions Moi je le sais; C'est moi; C'est pour moi; Moi, toi, lui, elle, eux, elles, &c.—WEALD.

[61099.]—**A Rule of Grammar.**—Having been engaged in the tuition of languages both here and abroad for nearly 40 years, I venture to state a few reasons why the verb *to be* in all languages can only take one case. It must be quite evident that any one who *is* cannot *be* some one else. Hence, if I am he, it is very evident that he is I. Now, *him* is not the nominative to any verb in English, so as you cannot say him is I, therefore you cannot say I am *him*, or it is *me*. The French say *C'est moi;* but *moi* is another form of the nominative case, witness *moi qui vous parle*, &c. (I who speak to you, &c.) There is no *reason* like the above why we should continue the use of case endings rather than case prefixes; it is only a matter of convenience, and does not jar against common reason.—S. BOTTONE.

[61099.]—**A Rule for Grammar.**—"Doctor Medicinæ" certainly requires to appeal to the philological readers of the ENGLISH MECHANIC, for he appears not to have thoroughly grasped one of the first rules of syntax—i.e., "The verb 'to be' through all its variations takes the same case after it as that which next precedes it," as a glance at a modern grammar will show. Such expressions as "It is me," or "that is him," are well calculated to shock the sensitiveness of "strict grammarians." "Custom" may certainly "favour the expressions" among the ignorant or unenlightened; but "Malus usus abolendus est," and to the educated such "rules of grammar" are painfully irritating. "Doctor Medicinæ" appears to be better versed in the grammar of our "Anglo-Saxon forefathers" and "the latter part of the 18th century" than that of modern times, and the opinion (as asked for) of at least one of the readers of the "E. M." is that school is the best place for such persons.—W. C. HALL, Newport, Mon.

[61101.]—**Stars Visible from Bottom of Well.**—The only star likely to be visible in the daytime in the latitude of London is γ Draconis. Troughton, the celebrated instrument maker, said that he often saw this star by looking up the chimney of his workshop in Fleet-street. "Our latitudes" may include anything between the Lizard and Dunnet Head—a difference of more than $8\frac{1}{2}$°, so that other stars will be visible according to locality. It is not necessary that the observer should be actually at the bottom of a well, as the stars may be seen from the surface reflected in the water.—R. E. F.

[61101.]—**Stars Visible from Bottom of Well.**—Does "Faciebat" mean what magnitude stars would be visible during an eclipse of the sun? If so, I should say none under 2nd mag. Chambers says ("Handbook," p. 183, 3rd edition), "In the case of the eclipse of 1842, it was remarked by Piola at Lodi, and by O. Struve at Lipesk, that although the obscurity was such that stars of the 2nd and 3rd mags. ought to have been visible, yet only those of the 1st mag. were actually seen." The author goes on to say that this can be explained physiologically by the eye not having sufficient time to recover from the bright sunlight, and consequently not being able to take advantage of the obscurity which actually prevails. If what "Faciebat" wishes to know is the actual stars that would be visible, this, of course, almost entirely depends on the season that the eclipse takes place. I do not know what mag. stars can be seen from the bottom of a well.—A. R. B.

[61102.]—**Bending Beech.**—Hold the strips of beech in steam for a few minutes, or lay them in a copper of boiling water; then bend round a circular block to size required, fastening with a hand-screw or French nail until cold.—C. A. W.

[61105.]—**Exhaust Pipe.**—Start the engine very slowly, and open both cylinder taps that the water may have time to get out without being forced up exhaust pipe, and that is the only remedy. There would not be draught enough if exhaust were removed from chimney.—F. R. DAVIS.

[61105.]—**Exhaust Pipe.**—The water is evidently in the cylinder; fit a drain-cock to each end of cylinder and also to exhaust if possible. Can you not lead chimney into some brick flue belonging to house, if chimney on boiler is not tall enough of itself to give sufficient draught if you have to remove exhaust from chimney? But, probably, drain-cocks will meet the case if not already fitted. —T. C., Bristol.

[61106.]—**Cheap Disinfectant.**—When a solution of a soluble chloride, such as common salt (chloride of sodium), is added to one of nitrate of lead, a precipitate of chloride of lead, rather soluble in boiling water, but less so in cold, is formed. Having regard to the deliquescent nature of common salt by reason of its contamination with chloride of magnesium, I should not advise "Sanitary" to keep the powders mixed unless in a dry, warm place, or he will find his mixture of a rather pasty consistency. Never having heard of its disinfecting properties, I can venture no opinion. —W. C. HALL, Newport, Mon.

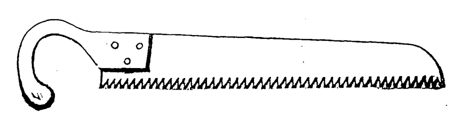
[61108.]—**Oil for Cycles.**—A mixture of common flask oil and paraffin (half-and-half) I think you will find answer very well, unless you object to its not very agreeable aroma.—W. C. HALL, Newport, Mon.

[61108.]—**Oil for Cycles.**—I am afraid "Lubricator" will not be able to find a more suitable lubricant than sperm oil. I use sperm oil, but I find the 10 per cent. of paraffin I put in helps to do away somewhat with the smell of the sperm. Every other oil I have tried—lard oil, olive, &c.—clogs up the bearings, and does not run freely. Has "Lubricator" tried plumbago and glycerine? I have tried it, but it is more expensive and not so satisfactory as sperm and paraffin. Many of the oils sold by the cycle agents do not smell badly; so I suppose they have something to neutralise the disgusting smell you speak of.—SUDBROOK.

[61109.]—**Defective Brickwork.**—Perhaps a little size incorporated with the whitewash would avail.—W. C. HALL, Newport, Mon.

[61110.]—**Dynamo.**—The calculations to find with a shunt-wound dynamo (which I presume yours is) the amount of resistance that would bring the E.M.F. down to a given figure are a little involved, but if you desire to go into them for future information, I should suggest your referring to Thompson's "Dynamo-Electric Machinery," and also availing yourself of the following formula from Munro and Jamieson. "The multiplying power of a shunt is the ratio of the current C which would flow through the galvanometer if not shunted to the current C_1, which flows through it when shunted. Thus $\frac{c}{c_1} = \frac{G + s}{s} = \frac{G}{s} + 1$, where G = resistance of galvanometer and s_1 resistance of shunt." This appears to give what you want; but I cannot say for certain, as I have not got the exact data for the purpose. S. Thompson's work would give it you better. When the E.M.F. of a machine has to be altered to such a large extent as you require, a much more useful and economical way is to slow down the engine, which reduces the E.M.F. at once, or, if driving off shafting, to put smaller pulleys on to the dynamo and shafting, so as to reduce the speed I have seen two pulleys on the shafting one half the size of the other, and two on the spindle of the dynamo, and two straps on the shaft, one running the dynamo at high speed for a certain purpose, and the other hitched up ready for use when a lower speed was requisite. If this be impracticable, insert a resistance in the shunt constituting the field-magnet circuit. I think you would get at the required resistance easier by actual experiment than by calculation, as by putting into the shunt circuit by a temporary attachment, say, the whole length of your iron wire, and then trying a lamp on the dynamo terminals for a moment. If the E.M.F. is reduced too much, cut out part of the coil by a temporary attachment at half length or otherwise, and so on until you get the resistance that will just allow of the lamp burning properly on the dynamo terminals. You can then reckon what extra E.M.F. to allow, so as to get through the 335 yards of wire the same light of the lamp as at the dynamo terminals (which extra E.M.F. will be 0·266 volt for each ampère of current you have to transmit), and allow enough E.M.F. to cover this loss. If you have no voltmeter, then you will have to fall back on trying the lamp at the ends of the No. 5 wires, until you reduce the resistance to the correct amount.—EDWARD CONRY.

[61111.]—**Hand Saw.**—I inclose sketch of a saw I have frequently seen used in Northern India and Afghanistan, in which the teeth being



exactly the reverse of European saws, the work is done by a pull in place of a thrust, and that more expeditiously than the uninitiated might suppose. If I remember rightly, a newspaper critic pointed out this matter of saw teeth when Holman Hunt's picture was first exhibited, censuring the artist, thereby ventilating his own ignorance.—OMPAX.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

QUERIES.

[61114.]—**Dynamo.**—To MR. BOTTONE.—Many thanks for answering my letter of 27th ult. Would you kindly say whether it makes very much difference in the power of the machine if the F. magnets are narrower, say 3in. wide and ½in. thick, for the dynamo in your book? Also if the laminæ for armature must touch each other on the spindle, or be a short distance apart?—ARTHUR J. KEMP.

[61115.]—**Gas-Engine.**—Could any reader kindly enlighten a novice on how the supply and exhaust valves of gas-engines are worked? Any information on the subject will greatly oblige—A. J. KEMP.

[61116.]—**Iron Boot—Used in Junod's Vacuum Treatment (Hæmospasia).**—Can any of "ours" kindly give me any information regarding this form of treatment—where the boot could be procured, or instructions for making it? Also name of any practical book on this mode of treatment? Any information will be most highly appreciated by—J. H. M.

[61117.]—**Horse's Action.**—Can any of "ours" kindly tell me how the Americans train their horses to lift their fore feet when trotting in the fine high showy manner they do? I have heard that it is done by fixing lead weights under their shoes. Any information will be most heartily welcomed. I am also desirous of procuring a really practical and useful book on the general management and care of the horse. Will someone kindly recommend such a work? Also, is there any work published treating on training horses to perform tricks, as circus horses do?—J. H. M.

[61118.]—**Electro-Magnet.**—Would Mr. Bottone tell me what size wire I should require for an electro-magnet to pull a 1oz. weight a distance of ½in. from core, and battery power I should want?—VOLT.

[61119.]—**100-Candle Dynamo.**—Please give me dimensions for 100-candle dynamo. I want to make my own patterns as per instructions in your book, but do not know size. I should like to have patterns same as Edison's, only a Gramme armature, and will you give me quantity of wire on F.M.'s and number of sections in armature?—VOLT.

[61120.]—**Ferrous Oxalate Developer.**—When this developer is restored, as given in replies to 60967, is the result a one solution developer, or has the iron solution to be added as before?—M.

[61121.]—**Wax or Paraffin Stains.**—Candles called "wax" or "paraffin" have replaced the old tallow dip. The melted wax is a very thin liquid, and falls over clothes and furniture. What will dissolve and remove it?—M.

[61122.]—**Magic-Lantern Slides for Boy's Lantern.**—I have made some very successful slides by smoking glass till opaque, then drawing motto or design with pencil or a needle point, and afterwards flowing varnish over to preserve. Of course, I can't see through glass so as to trace over a drawing. What can I use? Ink I find does not do. Will a pen do, or must a brush be used? I have heard of gelatine for slides. Can it be drawn on with a pen? Is it used alone, or must it be mounted on a strip of glass? If so, how?—M.

[61123.]—**Analysis of Kainit.**—Would any of our readers kindly give simple directions for testing the above substance, or say how I am to interpret the following results: H_2O 2·74 per cent. (@ 212° F.); H_2SO_4 23·76 per cent.; Cl 32·12 per cent.?—F. S.

[61124.]—**Analysis of Lime.**—In Dr. Lunge's "Pocket Book" we are directed to titrate with normal oxalic acid, using litmus or phenolphthalein as indicator. The colour is said to change when all free lime has been saturated, and before $CaCO_3$ is attacked. In adopting this method, I find that after the colour has once vanished it returns almost momentarily. How is this?—F. S.

[61125.]—**Cobalt.**—Will anyone kindly inform me where I can find a book, or article, giving an account, and plans, &c., of a cobalt-extracting works, and the best methods in use? I would pay for plans, if necessary.—EDGAR HALL, Queenboro'.

[61126.]—**L. and N.W. Engines.**—Can Mr. Stretton, or any reader of your paper, give me details of engine No. 955, Charles Dickens, Precedent class, as I see she has been to Crewe for repairs? I believe she has done good work. Also, why have they taken this engine off the 4 o'clock express?—OLIVER TWIST.

[61127.]—**Force Pump.**—Will any reader describe the simplest and best way to make a hand apparatus to force a large quantity of air or gas into a small cylinder?—SUBSCRIBER.

[61128.]—**Paper Valve.**—Can there be any objection to paper passing over reeds in organette (suction principle)? If so, what are they, and how remedied?—PAPYRUS.

[61129.]—**"Loeb" Battery for Electric Light.**—(As used at Burrows and Watt's, Soho-square.) This battery is stated to last 70 hours constant with a good light. I never heard of any such performance from a battery. Can any one give full description of cells and solution. No smell from them.—THOS. PLUNKETT.

[61130.]—**Spill-Making Machine.**—I am about to make a spill machine, both for wood and paper spills. Can any of your kind readers describe the best way for making the same? A sketch would greatly oblige—A YOUNG FITTER.

[61131.]—**Electric Cautery.**—To MR. E. CONRY.—What is the most economical and most satisfactory arrangement for obtaining the heating of a cautery the resistance of which is ·06 ohm? What is it that is here required? Is it current? How could the current flowing be scientifically—I mean accurately, not roughly—measured?—A. DUNLOP STEWART, M.B., &c.

[61132.]—**Glazing Red and Black Ware.**—Will some potter friend be kind enough to give the formula for glazing the common red and black ware, and if the ware is usually slipped before leading, and what part does the slipping play in the quality of glaze, and also where to get the lead ore, either ground or in the lump, with price?—POOR POTTER.

[61133.]—**Adiabatic Curve.**—Would any of "ours" please inform me how to describe the above curve, as I cannot find it in any geometrical work?—A. J. W.

[61134.]—**Small Electro-Motor.**—To MR. BOTTONE OR G. BOWRON.—To obtain the best results from a small motor, should the resistance of the fields be exactly balanced by resistance of armature?—ALCHEMIST.

[61135.]—**To Mr. Bottone.**—I made a dynamo according to your dimensions, and I cannot get it to work. When I coupled it up with another dynamo it worked as a motor. The connections are all right. When I short-circuit it at the binding screws, small sparks appear at the brushes, and it gives a small spark when the contact at binding screws is broken. There is 10lb. No. 22 on the field magnets, and 4lb. No. 18 d.c.c. wire on the armature.—ELECTRICITY.

[61136.]—**Screw-cutting.**—Many thanks to my brother readers answering my query on the above. I find by marking the face-plate and the leading screw wheel will answer; but what I want to know is the distance the saddle must travel in inches before it will gear right for taking the second cut. I will say 11 threads per inch. I have tried "J. H.'s" plan, but find it not to answer with my lathe, four threads per inch leading screw, but it will with two threads per inch leading screw.—ONE IN A FIX.

[61137.]—**Regulating Current.**—I have a 20c.p. dynamo. Sometimes I only require one 16c.p. lamp on, other times a 10c.p. lamp, sometimes a 5c.p. How can I regulate the current for the various lamps?—AMATEUR.

[61138.]—**Yacht Steering.**—Can "Vulcan," or any-one else, tell me if there is any known way of taking part of the pressure of the weather helm off the tiller of a sailing yacht? I do not mean by altering the centre of effort of the sails by increasing foresail; but some method of balancing the rudder, so as to ease, but not destroy, the weather helm—in short, to admit the use of a short handy tiller in place of a long one.—G. H. V.

[61139.]—**Chromic Acid and Bichromate Batteries.**—Will any of your readers kindly give their experience of chromic acid in batteries? For some time past I have been using seven large cells with porous pots for zinc. The solution I have used in carbon cell was: water, 18lb.; bich. potash, 2¼lb. at 6d. per pound, equal 1s. 1½d.; sulphuric acid, 8lb. at 1½d., 1s.; total, 2s. 1½d. This makes about two pints per cell. This charge will last for about 90 days, using one 10-volt 10-candle-power lamp about 15 minutes per day. This is about altogether 22 hours of work. I know that if I had used the batteries, say, two hours per day the solution would have given better results, say 30 hours for 2s. 1½d. Chromic acid is a better depolariser, but it is dearer. I believe the proportions for use are: chromic acid, 1lb. at 8d., equal 8d.; water, 2 pints; sulphuric acid, ½lb. at 1½lb., ¾d. 8¾d. for 2 pints solution, or for 7 cells, 14 pints, costing 5s. 1¼d. Would this give me 65 hours of work. By advertisements it should do much more than this (same in proportion as bichromate of potash), or 15 times 65 hours. Any facts will be useful.—W. W. N.

[61140.]—**Grey Stains on Black Marble.**—We shall feel grateful if someone will inform us how to remove the grey or whitish marks which make their appearance on polished black marble after being exposed to the action of the atmosphere of a shop. In the Nov. 19th issue, we were referred to p. 456, No. 1088; but we find this article only describes the method of polishing, not removing stains or marks. We find many housewives and shop-keepers thus troubled with their mantel pieces and marble clocks, and think a cure will be well esteemed.—AJAX.

[61141.]—**Screw-cutting.**—Will any reader of the "E. M." be kind enough to give a few methods for calculating screw-cutting by four wheels, or double train, with a few examples of, say, 13, 15, and 19 threads to the inch, the leading screw having two threads to the inch?—CHASER.

[61142.]—**The Wimshurst Machine.**—Would Mr. Wimshurst explain why, at each discharge given by one of his 17in. machines, brilliant sparks rise upwards from what appears to be the edge of outer coating of each Leyden jar? Is it a loss of electricity, arising from some fault in construction? I can only obtain a 2½in. spark between terminals, and only given at long intervals. I, however, manage to coax a somewhat long spark by holding a glass rod to larger ball. The discharge is loud and brilliant; but not the length I expected. Should be glad of any suggestions for improvement.—SHORT SPARK.

[61143.]—**Launch Engine.**—Will one of our practical readers help me as follows? I have engine, say 3in. by 5in., running at 300 per min., cutting off at two-thirds stroke; pressure, 60lb. I wish to get a little more power. I do not want to enlarge bore of cylinder, because I do not want to use any more steam or increase pressure. Suppose I increase stroke to 6in. and cut-off as before, what would be the result? Is power gained equal, whether bore or stroke is increased. My idea was that increase of stroke was more economical.—CANTAB.

[61144.]—**To "O. J. L.," "J. H.," and Others.**—With a screw-cutting treadle lathe, 6in. centres, would you consider 34 cuts to the inch, and a cross feed of 1-16th, reducing a bar of 1½in. soft steel to 1in., fast enough for a roughing cut, and would you recommend to take it off at one cut, or would you prefer to do it at twice?—EVOD.

[61145.]—**Does it Boil?**—What is the scientific account of a cup of hot water which steams though certainly not anywhere near the boiling temp.? How reconcile this fact with doctrine that there is a certain *sine quâ non* temp. at which water begins to leave the liquid form and take the gaseous form, or is such a doctrine a mis-statement on my part? Answerers requested not to urge that visible steam is not "gaseous" water; surely it is water that has been gaseous? Is it that the parent water-gas was a solution in warm air over surface of fluid, which, on rising up, cools and forms mist?—WEALD.

[61146.]—**Battery.**—Would Mr. Bottone kindly say how many cells (as described by him on page 561, last vol.) it would take to light one of Messrs. Shippey Bros. 5c.p. lamps? What size wire should I require from battery to lamp? Also the proportions of chromic and sulphuric acid? Would the light last longer if the glass cells where larger in diameter and contained more solution? Should the zincs be amalgamated?—MEPHISTOPHELES.

[61147.]—**Red Steam.**—In holding steaming cup of coffee between self and globe of paraffin lamp, not quite in the direct line, I have noticed decided red hue in steam rising; suspicion of other spectrum colours, but red hue predominant, and very like tinge of angry sunset sky preceding rain. What is the cause of colouration, and why red? I have no colour-blindness.—WEALD.

[61148.]—**Screw-cutting.**—I have two screws to cut—one that will traverse a nut the 20th part of 3in. at the 5th of a revolution, the other that will traverse a nut the 20th part of 3in. at the 4th of a revolution. What is the pitch and wheels required and the easiest method of arriving at the same?—PERPLEXED.

[61149.]—**Dynamo.**—Will some one possessing practical experience tell me how to cut out of circuit a heated coil in a dynamo? I have had experience with the Crompton, Pilsen, Joule, Siemens, and other dynamos, and to be able to stop the machine, cut out the heated coil, and let the dynamo go on with its work again is what I desire; and any practical rule by which a dynamo guilty of this transgression can be effectively dealt with will greatly oblige—A. B. C. DYNAMO.

[61150.]—**Hydraulic, or other Press.**—I shall be glad of the assistance of any brother mechanic who can advise as to the best press for pressing crushed ore into blocks, say, similar to the ordinary filter blocks made of charcoal. Have succeeded fairly well with a hand press; but I require from four to six tons pressure, which cannot be obtained with any arrangement I have. What would be a good form of mould for my purpose?—A VERY OLD SUBSCRIBER.

[61151.]—**Liquid Fuel.**—Having a cheap supply of coal tar creasote, and being desirous of utilising it for steam-raising purposes, I shall be glad of any hints from experienced readers. The small boiler set apart for the experiment measures 15ft. by 4½ft., with a 2ft. 6in. flue. The steam is required at 70lb. pressure. The best method, I understand, is to break up or pulverise the creasote with a jet of steam, so that it shall enter the fireplace in the form of very fine spray. I desire to learn what size of pipes for conveying the creasote and steam will be required for a boiler of the dimensions given, the best kind of spray producer, and whether the fireplace ought to be protected with firebricks? At present engine slack is being used for firing, and I should like to arrange matters so that either creasote or slack can be burned at will.—K. N. S.

[61152.]—**Spanish.**—I am studying Spanish with "Ollendorff's Spanish Grammar for the use of Italians," and I find it a good system for studying by one's self. Is the method mentioned by "W. J. R." (60802) superior? I should be glad to know, as I want to learn the language quickly, and I have no means of getting a teacher.—NELIGEL.

[61153.]—**Blowing Fan.**—Can any of your readers kindly give me an approximate rule to find the number of cubic feet of air delivered by a blowing fan per minute? Also any particulars relative to the use of forced draught, which I see is rather coming into use in the Navy?—G. STOCK.

[61154.]—**Lens Measurement.**—Will a subscriber kindly give an arithmetical example showing how to divide the diam. of a stop into the focal length of a lens, supposing the measurement to be ⅝in. into 6½in. of a lens?—PHOTO.

[61155.]—**The Pantanemone.**—In Vol. XXXIX., page 391, 1884, this machine is described, and in subsequent numbers it is very well spoken of. After more than two years, can any reader give any account of its working? Has anyone got one in use, and what is its power? I am proposing a windmill pump, and should feel inclined to give this machine a trial, if its power is equal to lifting 30 gals. an hour 25ft. high.—SURVEYOR.

[61156.]—**Battery for Lamps.**—I have a battery of eight double-fluid cells, two zincs and carbons in each, size of plates, immersed, 8in. by 6in., which is used for lighting ten Edison Swan 6c.p. 10-volt lamps in parallel. It is only used once a week for about 1½h., and as it is considerable trouble filling and emptying the cells, besides moving all the plates, I should esteem it a favour if Mr. Bottone, or some other reader, would kindly inform me whether it would answer to alter the battery into a single-fluid with a lifting arrangement, or if I could use a double fluid which would not deteriorate if left standing in the cells, of course with the plates out. How long would such solutions last? The one I am using at present is reckoned to last 16 hours. Also, is it any real advantage to amalgamate zincs when the plates are only immersed during the time the current is required?—ALBO-CARBON.

[61157.]—**Condensing or Non-condensing.**—We have a non-condensing steam engine; cylinder, 20in. diam.; pressure of steam, 50lb. The exhaust is connected to pipes containing steam at 10lb. pressure. We use a large quantity of steam for heating purposes, and pass steam at 50lb. through a valve to reduce it to 10lb., and we use this and the exhaust together; we blow none away. Should we gain anything by making it a condensing engine, and make up for the loss of the exhaust by taking more steam through the reducing valve?—R. R. R.

[61158.]—**White Enamel or Paint.**—Can any subscriber inform me if there is a white paint or enamel which will stand heat? If so, give price and where to be obtained. I want it to put on the back of kitchen range to give the brick and ironwork a lighter and cleaner appearance than the usual black.—JIMBO.

[61159.]—**Electrical.**—Will some reader be so kind as to tell me where I can find an explanation of Bennet's "Doubler," or will he give me a short explanation?—ELEM.

[61160.]—**Herbs.**—Could any kind reader give names and proportions of herbs to make what the French call "Tisane aux quatre herbes"?—URANOS.

[61161.]—**Converging Lenses.**—Would any of your readers discuss the relative qualities and advantages of plano-convex compared to double-convex lenses, my particular object being to obtain interference rings by means of polarised light, and could they recommend any book on practical optics or physics which might prove an aid in the construction of such apparatus?—NEW SUBSCRIBER.

[61162.]—**Sewing Machine (Wheeler and Wilson's).**—I have one of these machines which, when doing any stiff or rather thick work, leaves loops at the

back ½in. long, or more. I cannot find out the cause. I have polished up the bobbin, and the loop passes easily over it, and is held by the brush till the next stitch is caught, when the chamfered part of the hook releases it promptly. After that the loop goes up very tardily, and does not draw up tight. It is not held by the bobbin and spool ring at all to retard it, nor does it hang between the finger and the hook, as there is plenty of room. As the work did not travel straight when left to itself, but quickly travelled out to the edge of the material, I soldered a small piece of steel to the feed-bar where it was worn away, so that it should not be lower on one side, and the work now travels better, but is still inclined to go on towards the edge unless guided. I supposed that the feed-bar, by not pushing the work straight, had forced the loop hard against the back of the slotted hole in the plate, and so caused too much friction on it. I found a nick worn at the back of the needle hole, which served to corroborate this view. I chiselled away the sharp corner which this nick made at the entrance of the slot, and drew a strip of fine emery cloth in and out to smooth it, and the needle hole is now like a one-sided pear in shape. I observe that the eccentric which lifts the feed-bar is rather worn at the edges. I see it lifts the feed-bar before impelling it forward and at the same time as the loop is drawing in? Is this lifting intended to lessen the abrasion on the loop? If so, perhaps the worn eccentric is the cause, by its not lifting sufficiently. I see the loop after having caught the hook slightly, rubs against the hollowed part of the finger as the hook revolves. Should this be so? The loops are no better for what I have done at present. Could any reader suggest the cause of them?—PESTERED MAN.

[61163.]—**Faulty Dynamo.**—TO MR. BOTTONE.—Many thanks to you for information regarding dynamo in "Ours" of Nov. 26th. I tried the suggestions. I had not connected terminals. As soon as terminals were connected I had a spark on commutator; but I could not get any light in lamp. It is a Swan incandescent lamp. I reversed the motion of armature, and got as much current one way as the other. I cannot get any current on commutator, unless I join the lateral ends of F.M. coils; then it goes through a second time. It shows on the brushes if I run it at a medium speed. I find I can get more current through it than when run too fast. The size of machine is: armature, which is Siemens H pattern, 6in. by 2in.; about ¾lb. of No. 18 d.c.c. wire. The F.M. has poles 4in. by 3in., 1¾lb. No. 18 d.c.c. wire on each; pole pieces, 5½in. by 2½in. by 1in. thick in the core. The F.M. and armature are cast iron. It is built in a vertical form on brass plate screwed on wood base, brass bearings and brass brushes, ebonite insulated commutator. It is well insulated throughout.—ANXIOUS.

[61164.] — **Tackle for Moving Observatory Roof.**—In the directions for building a Berthon observatory, given in the "E. M." of Oct. 13, 1871, mention is made of a "gun-tackle purchase" for moving the roof. As I am at a loss regarding this arrangement, may I ask for information on the subject? Full details, with hints as to the means of obtaining what is necessary, will greatly oblige. Should any kind reader be disposed to describe any other practically useful and simple arrangement for the purpose, I shall be thankful if he will kindly do so.—OBSERVER.

[61165.]—**Spectral Colours and Diffraction.**—If I hold a piece of paper with a straight margin between my eye and the window on a day with a white cloudy sky, in such a manner as to leave only a narrow line of white light, the paper is fringed with red and orange, the edge of the window with violet and blue. Why is this? It is no doubt some result of diffraction; but why is the nearest edge fringed with red and yellow and the furthest with blue and violet?—F. BENNETT.

[61166.]—**Engine for Boat.** — Will "Glatton," or some other reader, assist me out of a difficulty—viz., what size of engine (compound) will it take to drive a 36ft. boat (6ft. beam) 12 miles an hour, and at what steam pressure? What would be probable cost of steel boiler for same, boat to weigh about 1 ton?—NOVICE.

[61167.]—**Water Tanks.**—I have to construct some water tanks, and receive no other instructions but the number of gallons they are to contain. Will some of your kind readers inform me of a short rule to find the dimensions (the three)? The tanks are parallelopiped and the frustum of a cone in shape.—B. M. AND J. S. B.

[61168.]—**Enamelling on Coins.** — Will anyone kindly tell me how the above is done in all colours, leaving the raised parts of the print perfectly clear, as one often sees in jellewers' shop windows?—J. BRIGGS.

[61169.]—**Safety Couplings.**—Can anyone give a description and drawing of the Gedge safety coupling recently adopted by the M.R., L. and N.W.R., L. and S.W.R., and other railways, and say when it will come into use?—R. E. F.

[61170.]—**Leather-covered Glazers.** —What is the best kind of leather to cover small glazers about 5in. diameter?—F. STELFOX.

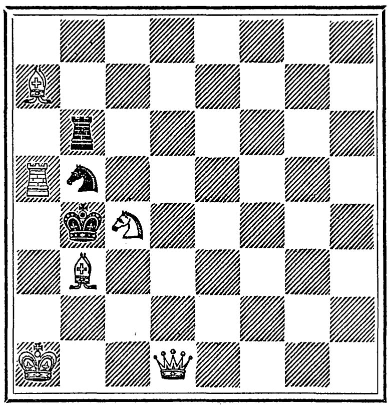
Carbon Lamp Filaments.—If steam be raised to a high temperature (to what is called a white heat) it is decomposed into the elements of which it is composed. Very high temperatures tend to break up chemical compounds. Place any kind of a wire, platinum, iron, carbon, &c., in a vessel containing a hydrocarbon gas (coal gas or gasoline vapour) and rise the wire to a white heat by a current of electricity. Those particles of the gas which are next to the hot wire are decomposed or broken up into carbon and hydrogen gas; the carbon is solid, and is deposited on the hot wire. In a short time a considerable layer of carbon will be deposited. Any portions of the wire thinner than the rest are heated by the current to a higher temperature, and consequently more carbon is deposited on that part until the wire is of the same size throughout its length. In the manufacture of incandescent lamps the carbon filment (or wire) is made uniform by this process.

CHESS.

ALL Communications for this department must be addressed to J. PIERCE, Langley House, Dorking.

PROBLEM MXXI.—BY T. H. BILLINGTON (Wolverhampton).

Black.



White. [6 + 3

White to play and mate in two moves.

SOLUTION TO 1,019.

White.	*Black.*
1. Q-Q Kt 6.	1. R-K sq (*a*).
2. Q-Q 4.	2. Anything.
3. Q or R mates.	
	(*a*) 1. R-K B sq (*b*).
2. P takes R, &c.	
	(*b*) 1. B-Kt 3 (*c*).
2. Q-K Kt sq, &c.	
	(*c*) 1. R-Q B sq.
2. Q-Q 8, &c.	

NOTICES TO CORRESPONDENTS.

CORRECT solutions to 1,019, by F. Krasser and Link; to 1,018, by Link (very interesting); to 1,020, by Black Pawn and A. Bolus.

HANDSAW.—Name entered for Tourney B.

J. MACKENZIE.—Your attempt at 1,018 is incorrect.

A. DEAN.—If in 1,019 1. $\frac{\text{Q takes P}}{\text{B-Kt 3}}$ 2. $\frac{\text{Q-Q 4}}{\text{B checks}}$.

A. BOLUS.—There is something wrong about your solution of 1,019. You have 1. $\frac{\text{Q-Kt 7}}{\text{R-K sq}}$ 2. $\frac{\text{Q-K 4}}{\text{Anything}}$ 3. Q-K R 8, mate. This move is impossible; nor is there any mate.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 332, *Strand, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, Dec. 8, and unacknowledged elsewhere:—

D. W. ARMSTRONG.—E. P. Alexander.—C. S. Stock.—T. F. S. T.—J. B. Medland.—Blakey Emmott and Co.—Wool.—Green Lad.—B. A., Handsworth.—W. M.—J. C.—A. E. Richardson.—Amateur.—J. Seal.—Irish Contractor.—S. M. S.—Engineering, Manchester.—Country Solicitor.—A. W. Stokes.—J. Beardsall.—Les Dents.—A Fellow of the Royal Astronomical Society.—H. S. H.—A Belated Foreman.—J. H.—C. N. P.—Ignorant.—A. Treyer Evans.

A NEW READER, Londonderry. (On p. 562, No. 1117, there is a recipe for removing stains from marble. Two parts of soda, one of chalk, and one of pumice, are to be powdered, intimately mixed by sifting, and made into a paste with water. Rub that on well, and wash off with soft soap, polishing with a soft cloth. Something depends on the nature of the stains, but you will find many suggestions in back numbers.)—J. HUNT. (Pitch and rosin are both too brittle. A common cement is made by melting equal parts of pitch and guttapercha together. Perhaps a better is made by melting together 1lb. of guttapercha, 4oz. of indiarubber, 2oz. of pitch, 1oz. of shellac, and 2oz. of linseed-oil.)—F. BENNETT. (Good lime will be purchased by keymakers for organ, piano-keys, &c., and by carvers; beech by plane-makers and turners generally If by Portugal laurel you mean Cerasus lusitanica, it is used by cabinet-makers, stick-makers, pipe-makers, &c.)—SEGRO. (Many cigarettes are made by machinery, but others are made by hand. See Hints No. 4.)—ALBERT J. SELLS. (You can terminate the tenancy with the expiration of the agreement. If there is nothing said in the agreement about continuing the tenancy, it is a matter for another agreement.)—VIOLIN. (It is usual to stain and French polish. You can probably remove the present varnish with warm spirit. If not, rub off with fine glass-paper.)—RALPH LOUDON. (See the indices of back volumes, and the textbooks of astronomy.)—PERSEUS. (Your first question has been answered many times, even in recent numbers—last week, for instance, on p. 310. 1. How can anyone tell without examining them?) — DECORATOR. (What is the cement for? If you consult the indices, you will no doubt find references to one or more preparations, which may suit your purpose.)—CLIMAX. (You do not say what you wish to electro-plate; so the short answer must be Yes, and for further information consult the back volumes.)—OCTO. (Not that we know of. Red noses are natural enough in cold weather.)—R. S. P. (If you have used potash, no wonder that you cannot get it to set hard. See No. 1004, p. 355, or apply to the Greenbank Alkali Co., St. Helen's, Lancashire, for one of their circulars, in which they describe a process of soap-making without boiling.)—CONWAY. (How can anyone say without more particulars? Perhaps the insulation is not good; perhaps you do not turn fast enough; perhaps the machine is not so large as you require.)—TUNING KEY. (Tuning a piano has been frequently described. Nothing special about it, for it is purely a series of mechanical operations performed by a man who possesses an ear that can distinguish beats, and say at once whether any interval is rough or smooth. See No. 830, p. 571, and the indices of back volumes.)—ELECTRA. (How to make a phonograph was given in No. 683. See also the indices of back volumes, and if you will kindly look in any number you will see the rules relating to advertising for addresses, "Hints," &c., No. 4 above.) — AN ANGLO-ITALIAN. (Ville's "Artificial Manures," which we reviewed in No. 746, is published by Longmans, price 21s. It is of more use to the agriculturist than to the manure maker. We are afraid there is no satisfactory method of dealing with the matter referred to, if transport is prevented; but from a sanitary point of view the dry earth system would answer.)—W. H. J. (If you refer to the query, you wil see that it is for a pocket-coil. It would do for electric lighting if you have enough cells. See indices and recent back numbers.)—MUSICAL. (There is no charge for "copyright." That applies by law to any original work; but for the sake of having indubitable evidence of ownership, it is usual to register at Stationers' Hall, the charge for which is five shillings. A copy of the work to be registered must be presented at the time. In the case of a "play," a copy of the bill announcing its performance.)—J. E. W. (What has "auricular confession" to do with "ventriloism"?)—F. G. (Answered many times. A simple way is to make the iron red-hot and rub over with yellow prussiate of potash; but that only casehardens skin deep. The best method is to place the articles in an iron box and surround them with leather cuttings, filling up with sifted animal charcoal or bone-black. Lute on the lid and raise to a red heat in a furnace. Keep in that state for two hours at least, and then empty the contents of the box into water. 2. A pale gold lacquer is made by dissolving 10oz. of bruised seed ac and ½oz. of red sanders in a gallon of methylated alcohol. Strain. The brass must be thoroughly cleaned by dipping in acid and polishing, and then after being made quite warm, the lacquer is put on with a camel-hair brush, taking care not to go over the same part twice.)—O. G. A. (Gasoline is the best if you can procure it. Several apparatus of the kind are advertised; but if you look in the indices of recent back volumes you will see much about the subject. Try the "gas-maker lamp," sold by Mr. Wood, Blindley Heath, and Fletcher's gasoline furnace.)—C. KEMP. (Write on cream-laid paper with the ink made as described, and when dry place face down on the jelly, passing the hand lightly over the back of the paper. After a minute or so remove carefully, and a large proportion of the ink will be found to have been transferred to the surface of the jelly. Place a piece of dry paper on it, pass the hand lightly over, and remove, when a copy of the writing should be found transferred to the paper. When a sufficient number of copies have been taken, remove the remainder of the ink with water and a sponge. When the jelly is worn so as to be uneven, or is too much charged with ink, remelt and add fresh ingredients, pouring out into shallow trays, and removing bubbles by drawing a piece of card or stiff paper over the surface.)—TELEGRAPH POLE. (No; but such poles are always stayed.)—S. H. J. (See the indices of recent back volumes, wherein you will find references to descriptions of dynamos of somewhat similar dimensions.) — NICK. (Methods of nickel plating have been frequently described; but a full account of the art will be found in Nos. 993, 994, and 995. It can be done with a battery, but it is better to use a dynamo. Cost of battery apparatus, &c., can be obtained from Elmore and Co., Charlotte-street, Blackfriars, London, S.E.)—ELECTRIC. (With a saw, or with a piece of hoop-iron, some sharp sand, and water.)—B. R. (The question is, can you raise a *ton* weight in the manner described on p. 195? That is what requires demonstrating.)—J. M. (Flints are now considered to be, as a rule, the silicified bodies of sponges, sea-urchins mollusca, &c., which caused the silica to deposit around them; but occasional amorphous concretions may have failed to entomb the at one time living organism which caused the deposition of the silica.)—J. D. M. (Apparently a specimen of double dovetailing—a joiner's puzzle, in fact. Most people would prefer to see the model before guessing "how it's done"; but if you can take it apart you will perhaps find that the part between the dovetails or tenons is wedge-shaped in section, and has a much thinner edge on the inside than it shows outside. An article in No. 513, and some diagrams in No. 520, may help you. See also pp. 17, 125, 175, Vol. XXI. No drawing such as that you send can give any clue.)—TUBUS. (No remedy. Rubber tube should be kept under water if it is desired to preserve it.)—MAGNETO. (Draw a magnet over the pieces, or encircle them with a coil of wire through which a current is passing. The process is described in all the textbooks, and many

times in back numbers.)—CHING. (Is it necessary to ask such a question? To delicate people a cold bath might be an injury, but not to the healthy.)—F. W. G. (Good pieces are in demand for cutting prisms; it is also used for preparing the compounds of fluorine and as a flux in metallurgical operations.)—CONTRIVER. (Carpmael's "Patent Laws of the World," Clowes and Son; Johnson's "Patentee's Manual," Longmans. You will find all the information you can want in those.)—O. K. (Yes, no doubt.)—C. A. W. (The construction seems right. What battery did you use?)—T. D. COOK. (A full description of how to make a medical coil appeared on p. 52 of this volume.)—TOURIST. (The Canary Islands are so well known, especially Teneriffe, that you will find abundance of information in the cyclopædias and gazetteers. The subject is scarcely of sufficient interest to our readers.)—J. F. C. (What do you mean? They are moulded up in the usual way on the potter's wheel from clay, which remains porous when burnt. 2. Iron can be used, but will not last so long.)—NEMO. (Perhaps it has not been sufficiently purified. It is in crystal until ground to powder, and in that state is slightly affected by damp. For tests for adulterants see "Argol" in Slater's "Manual of Dye Wares," or Allen's "Commercial Organic Analysis," Vol. I. There is no rough and ready test.)—B. M. AND J. S. B. (There are several almanacs of the kind; but we presume you mean that devised by the late Rev. J. Pearson, which appeared in No. 933.)—TINPOT. (See the Ferguslie balling machine, exhibited at the "Inventions" by Mr. Brooks, of West Gorton, Manchester. In Brunel's original balling machine the ball is made on a rotating spindle, the thread being laid on by a rapidly revolving flyer, the axis of which is oblique with that of the spindle.)—S. (A sketch of the place would be necessary to give a definite answer. What you suggest might be done; but valves would have to be fitted to divert the current of hot gases—otherwise they would take the most direct course.)—EBONITE MAKER. (Indiarubber means pure rubber as sold in commerce. Sulphur means brimstone sold in rolls. Try 3 to 5 per cent. of sulphur. Plaster of Paris makes good moulds. Read the articles on the "Indiarubber and Guttapercha Industries," in Vols. XXXI. and XXXII., or procure the book from the Society of Arts, John-street, Adelphi. There are articles on the subject in most of the cyclopædias, and much special information in our back volumes.)—SPARK COIL. (You will find full directions in many back numbers; but why not look at a coil and make a copy of the contact breaker?)—A. B. (Writing done with a weak solution of sulphuric acid and a quill pen becomes visible when heated; but the best ink of the kind is the solution of chloride of cobalt, which becomes visible when heated and vanishes as it cools.)—J. B. (Set it spinning, and keep it spinning in various positions between the poles of an excited electro-magnet, or between the field magnets of a dynamo. See No. 762. 2. Certainly it would do, and any available motor could be used. The machine is not designed for the purpose; but as it generates current you can use that current for any purpose. Hand-power could not be depended upon.)—AQUA. (Sketches and descriptions of so-called self-acting fountains in Nos. 459, 582, 801, 967, 973, 974.)—YOUNG MU. (Rules have been given over and over again in back numbers, with many tables as well. There is a "universal" table in No. 1115. See p. 543, No. 1092, and the indices.)—PLOFED. (The camphor would dissolve in the wine, but not the sulphur. There must be some error, or perhaps it is meant that it is present in the form of a sulphide. An excellent wash is made of 8 fluid ounces of Eau de Cologne, 1 fluid ounce of tincture of cantharides, and half a drachm each of oil of rosemary and lavender.)—A SOCIALIST. (We have closed the discussion, and cannot reopen it.)—GULLIVER (We could not possibly spare the space the delineation of the gradients would take, and we must limit the room occupied by railway details, many of which are of interest to very few readers indeed.)—X. Y. Z. (In type.)

To Tell the Age of Eggs.—We recommend the following process (which has been known for some time, but has been forgotten) for finding out the age of eggs and distinguishing those that are fresh from those that are not. This method is based upon the decrease in the density of eggs as they grow old. Dissolve two ounces of kitchen salt in a pint of water. When a fresh laid egg is placed in this solution it will descend to the bottom of the vessel, while one that has been laid on the day previous will not quite reach the bottom. If the egg be three days old it will swim in the liquid, and if it is more than three days old it will float on the surface, and project above the latter more and more in proportion as it is older.—*La Nature.*

Detecting Barytes in White Lead.—The most common adulterant of white lead is permanent white, or sulphate of baryta. This admixture may be recognised by boiling a small quantity of the pigment in a glass test tube or flask, with nitric acid diluted with an equal measure of water. The white lead dissolves, but any sulphate of baryta remains as a white residue. To prevent any chance of error, the residue should be allowed to settle, the clear liquid poured off, the deposit again treated with nitric acid, and then boiled with water.

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a PINK Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

6s. 6d. for Six Months and 11s. for Twelve Months, Post Free to any part of the United Kingdom. For the United States, 13s., or 3 dol. 25c. gold; to France or Belgium, 13s., or 16f. 50c.; to India (via Brindisi), 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office Order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 4d. each to cover extra postage.

Messrs. JAMES W. QUEEN and CO., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes, they must be paid for at the rate of 4d. each copy, to cover extra postage.

Vols. IV., VII., XXVI., XXVIII., XXX., XXXII., XXXIII. XXXIV., XXXV., XXXVI., XXXVII., XXXVIII., XXXIX., XL., XLI., XLII., and XLIII., bound in cloth, 7s. each. Post free, 7s. 9d.

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in February and August, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d. each, through any bookseller or newsagent, or 2½d. each, post free from the office (except index numbers, which are 3d. each, or post free, 3½d.).

Indexes for Vols. I., VI., VII., VIII., and IX., 2d. each. Post free 2½d. each. Indexes to Vol. XL., and to subsequent vols., 3d. each, or post free, 3½d. Cases for binding, 1s. 6d. each.

CHARGES FOR ADVERTISING.

	s.	d.
Thirty Words	2	6
Every additional eight words	0	6

Front Page Advertisements Five Shillings for the first 40 words, afterwards 9d. per line. Paragraph advertisements One Shilling per line. No front page or paragraph advertisement inserted for less than Five Shillings. Reduced terms for series of more than 6 insertions may be ascertained on application to the Publisher.

ADVERTISEMENTS in EXCHANGE COLUMN—for

	s.	d.
Twenty-four words	0	3
For every succeeding Eight Words	0	3

ADVERTISEMENTS in the SIXPENNY SALE COLUMN.

	s.	d.
Sixteen words	0	6
For every succeeding Eight words	0	6

*** It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions and in cases where the amount sent exceeds One Shilling, the Publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement, and charged for.

Advertisements *must* reach the office by 1 p.m. on Wednesday, to insure insertion in the following Friday's number.

OUR EXCHANGE COLUMN.

The charge for Exchange Notices is 3d. for the first 24 words, and 3d. for every succeeding 8 words.

Good Value Offered (cash or instruments) for all kinds of sound or repairable Scientific Appliances.—CAPLATZI, Science Depot, Chenies-street, near British Museum. Established 1862.

Wanted, **Photo Apparatus**, wet or dry, cameras, sundries, &c., in exchange for Microscopic or Magic Lantern Slides.—Apply, PIGGOTT, Chemist, Huddersfield.

Wanted, **Launch Boiler**, Engine, Propeller, &c., for 16 by 5ft. boat. Can offer lot new Hammers, Axes, Planes, Ironmongery, Cutlery, &c.—HARRISON, Devoran, Cornwall.

Gas-Engine (Bisschop), 1 man power, cost £25; Water Engine, 1 horse, by Ramsbottom, working order; 2,000c.p. Arc Lamp. Offers.—W. HUTCHINSON, Liversedge.

Dynamos, four, two by British Electric Light Coy.; 3 Serrin Arc Lamps, switch boards, brushes, carbon, speed indicator, coil, &c. Offers.—W. HUTCHINSON, Liversedge.

Wanted a 4½in. or 4in. Iron **Lathe**, or pair 4½in. Lathe Heads, cheap, in good condition, in part exchange and part cash.—A. TURNER, Roydon, Ware, Herts.

Photographic Rolling Press, size of steel plate 18in. by 12in.; exchange for back-geared lathe, 5in. centres, iron bed with slide-rest.—C. H. HATCH, Photographer, Alderley Edge.

Iron **Foot-Lathe**, 4in. centre, 3ft. 6in. bed, 3-speed flywheel, crank and treadle, compound slide-rest (nearly new), hand rest, and 3 Tees, 3 face plates, 3 chucks, carriers and tools, fret-saw attachment, saws, &c., all as good as new. Offers.—EDWARD FRANCIS, St. Austell.

One dozen pure nickel silver **Teaspoons**. Will exchange for anything to value of 3s. 6d.; sample, 4½d.—GILBERT, Oxford-road, Sheffield.

Wanted, a 2 H.P. **Steam Engine**, complete and in good condition. Will exchange cash and a ¾ H.P. Engine, valued at £7.—Particulars to S. H. HIGGS, 20, Castle-street, Reading.

Organ Bellows, for 6 or 8 stop organ; Organ Accordion (Busson's) on stand. Exchange, offers; fretsaw wanted.—B. MARTIN, Overton-road, New Humberston, Leicester.

52in. **Bicycle**, in good condition, with lamp, bell, spanner, &c., strong, and suitable for a beginner. Can be seen by appointment. Wanted good air-gun, and part cash. For value see Sale Col. advt.—C.E. K., Lady Cross, Gayton-road, Harrow.

Lancaster's **Lens**, worth £1. Will exchange for electro-motor to drive sewing machine.—LAING, Bridge of Earn, N.B.

Vertical **Slide-Valve Engine**, brass cylinder, 2in. diameter, 3½in. stroke, cylinder tight and perfect, worth 50s.; offers. Wanted dynamo, lantern slides, &c. Photo two stamps.—DUCKWORTH, 10, Cedar-road, Leicester.

Saddle Boiler and Piping, &c., new, 34s., or exchange lathe.—J. LAND, Miller's-green, Wirksworth, Derby.

Coil, on polished mahogany stand, dovetailed, ebony ends to coil, with condenser, 100 sheets, quite new; exchange for microscope or anything in the mechanical line.—H. J. LONEY, Post Office, Gosport.

Wanted, a strong 5in. **Poppet Headstock** in good condition. Offers.—WALKER, JUN., Balance-street West, Uttoxeter.

Wanted, small Screw-cutting **Lathe**, in exchange for two good bicycles, 53in. and 55in., this season. What offers?—PETER GOUGH, Wellington-street, Bilston.

Vertical **Slide-Valve Engine and Boiler**, 1in. bore, 2in. stroke, with water gauge and fittings complete. Will exchange for organette and music. — E. BAILEY, 2, Bainsbech-terrace, Northwich, Worcester.

For exchange, Stanley-Gibbens **Stamp Album**, in good condition, containing 420 stamps, for Newman's "Butterflies and Moths," or entomological apparatus.—S. HOPKINS, Elmwood Villa, Poole.

Dynamo Castings for six 5 candle-power lamps, partly finished. What offers?—HAMES, 5, Oriel-terrace, Oriel-road, Homerton, E.

Offers wanted for first 22 parts of "**Dante's Inferno**," by Cassell, excellent condition.—W. ARMSTRONG, 30, Queenshead-lane, Handsworth, Birmingham.

Conservatory Stove, terra-cotta, Doulton's make, nearly new, and stove-pipe, cost £5 10s. What offers?—C. J., 17, Elam-street, Camberwell.

12 **Magic Lantern Slides**, in mahogany frames, 12in. by 3in. Wanted graphoscope lens, or reading glass, about 5in. diam.—J. BRYAN, Photo, Bridlington, Yorks.

Wanted, **Magic Lantern and Slides**. Exchange horizontal trunk steam engine, medical coil and battery.—W. FREEMAN, 4, Powlett-street, Throston, Hartlepool.

Gunmetal hand **Numbering Machine**, 1⅝lb. Covered Wire (been used on coil), and Crest Album, for large lens.—JOHNSON, 64, Wellingborough-road, Northampton.

Wanted, 4in. **Expansion Joint Hot Water Pipes** in exchange for "Thompson's Gardener's Assistant," in good condition.—D., 8, Marston-place, Cottle's Oak, Frome.

Horizontal **Steam Engine**, 6in. stroke, 3in. bore, 24in. flywheel, new. Exchange for a small lathe, complete, to the value of £3.—Stamped addressed envelope to P. PITMAN, Mellor, Marple, near Stockport.

Chest of **Mechanic's Tools**; book, "Every Man His Own Mechanic," Spon's "Mechanic's Own Book," Engine-making, finished Parts of Engines, Musical Box, Exchange.—Above.

Splendid **Magic Lantern**, with 60 slides, all complete, in fine mahogany case. What offers?—J. GREIG, Rock-road Cottage, Killarney.

Dynamo (small), lights four 5 c.p. lamps, laminated armature, mahogany base, in good order. What offers?—H. BOARDMAN, 26, Mill-street, Luton.

Wanted, a round **Brass or Copper Tube**, about 18in. long, 7 to 9 diameter. Offers. Must be true inside. Exchange.—T. TIPPING, Painswick, Gloucestershire.

48in. **Bicycle**, nearly all bright, condition as new, pair 5½in. Lathe Heads. Ornamental Slide-rest, with tools. Exchange Safety Bicycle.—F. POYNTER, Eton College.

Large cylinder **Electrical Machine**, Leyden jars, mahogany stand, and 48in. Bicycle, Roller Bearings, Lamps, &c. Exchange for Lathe or Telescope.—WALKINGTON, Stoneyrock-road, Leeds.

Wanted, Hopkins's and Rimbault's work on the **Organ**. Offers. Also to exchange Quarter-plate Camera.—BURTON, Ringwood.

Bicycle, 52in., good, no rubbish; exchange for lathe or Engine, or useful Tools.—GLOVER, 12, High-street, Derby.

4-stop **Organ Soundboard**, new, professionally made; 12 extra channels for octave coupler. What offers? Lathe wanted.—J. BELL, 58, Gladstone-street, Monkwearmouth, Sunderland.

8in. Magnet, 3in. **Electric Bell**, best make, battery and case, and bottle Bichromate, good as new. Violin or Lantern wanted.—NEWMAN, Boarded-lane, Reading.

Vertical **Boiler**, 2ft. high, new water gauges, safety-valve, small steam gauge, ⅞ pump. Offers. Sketch, 2 stamps.—Letters, W. SMITH, Bilston-road, Wolverhampton.

Wanted, half-plate **Symmetrical Lens**. Will exchange Electrical Apparatus Motor, Coil, Batteries.—W. RICHARDSON, Day and Son, Westtown, Dewsbury.

Cylinder **Electrical Machine** and accessories, in box fitted. Cash, or good 14 keyed A Clarionet, Albert Model Patent C Sharp.—Particulars, TEAGUE, Ashcott, Bridgwater.

Scientific Books.—What offers? "Steam Engine" (Goodeve), pub. 6s.; "Electricity" (Jenkin), pub. 3s. 6d.; "Popular Lectures on Science" (Helmholtz), pub. 12s. 6d.

Books.—"Electricity" (Fergusson), published 4s. 6d.; "Electricity" (Deschanel), pub. 4s. 6d.; "Electricity" (Pepper), pub. 2s. 6d.; "Electricity" (Tyndall), pub. 2s. 6d.; "Acoustics, Light, and Heat" (Lees), pub. 2s. 6d.

Books.—"Advancement of Learning" (Bacon), published 4s. 6d.; Dr. Scheiegel's "Philosophy of Life," pub. 3s. 6d.; Works of Shakespeare (Globe Edition), 3s. 6d.; "Faraday as a Discoverer" (Tyndall), 3s. 6d.

Books.—"Theoretical Mechanics" (Twisden), published 4s. 6d.; "Practical Mechanics" (Twisden), pub. 10s. 6d.; "Applied Mechanics" (Rankin), pub. 12s. 6d.; "Mechanics for Beginners" (Todhunter), 4s. 6d.; "Mechanics" (Wormwell), pub. 3s. 6d.

Books.—"Geometrical Drawing" (Binns), published 5s.; "Solid and Descriptive Geometry" (Edgar and Pritchard), pub. 3s. 6d.; "Solid Geometry and Conic Sections" (Wilson), pub. 3s. 6d.

Books.—"Elementary Geometry" (Wilson), published 3s. 6d.; "Conic Sections" (Drew), pub. 6s.; "Practical and Solid Geometry" (Payne), pub. 2s. 6d. What offers for part or whole of the above books, in good condition.—MR. ANDREWS, 35, St. Martin's-street, London, W.C.

"**English Mechanic**," Vols. VIII. to XX., unbound, XVIII. to XXVI., bound, all clean and perfect. What offers?—MCCULLOCH, 10A, North-street, David-street, Edinburgh.

Fifty Photo. **Lantern Slide Views**, mostly Scotch. What offers? want ¼-plate camera.—Address, FINLAY, 182, Trongate, Glasgow.

THE SIXPENNY SALE COLUMN.

Advertisements are inserted in this column at the rate of 6d. for the first 16 words, and 6d. for every succeeding 8 words.

Economic Cookery.—Patent Heat Conductors for roasting, 2s. 6d., baking, 2s. 3d.; boiling, 2s. per pair, carriage paid. See ENGLISH MECHANIC, Oct. 15, 1886, page 147.

The Patent Heat Conductors save a family pounds a year.—Agent, TALLACK, 28, Hatton-garden, London.

New Illustrated Price List of **Screws, Bolts, and Nuts** for Model Work, drawn to actual size, sent on receipt of stamp.—MORRIS COHEN, 132, Kirkgate, Leeds.

Fretwork.—Catalogue of every requisite, with 600 illustrations, free for 6 stamps.—HARGER BROS., Settle, Yorks.

Wimshurst Influence Machine.—Sole manufacturers of new and improved pattern. 12in. from 30s.—KING MENDHAM, and Co., Bristol.

Deposition of Smoke.—Complete Apparatus to perform this never failing experiment, with static electricity, 5s. 6d. and 10s. 6d.—As above.

Standard Ohm, in boxwood cylinder, guaranteed correct to ten thousandth of ohm, 18s. 6d., with copper poles, 21s.—As above.

Galvanometer Cards for tangent and ordinary combined, vertical, astatic, reflecting, and unmounted compass cards.—As above.

Variable Resistance Incandescent Lamp Stand, invaluable for battery power, vide ENGLISH MECHANIC, Oct. 16, 1885, price 3s. 6d.—As above.

Write for **King, Mendham, and Co.'s** large new and reduced Price List, post free, 4 stamps.

"**Beginner's Guide to Photography**," one shilling. Wholesale of the publishers, LEJEUNE and PERKEN Hatton-garden, London.

"**Beginner's Guide to Photography**," one shilling. Free from abstruse technicalities. Retail of Opticians and Booksellers.

Electric Depot, 10, Deansgate, Manchester. Handiest shop in the trade. Largest stock. Greatest variety. Lowest prices.

Catapults, 7d., 1s., 1s. 2d. Square Elastic, 2d., 3d. 4d. yard. Round, 6d., 9d.—MOODY BELL, Cheltenham.

Leclanche Batteries, 14s., 16s., 24s. per dozen. Sample, 1s. 9d., free.—SEDDON, 5, Queen's-road, Chadderton, Oldham.

Wheel-Cutting to 12 inches diameter in brass only.—CLEGG, 18, Belinda-street, Hunslet, Leeds.

Planing to 12in. by 12in. by 8in. Boring, Turning, Screw-cutting, Slide-rests, &c.—CLEGG, as above.

Aerated Water Machinery.—Repairs, Renewal, Additions, &c., skilfully executed.—N. St. G. WILCOCKS, 45, Avon-street, Bath.

Soda Water Machine, bargain. Engraving free post.—NATHANIEL SAINT GEORGE WILCOCKS, Bath.

Carbon Plates, best quality, cut and moulded, plain and capped; quality cannot be surpassed.—GEO. G. BLACKWELL.

Pebble Carbon.—Graphite for Leclanche cells, splendid conductor; price very low.—GEO. G. BLACKWELL.

Manganese Oxide specially prepared for Leclanché batteries; high strength and purity, greater E.M.F., constant action; been in use 15 years with immense satisfaction; 7, 14, and 28lb. packets. Prices on application.—GEO. G. BLACKWELL, 26, Chapel-street, Liverpool.

Mica or Talc cut for all purposes by C. JOHNSON, 7, New Oxford-street, W.C. Mica chimney covers, &c.

Grease Making without rosin oil.—Sample and particulars from J. M., 6, Hamlet-street, Bootle, Liverpool.

Mica or Talc.—RICHARD BAKER and Co., 9, Mincing-lane, London.

Lathes for every trade and every fancy. We make upwards of 250 varieties.—BRITANNIA CO.

Catalogue of Lathes and Parts, finished or rough, also of other Tools, six stamps.—BRITANNIA CO.

List of Second-hand Lathes and Fret Saws, one stamp.—BRITANNIA CO., Colchester.

London Showrooms.—Britannia Co., 99, Fenchurch-street. All correspondence Britannia Works, Colchester.

Lathes, Files, Steel, Saws. Cheap, good. List, 2 stamps. Cash or hire.—ROBINSON, Catherine-street, Sheffield.

Printing Presses from 10s., complete with type. Instructions for amateur printers, 1d.—ADAMS BROS., Daventry.

Turning Woods for Amateurs.—Box, Cocus, Lignum Vitæ, Snake, from 3d. per lb.—HARGER BROS., Settle.

Skates (Acme), highly recommended, good value, steel plates, 4s. 3d. pair, free.—HARGER BROS., Settle.

Organ Metal **Pipes**, workmanship and material guaranteed; lowest prices.—SHIELD, Little Green-lane, Small Heath, Birmingham.

Wood Planing.—Hand power 120, steam-power 1,200ft. per minute. Illustrated circulars free.—G. HAZELAND, Par, Cornwall.

"**The Wilcocks Eclipse**" turnover bottler for patent stopper bottles.—Maker, N. ST. G. WILCOCKS, Bath.

"**The Wilcocks Power Cork Bottler**" for soda water, lemonade, &c.—N. ST. G. WILCOCKS, Bath.

Lathe Castings, &c.—See T. Taylor's advertisement in ENGLISH MECHANIC every other week. Established 1847.

6s. 6d. Complete.—Electric Bell, Battery, Push, Wire, Staples, and instructions for fittings.—WHITAKER, Electrician, Blackfriars, Salford.

"**The Electric Light and How Produced.**"—A pamphlet of illustrated instructions for making dynamos sent post free postal order One Shilling.—ALFRED CROFTS, Dover.

Carving Tools.—Set of 22, warranted, handled, well assorted, by post, 11s. 6d. See illustrated catalogue.—LUNT'S.

Saws, Disston's American, agent for same. Planes, new, London, malleable iron and gunmetal, every description.—LUNT'S.

Vices, bench, parallel steel jaws, to open 3½, 9s. 6d.; ditto 4, 15s.; ditto 4¾, 21s.—LUNT'S.

Tools, every description. See illustrated catalogue. 90 pages. Send 4 stamps.—A. S. LUNT, 297, Hackney-road, E.

Corundum for Aluminium or other purposes.—RICHARD BAKER and Co., Mica Brokers, 9, Mincing-lane, London.

Brass Castings of Model Engines of all classes, in sets or otherwise. These castings are the best in the trade, and have obtained the highest testimonials from amateurs and others in all parts of the United Kingdom for cleanliness of moulding, ease in finishing, and correctness of detail and design; being models of engines of modern construction. Boilers supplied of every type to suit the above from stock or to order. Fittings of all kinds, feed pumps, governors, safety valves, steam gauges, water gauges, &c. Comprehensive price list, post free, two stamps.—LUCAS and DAVIES, 21, Charles-street, Hatton-garden, London.

Corundum Wheels.—RICHARD BAKER and Co., Mica Brokers, 9, Mincing-lane, London.

Electrical Stock.—Clearing surplus under cost. Medical Coils, plated, with slide, 15s. Invalid Bell Sets, 8s. 6d.

Terminals, 20 per cent. off list. Wire, Electro-Motors, Batteries. Write for list.—759, Old Kent-road, S.E.

Two built **Wooden Booms**, about 60 feet lengths, by about 30in. diameter, with 16 and 18 strong iron hoops, also rings on each. Used for ballasting light ships during removal.—42 Box, Post Office, Newcastle-on-Tyne.

An **Overhead Traveller**, with winch attached, to lift 2 tons.—42 Box, Post Office, Newcastle-on-Tyne.

A heavy **Circular Saw Bench**, in good condition, with about 15 5½in. metal rollers, in strong metal standards.—42 Box, Post Office, Newcastle-on-Tyne.

Electric Bell Sets, comprising bell, battery, push, and 25 yards of wire, 7s. 6d. Catalogues of apparatus free on application to HUNTER and Co., 56, Wincheap, Canterbury.

Boilers, Vertical, Portable, and Cornish, one horse-power upwards.—GRANTHAM CRANK and IRON COMPANY (Limited), Grantham.

Strong 3½in. **Lathe Head Castings**, powerful back-gear, 32lb., 5s. 6d. Bearings conical or plain.

Taps, Dies, Reamers, Screws made to order. Reply stamp.—JARRATT, 15, Short-street, Queen-street, Leicester.

Lead Electric Accumulators made up and burned. Any class of chemical work done. Soldering superseded.—HOWELL and BRIGGS, Practical Plumbers, 58, Rokeby-street, Stratford.

Marlborough **Tricycle**, quite new, to be drawn for, tickets 1s.—SMITH, 40, Calverley-road, Tunbridge Wells.

Self-feeding and Hand-feeding **Drilling Machines** for fine work. Write for list.—F. GREENAWAY, Maker, Slough, Bucks.

First-class **Lathe** (equal to new), with compound geometric, eccentric, and spherical chucks.—GEO. PLANT, Alsager, Cheshire.

Selection of interesting **Microscopic Slides** for Sale, from 6s. doz.—S. HARRISON, Dalmain-road, Forest Hill.

Powerful **Hydraulic Press**, to 500 tons, steel cylinder, 18in. ram, to be Sold, a sacrifice.—CAM.

Splendid **Launch Engine**, two 3in. single-acting cylinders, £25.—CAM and SON, Excelsior Works, Worcester.

Notice.—The following **Instruments**, by Troughton, and Sims are for Sale at CLARKSON'S, Astronomical Telescope Maker, Bartlett's-buildings, Holborn:—4in., 5in. Y Theodolites; 5in., 6in. Transits; 10in., 14in. Dumpy Levels; Miner's Theodolite, Pentagraph, Pillar Sextant, Pocket Sextant, 20in. Transit, 3¼ Astro. Telescope, well mounted, and 2¾ Astro. Telescope, Dollond, equatorially mounted, cost £50; price of this, £20.

Painter's Stencil Patterns; 6 dado borders, 2s. 3d. 6in. Alphabet, 3s. 3d.—J. DEAN, 179, Princess-street, Manchester.

Gas-Engine, one H.P. Otto (Crossley's), in first-rate condition.—98, King's-road, Camden-road, N.W.

Wood Planing.—Hand-power 120, steam-power 1,200ft. per minute. Illustrated circulars free.—G. HAZELAND, Par, Cornwall.

Metallic **Violin Strings**, acknowledged success, six Firsts, post free, 1s.—JOHN ELARCO, 24, Fern-grove, Liverpool, S.

Soda Water Machine, gas-work, turn-over bottler, recipes, &c., for working, £20; particulars free.—WILCOCKS, Bath.

Bentley's Electrical Stores.—The cheapest house for bells, batteries, wires, and fittings.—7, Newton-street, Manchester.

Dynamo, 60-candles, improved armature, 40s. Photo., 5 stamps.—D. WALTON, King-street, Hebden Bridge, Yorks.

Dynamo, 30c.p., improved armature, 26s. Photo., 5 stamps.—D. WALTON, King-street, Hebden Bridge, Yorks.

Experimental Dynamo, improved armature, 14s. covered wires from 1s. 4d. per pound, castings, &c.—D. WALTON.

Piles.—Agonising cases cured first application.—T. Palmer's Indian Ointment, 13½d.—Chapel-terrace, West Auckland, Durham.

"**Palmer's Prescriptions, 2s.**," Positive Cure for Skin, Urethral Diseases, &c. State symptoms.—Chapel-terrace, West Auckland, Durham.

Lathe, 5in. centre, 3ft. 3in. bed, slide-rest, jaw and 4 other chucks and tools, £17.—S. SMITH.

Lathe, 4in., 4ft. gap bed, screw-cutting, change wheels and chucks, complete, £20.—S. SMITH, 11, West-street, Soho, W.C.

Model **Electro Motor Castings**, with base and wire, complete, free, 1s. 6d.—HAILEY, 19a, Villars-street, Liverpool.

Entirely New Discovery, **Tinolite Soldering Flux**, a crimson fluid, has no fumes and no after-rust.

Tinolite, a great boon to Jewellers, Metal Workers, &c. Ask those who have tried it.

Tinolite for easy soldering, tinning, &c., 1s.; double. 1s. 6d.—HERBERT JONES, Broadfield, Wallasey, Cheshire. Agents wanted.

Mesmerism.—Complete Written Instructions, sure and certain success, 1s. 6d.—W. THOMAS, 22, Clarendon-road, Anfield, Liverpool.

Circular Saw Table, suit 3in. to 6in. centre lathe, adjustable fence, loose piece full length of saw slot, takes saws to 9in. Particulars, stamp. Litho, 3d. Castings, 3s. 6d. Planed and fence fitted, 8s.—PATRICK.

Vertical Planer, utilises ordinary slide-rest on the lathe without alteration, suit 3in. to 6in. centre lathes, weighs 35lb. Photo, 6d. Castings, 10s.; planed, 22s.; finished, 50s. Reply, stamp.—PATRICK, Chelmsford.

"**Sheet metal Workers' Instructor**" (Warne's)—Few copies cheap, covers slightly soiled.—94, St. Augustine's-road, N.W.

48 plain photograph **Lantern Slides**, Windsor Castle and others, 3¼ square, 8s. Sample, 4d.—LIMBY, Kew, Surrey.

44 Java, 8s. Coloured Photographs, 8s. dozen. Sample, 8d. Coloured Tracings, 6s. dozen. Sample, 6d.—LIMBY, Kew, Surrey.

Brass **Model Engine Castings**, rough and finished, best quality. List, stamp.—WOOD, Dalley-street, Broughton, Manchester.

American Organ, full compass, new, perfect condition, fine tone, powerful swell, price only £5 10s.—J. HAYES, 32, Magdala-road, Upper Holloway, London, N.

"**English Mechanic**," for sale, 480 numbers, price £1.—W. HARDT, 165, Pentonville-road.

West London Electric Works.—Crampton Electric Bell, 3½in. nickel-plated, 7s. 6d. Indicators, Pushes, Burglar Alarms. Trade supplied. Lists, 1d.—4, Studland-street, Hammersmith, W.

Watt, Winnall, and Co., Electrical and Mechanical Engineers, Atlas Works, Bromley-street, Commercial-road, E. Electric Locomotives from 25s. each. All work done on the premises. Send for price list, 2 stamps.

Gelatines for tracing magic-lantern slides, 3¼ size 4½d. per dozen.—Address, PHOTO, 182, Trongate, Glasgow.

MICROSCOPICAL ADVANCES. — XV.

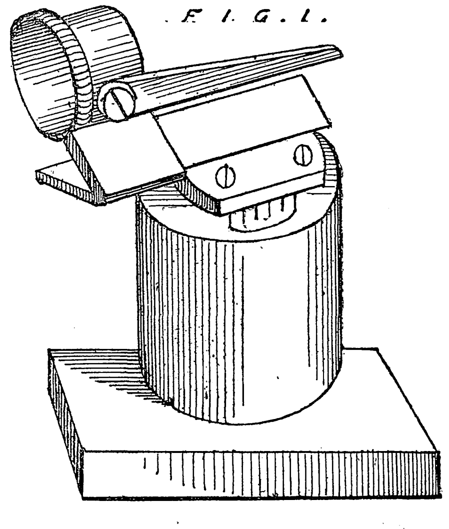
By DR. ROYSTON-PIGOTT, M.A. Cantab., F.R.S., F.R.A.S., Memb. Roy. Coll. Physicians, Fell. Cambridge Phil. Society; formerly Fellow of St. Peter's College, Cambridge.

On the Circular Solar Spectrum.

EXPERIMENT 1.—To proceed: A very fine 1-15th Ross, No. 20,315, mechanical action of screw-collar most admirable, marked *wet*, with large margin for correction. This glass is used to-day (Nov. 10, 1886) as a condenser; a mercurial bulb nearly 3-4th inch diameter is placed 18in. distant, opposite to a bright window. The exquisite miniature is most beautifully defined. Observed with a Seibert (1-16th) made to my order, the miniature is now magnified 1,000 times, and retains all its brilliance of detail; demonstrating the high quality of this very satisfactory Ross 1-15th.

Look at this picture and then on this. A travelling microscope, by Moginnie, enjoyed

FIG. 1.



a 1-4th objective. This very miniature, so exquisitely formed by the Ross 1-15th and displayed by the Seibert 1-16th, is ruined by it absolutely.

Substituting a white watchface, the whole thing is submerged in a sort of thick London fog; replace the Seibert 1-16th, everything is brilliant; the minute dots and the name James Pyott most perfectly distinct, yet the power with the Moginnie "quarter" was only 200! A eyepiece.

A plane silvered mirror spoils the definitions. An Amici prism nearly doubles the light by internal reflection. The details of its miniature prospect are most clear. As a rule the observing objective should only be about half the power of the condensing objective.

The prospect is now observed with a superlative 1-10th immersion. The steeple of All Saints', 400 yards distant, is sharp and clear.

I may now relate the following experience:—I had constantly found, in pursuing these researches, that either achromatism was sacrificed to aplanatism, or that the attainment of achromatism destroyed the brightness and truth of aplanatism.* The following incident is worthy of attention:—Whenever, in watching the heliostat, the sun was clouded over, the microscopic miniature-perspective of the room and distant apparatus reappeared; and, after various adjustments, I obtained a perfect definition free from the white mist of spherical aberration,

* Aplanatism means absence of spherical aberration.

FIG. 2

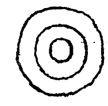


FIG. 3

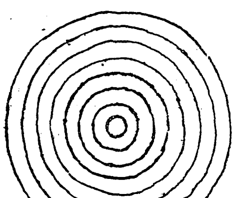

FIG. 4

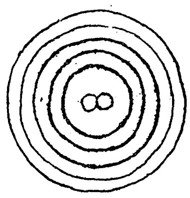

FIG. 5

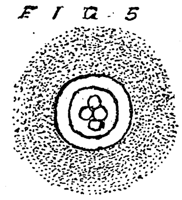

FIG. 6

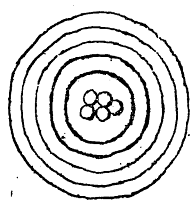
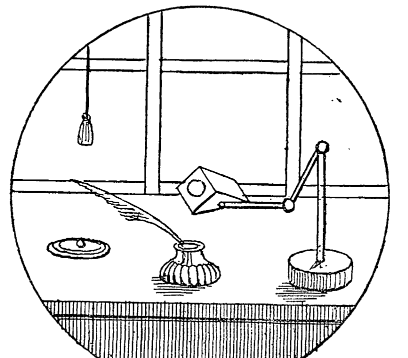


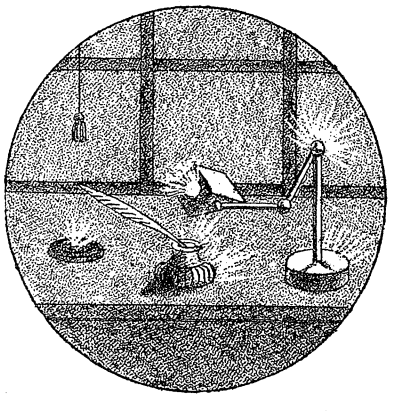
and as clear and sharp as the definition of a first-rate opera-glass. The prism and lens of the heliostat then gave a pretty picture of the passing clouds, as well as small details of

FIG. 7.



the distant objects*; but the instant the sun began to shine, before the rings dazzled the sight, every shining point appeared haloed with a corona of orange and red. I

FIG. 8.

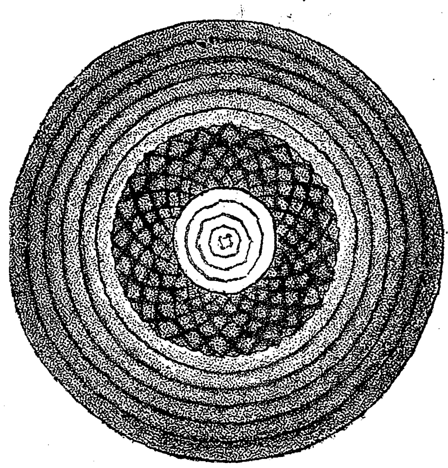


now turned aside the prism; then, every polished point in the full sunshine exhibited the same orange and red halo. Again, in the shade, the picture resumed its sharp definition. Waiting again for the sun, forth shone the orange haloes; the collar corrections were diligently plied till the halo nearly disappeared. The sun passed behind a cloud. To my astonishment, the former sharp clear prospect was now *bedimmed with a general white mist*, utterly obscuring all the details so beautifully clear before. The appearance of this white mist above the best focal plane now convinced me that the best modern English glasses, when rendered achromatic by screw-collar adjustment, beget a residuary spherical aberration, which obscures many delicate structures; and that until this important fact is acknowledged, an insuperable bar to the development of the finest definition will continue to exist.

* The window should be thrown open.

In these combinations regard was had to whether the pair of glasses were intended for the dry or immersion principle. The immersion system is valuable for the increased

FIG. 9.



volume of the cone of rays radiant from an illuminated particle mounted in balsam, a much larger pencil reaching the object viâ water than can possibly be effected viâ air; the critical angles of total internal reflection being so much larger in passing from glass into water than into air.

All these appearances were most gorgeous in brilliance on a fine day, when the sun blazed in a clear blue sky. The additional stand for carrying extra lenses or objectives is given at Fig. 1.

EXPLANATION OF FIGURES.

FIG. 2.—Primary rings finely defined at the first visible focal plane.

FIG. 3.—Secondary rings, at a deeper focus. The central disc should have been squared off.

FIGS. 4, 5, and 6.—Development of two discs instead of one; also of four irregular discs showing the existence of displaced centres and irregular diffractions.

FIGS. 7 and 8.—The miniature prospect of the distant window is displayed sharply in Fig. 8. So soon as the sun began to shine, the blazing prism being quenched by turning it aside, every brilliant point became irradiated with an orange-red halo (Fig. 9). If the colour were corrected by change of the general adjustments, so as to destroy halo, then the prospect in Fig. 8 became enveloped in a strong white mist of uncorrected residuary aberration.

FIG. 9.—In this case the heliostat was placed nearly 40ft. distant. The internal lenses of a fine $\frac{1}{4}$-objective being all removed, the thick front only was employed to form the miniature on the stage. A peculiar irregularity in the central jet-black rings is supplemented by extraordinary eccentric lines bordered by a new order of peripheral rings, obeying a different order of expansion. Viewed under Powell's best dry $\frac{1}{8}$th; a $\frac{1}{2}$in. single plano-convex lens being used as eyepiece.

In the next article I propose to describe my compensating eyepiece, given in *Proceedings* of the Royal Society, 1873.

SIMPLE EXERCISES IN TECHNICAL ANALYSIS.—XVII.

By an Analytical Chemist.

Boiled Oil.

(233.) THIS is ordinary linseed oil which has been boiled with a certain proportion of "driers." The object of boiling and of adding driers is to increase the drying properties of the oil. In this operation the specific gravity is increased more or less, according to the length of the boiling; and the colour is darkened. Generally speaking, the longer the boiling, the higher the specific gravity, the darker the colour, and the better the drying properties. This darkening of colour is one of the great drawbacks to the success of the process, and the adoption of steam heat, instead of that of a direct fire, has not only diminished the number of accidents, but has also enabled the manufacturer to produce a paler article for the same degree of boiling.

(234.) The tests are practically the same as for linseed oil.

The specific gravity, however, is liable to much variation, depending, of course, on the use for which the oil is intended. It may vary from ·933 to ·967. Oils of ·933 gravity are, as a rule, under-boiled, and are little (if at all) superior to unboiled oil. Some of them, however, dry very well, even with a small proportion (about ·2) of driers. Oils of ·967 gravity are called "burnt" oils, and are prepared specially for printing purposes. These do not contain driers always. Of "burnt" oils there are three varieties—"weak," "medium," and "strong." The gravities vary from ·939 in the "weak" to ·957, or more, in the "strong."

"Double-boiled" oils are also met with. The gravity usually varies from ·945 to ·957; but occasionally falls as low as ·939 and rises as high as ·962.

"Steam-boiled" oils usually range in gravity from ·938 to ·953.

The great bulk of boiled oils—at least 70 per cent.—lies between the gravities of ·939 and ·949; and for general purposes oils of these gravities will be found suitable. From ·940 to ·945 are perhaps the best limits.

(235.) *Drying properties.*—Spread on glass, as described in Art. 230 C, an ordinarily good oil should dry in from 16 to 24 hours.

(236.) *Driers.*—The estimation of the amount of driers in boiled oil is of some importance. Five grammes of the oil are weighed in a porcelain basin, and gently ignited over an Argand until all the carbonaceous matter is destroyed, and nothing but a pinkish-grey ash remains. This is then weighed, and multiplied by 20 for the percentage. An oil containing too little driers will probably dry very slowly, while one containing an excess will dry so rapidly that the paint in which it is used will have an undesirable tendency to crack. The quantity of driers may vary from mere traces to 1·4 per cent. Out of some 250 samples recently examined, only three exceeded the higher limit, these amounting to 1·5, 1·8, and 2·8 per cent. respectively. Only 20 per cent. of the samples examined contained more than 0·5 per cent. of driers, so that one-half per cent. may be regarded as the ordinary maximum limit. Of those falling below 0·5, fully 66 per cent. lay within the limits of 0·1 to 0·3.

The ash should be tested qualitatively for the presence of lead by adding a few drops of acetic acid and of a solution of chromate or bichromate of potash, to produce a yellow precipitate.

(237.) The presence of adulterants is more difficult of detection in boiled than in raw oils. The oil may have been adulterated before boiling, or of very poor quality. Due attention to the tests given above, and under the head of Linseed Oil, will, however, enable one to distinguish between the suitability or otherwise of any sample. The time required for drying to a hard surface is all-important, for unless a boiled oil dries rapidly it has no special value above an unboiled oil; and although it may be absolutely pure, still, as a boiled oil it must be regarded as a failure. If the specific gravity be low and the driers high, these are indications that the oils have been boiled insufficiently, and that an excess of driers has been added to improve the drying properties; and although the oil may dry rapidly, its commercial value must be less than that of an oil properly boiled. In drying, an oil must neither be too quick nor too slow.

(238). There is one fraud which is very commonly practised, very difficult of detection by chemical tests, and quite as objectionable as any other form of adulteration. I refer to the addition of raw linseed oil to boiled oils of high specific gravity. A mixture of the two is made to bring the gravity within the approved limits, and then sold as boiled oil. This mixture dries very slowly, and is in every way inferior to a genuine boiled oil. A little experience enables one to recognise it; the odour of raw linseed remains undisguised, and the percentage of driers usually falls below the average.

NOTE.—The position of the parenthesis—(" at 100° F.")—in the table of specific gravities given in No. 1130, p. 253, is incorrect. The words refer to cocoanut oil only, and therefore belong to the line immediately below. The other gravities are taken at 60° F., as stated in par. 217.

(*To be continued.*)

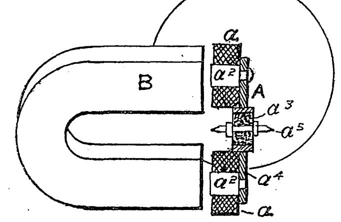
PROF. S. P. THOMPSON'S DYNAMO TELEPHONES.

A METHOD of making more powerful telephones than those of the well-known type has been recently patented by Prof. Silvanus P. Thompson, who describes his invention as consisting of dynamo telephones which will serve either as transmitting or receiving instruments of great power. It is well known that any dynamo-electric or magneto-electric machine will serve either as a generator of currents or as a motor. In such machines there are usually two distinct parts respectively called the field magnet and the armature; the relative motion of one or both of those organs generate currents, or if currents from an external source traverse the armature, mechanical motion results. And in such machines it is usual to make the field magnet a very powerful magnet (either permanent or temporary) having great magnetic inertia and the armature of small magnetic inertia and relatively light.

The improved telephones act on the same principle as that on which dynamo electric machines (including magneto-electric in that term) of any one of the known types act, but Prof. Thompson makes the armature, or some part thereof, capable of vibration instead of the usual rotation on an axle, these vibrations being communicated either from the armature to the listener's ear or from the speaker's mouth to the armature by suitable mechanism or mechanisms or simply by the intervening air. The form of the armature may be any of the well-known patterns—such as the Gramme ring, the Siemens drum, or other form—but he prefers in some cases to modify and simplify the manner of grouping or connecting the coils. The commutator common in dynamo-electric machines is not used. It is of advantage that the coils of the armature should be so grouped that they occupy the position where the magnetic field is strongest, so that any small motion given to them may have the greatest induction effect in transmitting or receiving, and so that any small current traversing the coils may produce the most powerful effect in receiving, the coils of the armature, which may be of fine well insulated copper wire, are connected in the line circuit. The coils on the field-magnets (if any) may be arranged either in a local circuit or in line or as shunt to the armature coils. It is advantageous to laminate the cores both of the armatures and of the field-magnets. When the armature is pivoted on or about an axis, a cushion or sleeve of elastic matter may be applied at the said parts or axis. When the armature or its core is mounted on a spring, the spring may be either straight or coiled, or instead of a spring or cushion, a mass of yielding material may be substituted. Internal magnets or electro-magnets may be placed within the armature to reinforce the magnetic field, thus enabling the self-induction and resistance of the armature coils to be reduced.

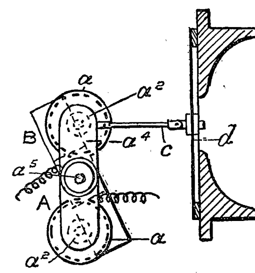
Figs. 1 and 2 of the accompanying drawings show in views at right angles to each other a dynamo telephone on the magneto principle, the armature A being mounted to vibrate (on the pivot a^5 mounted in any suitable supports) in front of the poles of a permanent magnet B. The are two coils a, on the iron cores a^2, carried by an iron yoke a^4, mounted on an elastic hub a^3, and suitably pivoted. A short and light stiff connecting-rod c makes the necessary communication between the armature and the

FIG. 1.

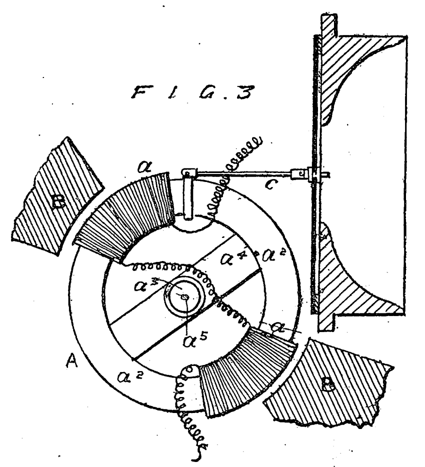


diaphragm d. It is found desirable in setting up the instrument to give to the armature a slight lead with respect to the field-magnets. This has double effect, it causes any small change in position to have a greater influence on the magnetic field, and it also gives a mechanico-magnetic back attraction which serves to keep the diaphragm in a state of initial tension. The diaphragm may be of mica, celluloid, parchment, aluminium, or any metal, whether magnetic or not, its functions being purely

FIG. 2.



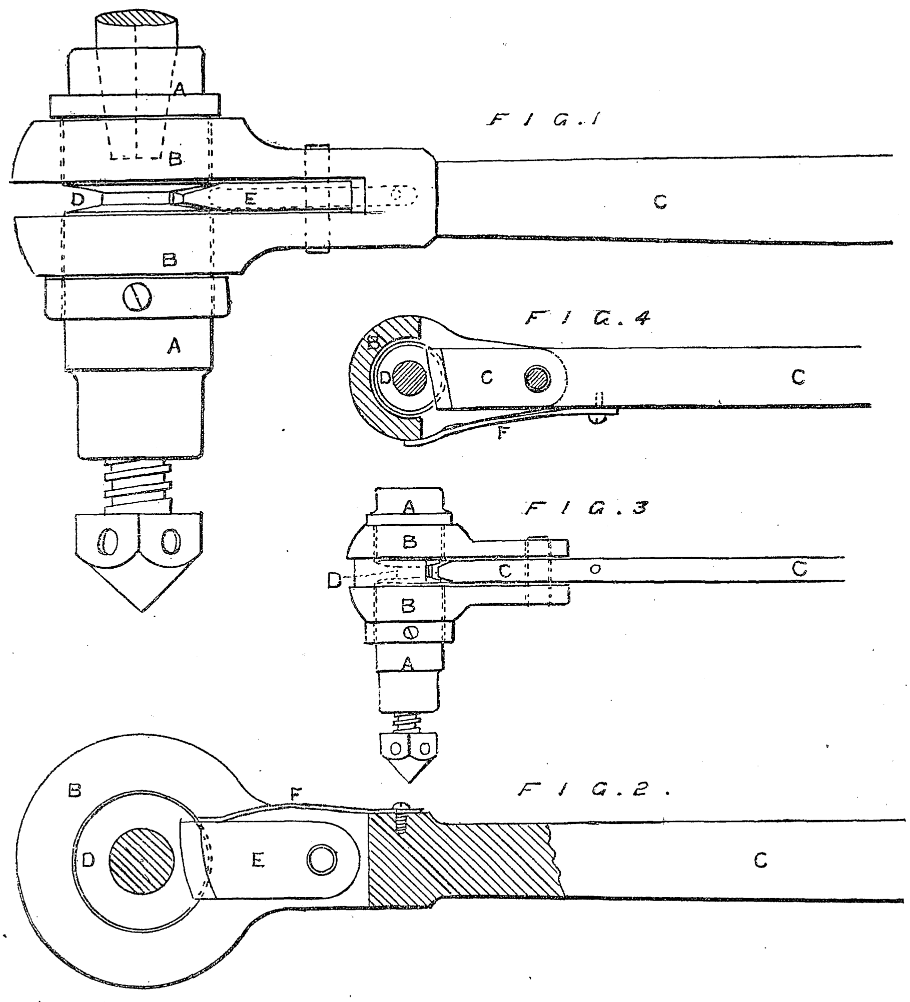
acoustic. Fig. 3 shows a ring armature, resembling that of the well-known Gramme dynamo, but having coils grouped in two sets only, connected in series (or parallel, if desired, for low resistance). The ring is pivoted as before described and connected to the diaphragm as shown, and corresponding parts to those shown in Figs. 1 and 2 are marked with the same letters of reference. The ring may be



made with protruding teeth, as in the Pacinotti dynamo. The patentee does not limit the invention to the precise details described in his specification, for they can be varied without departing from the nature of the invention; for example, the armature may be a soft iron piece without coils, mounted and connected as described in proximity to the poles of an electro-magnet.

IMPROVEMENTS IN HAND DRILLS OR TOOL CARRIERS.

THE annexed diagrams illustrate the improvements in hand drills or tool carriers recently patented by Mr. J. L. Shorrock, of Manchester-road, Accrington. The body of the



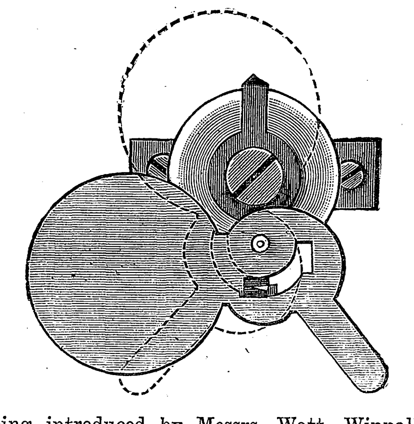
drill carrier A is turned down in the centre, to carry the box or bearing B of the handle, C, of the brace; in the central part are a groove or grooves D, which are turned slightly out of truth, or may be true, and in a recess or recesses formed in the box B are a corresponding number of pivoted tongues E, their ends clipping or gripping on the sides of the groove or grooves D. The pivots of the friction tongues in the box B being parallel to the tool holder A, when moving one way the tongues bite on the sides of the V or other shaped grooves D, and by reason of the grooves being out of true the tongues bite at different points each movement during one revolution, which thus renders them lasting and durable. A spring F is used to keep the tongues E in action, and retain them in their bearings. The tongue or tongues, instead of being pivoted, may form part of the handle or lever C (see Figs. 3 and 4.) The tongues and grooves may be either semicircular V, or any other suitable recessed form, the lever C being pivoted to the box or bearing B. The number of pivoted friction tongues may be increased as required. Fig. 1 represents the improved tool in plan; Fig. 2 is an elevation partly in section. Fig. 3 shows in plan a pattern in which the end of the handle forms the gripping tongue, and Fig. 4 is a sectional elevation of Fig. 3.

AN EXHIBITION OF REPOUSSE WORK.

ONE of the most attractive shops in "Old London Street," at the Inventions was that wherein Mr. Gawthorp and his assistants gave practical demonstrations of the art of hammering thin brass into artistic designs—known as Repoussé work. We gave Mr. Gawthorp's instructions in the last volume (pp. 182, 204), and announced that he intended to hold an exhibition of amateur work in the present month, under the patronage, amongst others, of the Marquis and Marchioness of Breadalbane. At 16, Long Acre, then, a very creditable display of amateur work can be witnessed by any one who likes to call up to the 23rd inst., a variety of objects being on view which will not unlikely set a good many amateurs at work in a rather neglected branch of art. There are altogether six classes, two being confined to set pieces. The first, Class A, is a head of "Ceres" on a panel, for which Mr. J. E. Lucas takes the silver medal, and Mr. H. Hodge, the bronze medal. In Class B, a panel with a design of "Laurel and Snake," Mrs. W. Clarke takes the silver medal, and she also obtains the bronze medal in Class C for an oblong salver in copper, the subject being a bird about to attack some cherries. Mr. L. Haslope has a nice pair of sconces in Class D, and Mr. H. Massé has a fine box in thick brass (Class F), the design being worked on the surface. Altogether there are 76 exhibits, which serve to show clearly enough to how many purposes repoussé work lends itself, and at the same time display the skill and artistic taste of the worker. We would recommend any of our readers who may be in the vicinity of Long Acre to pay a visit to this interesting "First Exhibition of Amateur Repoussé Work."

THE QUADRANT LOCK INDICATOR.

WE illustrate in the annexed engraving the "quadrant lock" indicator for electric bells which has been patented, and is now



being introduced by Messrs. Watt, Winnall, and Co., of Bromley-street, Commercial-road, E. The illustration sufficiently explains the construction. The catch is carried by the armature, which is attracted by the extended poles of the single magnet, and the indicator disc drops as shown. When replaced, the catch falls into the notch in the quadrant, and the disc is held securely in position until the armature is again attracted. The manufacturers say that a 12-hole indicator of this pattern occupies no more space than a 6-hole of other makes; but its chief feature is the fact that the indicator disc is practically locked in position, and is not likely to fall by the motion of a ship, for instance, or by being shaken.

JUPITER AND HIS "RED SPOT."*

By PROFESSOR C. A. YOUNG.

PROBABLY all our readers know that Jupiter is by far the largest of the sun's planetary family, and not only the largest, but in many respects the most beautiful and interesting. The sun and moon, and the earth's twin sister, Venus, are the only brighter objects in the sky; and Venus and the moon owe their precedence merely to their nearness. Jupiter makes his circuit around the sun in a little less than twelve years, travelling in an orbit about five and one-fifth times as large as the earth's. At "opposition," when he rises at sunset, and is nearest to us, his distance is about 390,000,000 miles; while six and a half months later he is remoter by the full diameter of the earth's orbit—186,000,000 miles. Of course, there is a corresponding variation in his apparent brightness; when nearest, he is nearly three and a half times more brilliant than when farthest away, and his light is about equivalent to that of fourteen first-magnitude stars like Vega. He is never, however, quite bright enough to be seen easily by day, as Venus can.

He is by far the largest of the planets, both in bulk and mass. His mean diameter is a little over 86,000 miles—nearly eleven times that of the earth, and fully one-tenth of the diameter of the sun itself. This makes his volume more than thirteen hundred times greater than the earth's. If we represent the earth by a marble, Jupiter would be a football, and the sun a globe 8ft. or 9ft. in diameter.

The planet's mass is not proportional to its bulk; it is only about three hundred and sixteen times that of the earth; and, comparing its mass with its volume, it appears that the planet's average density is about one-fourth that of the earth, and only a little greater than that of water—a fact always to be borne in mind in considering the phenomena which the telescope reveals upon his apparent surface; if the planet be not wholly a ball of vapours, it is clear that the outer portion which we see can hardly be more than a cloudy envelope.

In a telescope of any size, Jupiter is a splendid object—a noble disc accompanied by four bright moons, the first heavenly bodies of whose discovery we have the record. They were the earliest fruits of Galileo's telescope, found by him in 1610. The planet's disc is not quite circular, but is plainly flattened at the poles, and marked with dark belts, usually four in number, one on each side of the equator, and one near each pole. In a small telescope these belts generally look pretty smooth and regular; but in a large instrument they are seen to be made up of cloud-like wisps and filaments of a great variety of form and colour. The belts are not permanent features, like the markings visible on Mars, but evidently mere cloud-streaks, arranged and combed out, so to speak, by the rotation of the planet in some way not yet clear. The trade winds upon the earth, it is true, at once suggest themselves as an analogous phenomenon, but with a striking and important difference. Near the earth's Equator the motion of the atmospheric currents is always westward; so that clouds in those latitudes, as seen by an observer (on the moon, for instance), would appear to complete their rotation more slowly than clouds in higher latitudes, where (as in the United States) the prevailing drift is eastward. Now, on Jupiter the case is reversed; on this planet, as on the sun, all objects near the equator move eastward faster than those which are near the poles. Of course, the question at once arises, whether this does not indicate that the constitution of the planet resembles the sun more than the earth, as may well be the case. It seems likely that this peculiar law of surface rotation is in some way a necessary consequence of the loss of heat by a warm body in a gaseous or fluid condition; but the complete explanation is yet to be given.

The filaments and cloudlets of which the belts are composed are continually changing in form and size. The changes are apparently even greater and more rapid than the reality, because of the swift

* From the *Popular Science News* (Boston, Mass.).

rotation, which in two or three hours completely alters the aspect of the disc. As a general rule, the real changes are rather gradual, so that only seldom any considerable alteration, such as would be easily seen with a power of 300, would be effected in less than two or three days. Any well-marked, conspicuous feature usually persists for weeks, and even months; gradually passing, however, into something quite different from what it was at first. But, now and then, there are sudden, and one might even say paroxysmal, changes, which in a few hours transform the whole appearance of a region larger than the entire surface of the earth.

One of the striking things about the telescopic aspect of the planet is the richness of colouring in its various markings. Browns, reds, and yellows are predominant; but greens and purples are not infrequent. Probably their origin is similar to that of our own sunset hues, though less vivid, because the clouds and vapours of Jupiter's atmosphere are illuminated with a sunlight only a twenty-fifth part as bright as ours, and because, too, we are not favourably placed to catch the brightest of the reflected rays. Among the different conspicuous markings which every now and then appear upon the planet, the most noteworthy are certain large oval patches of a more or less pronounced ruddy hue; and in striking contrast with them, the so-called white spots, some of them so small and brilliant as to look almost like sparks of fire. The white spots appear most frequently near the planet's equator, and these are sometimes of considerable size; but they are found also in the higher latitudes. Usually they are rather short-lived, but sometimes endure for months. One which has been much observed of late has already been watched for several years. It is near the equator, and owes its interest to the fact that it is found to drift eastward relatively to the great red spot at the rate of 260 miles an hour, completing its diurnal rotation in about 9 hours and 50 minutes.

The great red spot, which for eight years now has been the object of so much interest, is an oval of about 30,000 miles in length, and 8,300 in width. It was first noticed in 1878, by several independent observers. Its genesis was not seen; but it was fully formed when first perceived, and probably originated a few months earlier, when the planet was near the sun, and out of reach of observation. It is situated at about 30° south latitude, and owes its name to the strong brick-red or maroon colour which characterised it during its earlier years.

There are some reasons for thinking it identical with markings of similar form and size (but not colour) which have from time to time appeared upon the same part of the planet's disc before (in 1792, 1858, and 1869-70); but of this we cannot be quite certain. If the spot had a constant, definite rate of rotation, which we could determine with accuracy, we could easily reckon back to 1869 and 1870, when Mayer and Gledhill observed their curious oval ring upon the planet, and determine whether or not their object occupied the same place upon the planet's disc. But the rotation period of the red spot is variable; not greatly, but still sufficiently to render hopeless any such attempts to determine whereabouts upon the planet's disc it ought to have been at any given moment a dozen or twenty years ago. In 1879 it made its diurnal circuit in 9 hours 55 minutes and 34 seconds. In 1881 the period was over 4 seconds longer, the seconds being 38·1; in 1883, 39·7 seconds; and last spring, 40·7 seconds. These differences are not caused by any uncertainty of the determination, but indicate a real change, due either to a *drift* of the spot, or a real lengthening of the planet's day.

The white spot before referred to showed a somewhat similar change of period, but more irregular, ranging from 9 hours 50 minutes and 2 seconds, to 9 hours 50 minutes and 9 seconds. It is worth remarking, by the way, that certain small, *dark* spots near the equator have showed the still shorter period of 9 hours 48 minutes; while certain white spots, observed in 1885, in the south polar belt (latitude 50° +), gave a period of 9 hours 55 minutes and 11·1 seconds—nearly half a minute less than the red spot, which was 20° nearer the equator.

In its youth the red spot was somewhat irregular in its behaviour, putting out prongs and processes here and there, and apparently crawling about a little on the planet's surface. At first the belts seemed to stand in no relation to the spot; in fact, in 1879-80 the usual south equatorial belt was either wholly wanting or very faint. But in 1882 this belt came out again strong and clear, and pushed its southern edge out to and past the spot, but without touching or distorting it in any way. A notch was formed in the edge of the belt, leaving a clear, bright channel two or three seconds wide between the belt and spot, as if there were some mutual repulsion between them, the two being nearly of the same colour, and apparently (but not, by any means, certainly) of the same constitution and material. The less conspicuous belt, south of the spot has not shown the same aversion to it; but in 1885, and again last spring, extended its filaments at times, so as to cover apparently about one-third of the width of the spot. I say apparently, because no one really knows which was uppermost. It is natural to suppose that the red spot, which has shown such a degree of permanence and stability, is lower down than the cloudy forms which make up the belts; and such is the general, though not universal, opinion among astronomers. But as to the real nature of the spot, we have no satisfactory explanation, and speculation is baffled. A continent emerging, a floating island on an ocean, lava poured out over a region exceeding the earth's whole area, smoke and steam from some long-continued eruption, such are some of the different hypotheses that have been suggested. But the low density of the planet (low in spite of its enormous mass) almost forces us to think of it as only a cloud formation of some kind.

How long the spot will continue visible, no one can tell; in 1882 it began to fade, and faded still more in 1883 and 1884. In 1885 it seemed to be on the verge of extinction; the central portion had either lost all its colour, or was veiled by a whitish cloud; so that, though undiminished in size, it was only a narrow, pinkish ring—a mere skeleton-ghost of its former self. Last spring, however, the veiling cloud was gone, and the spot was rather more distinct—certainly as easy to see as in 1884.

THE MICROSCOPICAL EXAMINATION OF BUTTER AND FAT.

THE question whether the microscope affords a sufficiently accurate means of distinguishing butter from fat and its preparations has attracted much attention in the United States, as will be remembered. The Editor of the *American Monthly Microscopical Journal* says:—"We first received some time ago slides from Dr. Taylor containing crystals from the fat of beef taken from the caul fat of the ox. We then, after examining them, obtained a sample of butter known to be good, and subjected it to microscopic examination. It contained no crystals of any kind except a few crystals of *halite* or common salt. This was a sign that the butter was good, according to Dr. Taylor's test, for butter ought to show no crystals of fats, because the fats of the butter have never been heated and allowed to cool and crystallise after the manner required by the condition for the formation of these crystals. The butter thus examined was then heated in a watch-glass to boiling, over a Bunsen lamp, and allowed to boil vigorously for a few moments, and then set aside to cool. Examined shortly after boiling, it contained no crystals, but after several hours it was again examined. It now presented a very different texture from that proper to butter; was granular, and broke up readily into a number of very small rounded masses. A bit of it was placed upon a slide and covered with a drop of oil. In this it readily broke up into a mass of very minute grains, distinctly visible to the naked eye, but very small. Microscopic examination showed these to be small spherical bodies, with a general mutual resemblance. The same facts as these were described in Dr. Taylor's article. Our observations were made for the purpose of confirming this description, and were in accord with those of Dr. Taylor. Very recently we have received from Dr. Taylor a set of thirteen very beautiful photo-micrographs, illustrating this subject. Two of these were taken by Mr. Walmsley, of Philadelphia, and the rest by Dr. B. Persh, of Washington. We cannot leave them without one word upon their beauty as works of photo-micrographic art, and perhaps that word can be as well said at the beginning as at the end of what we have to say of them. Of the photo-micrographs, four are of beef fat, and show plainly the characteristic crystal as figured in Dr. Taylor's article. Two of the micrographs are of lard crystals. Two more of the micrographs represent the crystals of butter. The other five pictures are from slides of oleomargarine. Of these, two contain, evidently, a great deal of butter, for in the picture at least one half the crystals are evidently butter crystals: but besides these are numerous crystals of beef and lard. From these photo-micrographs there would be no difficulty in picking out at once the one made from pure butter, and as these were made from pure butter it follows that pure butter can be detected at any time, microscopically, in this way. But while this study is full of interest in the investigation of the various butter crystals, and it is beginning to appear that various butters may be distinguished by slight variation in the butter crystals, it is not necessary in examining butter and its substitutes to detect frauds that the butter crystals be seen at all. The butter of the stores is not so formed as to give rise to any fat crystals. The fats in it are never heated beyond the temperature of the animal body, and hence are not placed under the conditions required for crystallisation. Therefore, butter unadulterated ought to show no crystals whatever present. Only yesterday, Nov. 13, we received from Dr. Taylor two samples, one of butter, the other of oleomargarine. We requested several persons to taste these and pronounce upon their relative merits, and attempt to distinguish them by the taste. The butter was universally pronounced to be the inferior article, and the experimenters, who had been farm-bred boys, though they didn't know oleomargarine by the taste or look, judged that sample the better article, and hence they concluded it more likely to be butter. To the taste it was butter, but under the microscope there was a great difference between the two. The butter sample was destitute of fat crystals of any sort; but the oleomargarine was largely composed of two sorts of crystals, resembling the one fat and the other lard.

LATHES AND LATHE CENTRES.*

THE requisites of a good speed lathe are a well-fitted spindle, having a taper hole bored in front end for centres, and a thread cut on the front end for face-plates, leaving a good liberal shoulder for them to bear against. The lathe should have wooden cones on both spindle and countershaft, in order that the lathe may be stopped and started quickly. The smallest end of cone on spindle should be towards the front end. This will give more room when working close to the lathe head, as in turning the back side of a piece on a face plate. The tail centre should be in line with the spindle, and have a taper hole the same as in spindle, then all centres and chucks that are fitted in the live spindle may also be used in the tail spindle. If the live spindle has brass boxes, see that they are well supported by the housings. The boxes should not be much longer than thickness of housing, otherwise they are liable to spring and wear unevenly, which will soon make them run hot. The tail spindle should be moved by a screw, and provided with a clamp for fastening firmly at any point.

The saddle and rest should be made so as to be adjusted and fastened in any position, without the use of a wrench, or any tool except what constitutes a part of the saddle or rest. A great many rests are fastened in position as regards height by a square-headed set screw, and every time any change is made in the position it is necessary to first find the wrench which fits this screw, and if a monkey wrench is used, it will, of course, have to be adjusted to fit the screw before using. How much better a set screw fitted with a lever handle works, both as regards the rest and also the operator's temper.

The speed at which a lathe should run depends upon its size and the work to be done. A very good speed for a lathe that will turn 12in. in diameter would be on the fastest speed 4,500 revolutions, and on the lowest speed from 500 to 800 revolutions. This cannot be considered as an arbitrary rule for all classes of work, as there is a great difference in the work done by the same size lathe in different shops, and it isn't every 12in. lathe that can be coaxed or compelled to run 4,500 turns a minute. Faster speed than this means an extra fine lathe or a loose spindle and excessive wear. If you are fortunate enough to possess a lathe that can be run at this speed and keep cool, don't let anybody tinker with it on any pretence, for in nineteen cases out of twenty they will do it harm. Even taking out the spindle to clean it is bad. It is better to clean it without removing it from the boxes, and a still better way is to use such oil as won't make any dirt, unless you let it get hot enough to burn the oil. To prevent this, put a piece of raw-hide between set screw and tail end of spindle, keep both boxes well oiled, and don't get the bolt too tight.

Never locate the counter directly over the lathe spindle. Put it back so that the belt won't be exactly vertical. This helps the belt a little. Then use a belt as wide as possible, lace the belt with wire or shave down the ends and lap them and glue them. After the glue has set, sew the splice as belts are sewed, which are made without rivets, using a small thin lacing and pounding it down flat after sewing. Make the belt just tight enough to do the work. Then if you find that the belt slips, it is likely that you are trying to make the lathe do a job that properly belongs to the big lathe, or perhaps you are working on the same principle as one of my former shopmates, who, when he had a piece in the lathe that had a good deal to be turned off, would point his gouge at the most prominent point, shut up his eyes, and jam in the gouge. If the lathe didn't stop, or nothing broke or gave way, he usually succeeded in jamming off considerable wood, but his method was rather hard on tools and on the lathe.

The centres for driving work may be of many different forms, some of which I have endeavoured to show by drawings.

Fig. 1 looks and works very nicely while it is kept in good order, but it is rather difficult to

* Extracted from a paper by Mr. F. W. BARROWS, in the *American Machinist*.

FIG. 1.

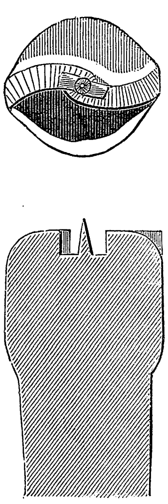


FIG. 2.

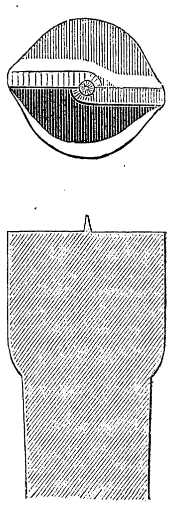

FIG. 3.

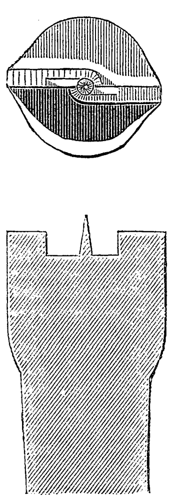

FIG. 4.

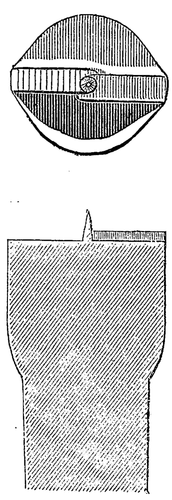

FIG. 5.

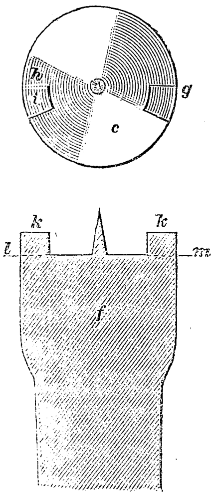

FIG. 6.

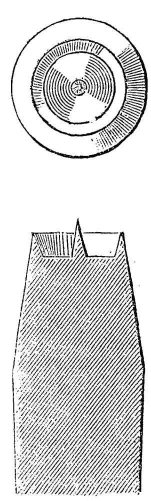


repair if the wings get broken, and it is also one that is expensive to make in the first place. That shown by Fig. 2 costs less and works fully as well as Fig. 1. This one may have a notch filed in one wing to locate its position in the piece to be turned, and insure its being always put back in the same position in a job that has been taken out of the lathe for any reason.

The one shown by Fig. 3 is the same as 2, except that a space is cut between the centre point and the wings, one of which is wider than the other, to locate its position in the piece to be turned.

Fig. 4 shows a form similar to 2, except that the line of wings form tangents to central point instead of radial lines. This form may be marked by filing a notch in one wing, as in 2, or by cutting a space, as in 1 and 3. It is best on all of these four centres to have the wings cut away where they join the centre point, as in 1 and 3, in order to sharpen the spurs without spoiling the centre point; also to give room to turn up the centre when necessary.

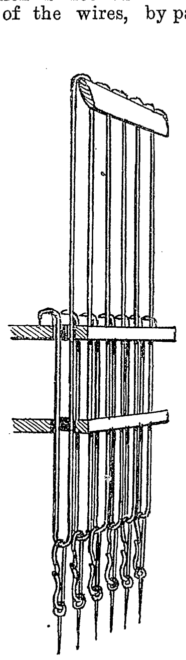
Fig. 5 shows two views of another form of spur centre, *c* being an end view, while *g h i* show the location of spurs. This is the best form I know of, and its having two spurs on one side and only one on the other makes it possible to replace any piece of work that has been taken out of the lathe, and to be sure that it will run true. More points may be left if it is thought best, as in making this centre it is turned up with a longitudinal section like *f*, then the ring at *k* is cut away, leaving the spurs *a g h i*, and as many more as you wish. This centre is intended to be forced into the work up to the line *l m*, then it has no corners to catch the clothing, or rap the fingers. This is another good feature.

The central point on all these different centres should be kept a little longer than the spurs or wings; in order to locate the centre in the work accurately, keep this point always turned true at an angle not over 23°, to avoid crowding open the joint on split patterns. The tail centre may be an ordinary 60° centre, but this form is likely to crowd open the joint, and for a job that has a long spell in the lathe it is liable to wear towards one side of a split pattern, as one side is almost invariably softer than the other. A centre having a slender point, with a ring around it from $\frac{3}{8}$in. to $\frac{3}{4}$in. in diameter, will prevent both these troubles. It should have a section like the one shown in 6. I have shown both this dead centre 6 and the spur centre 5, as being made from a single piece of steel, but an improvement is to put the centre point in each as a separate piece, then if Stubbs' steel is used for this point it may be easily replaced if it gets broken. I have turned small split patterns of hard wood without any fastening but the dowels, and such as was afforded by centres like 5 and 6. This wouldn't be a good way as a rule, but it shows that the centres are both excellent in their way. A centre might be designed for live spindle that would safely hold small light work, and would be a desirable tool.

IMPROVED JACQUARD HARNESS.

In the ordinary Jacquard machines, the devices carrying the harness of the loom consist of iron hooks provided on their lower ends with twisted cords, to which are attached the collets carring the respective threads of the harness. It has been found difficult to make these cords the same length, so that they would raise the threads of the harness equally. The invention herewith illustrated, which has been lately patented by Mr. James Jackson, of 18, and 20, Albion-street, Paterson, N.J., dispenses entirely with the twisted cords, and attaches the collets carrying the threads directly to the hooks.

Each hook consists of a vertical rod formed at its upper end with a bend, which engages in the well-known manner with the cross bar attached to the lifting frame, which raises the hooks and, consequently, the harness of the loom in the usual way. The lower part of the rod is bent upon itself, and in the bend is hooked a collet formed of spring wire bent and twisted, as shown. Each thread of the harness is provided with the usual loop on its upper end, which is hooked to the collet. The parallel parts of the wires, by passing through



apertures in the stationary grates, are guided in their up-and-down motion in such a manner that the hooks retain their relative positions to each other, having no sidewise or endwise motion whatever. On the lower end of the hook is a bend that passes over a ridge on the upper grate, in the downward movement of the hook. This prevents the hooks from going further down, and they assume the same position they had before being raised. In transferring the threads from one machine to the other, the upper ends are simply unhooked from the collets, or the latter are removed from the hooks.—*Scientific American.*

FILTRATION OF WATER.

At a recent meeting of the German Congress of Naturalists and Physicians, Dr. Plagge read a memoir on the filtration of water, in which he argued that the essential task of filtration is to free water from infectious matters. As such matters consist chiefly of bacteria, the value of a filter must be judged according to the efficacy in the destruction or removal of the bacteria present in the water. The distinction of the bacteria into pathogenous and non-pathogenous is here unimportant, since a filter which allows the non-pathogenous germs to pass will not keep back those which are pathogenous, while, on the other hand, we are justified in assuming that a filter which keeps back all other bacteria will give protection against infectious matters.

Most of the ordinary domestic filters, and especially those containing as their material spongy iron, carbon, stone, gravel, and cellulose, do not—according to the author's observations—come up to the above requirement. On the contrary, there is generally found a marked increase of organisms in the filtering material. Experiments made with pure cultures of typhus and cholera prove that such filters allow these infectious matters to pass without hindrance. Better results were obtained with clay and asbestos filters of different constructions (Chamberland, Breyer, Olschewsky, Arnold, and Schirmer), as for a certain time they yielded water perfectly free from germs. However, it was not found practicable with any of these apparatus to obtain water perfectly free from microbia. According to Hesse, asbestos strongly compressed, and especially dense cells of clay, form a filtering material which yields water permanently germ free. On this point the author is for the present unable to decide, since these apparatus have not been produced for practice, and he has not been able to procure such.—*Chemiker Zeitung.*

EXPERIMENTAL BALLOONING.*

By FRED. W. BREAREY, Hon. Sec. to the Aëronautical Society of Great Britain.

THE Society which I have the honour to represent has never advocated the employment of the balloon as a means of aërial locomotion for everyday purposes of transit. It is on record under what circumstances we value it, but ignore it as an auxiliary to mechanical efforts. We are passing through a period of excitement and extravagant expectation, the outcome of a few experiments with balloons conducted under favourable circumstances. The periodicals, scientific and otherwise, have accustomed us to a repetition of the experiments of those few French inventors who have been able, through the liberality of their Government, to put into practice their notions of the requirements of aërial navigation—viz., levitation as against gravitation. The newspapers in England have apparently confined their reports to experiments conducted in France by French aëronauts with French money. They have quite disregarded those equally successful attempts made in France by a late member of this society with the aid of English money prior to the Meudon experiments. The name of that member was Mr. Frederick A. Gower, who lately was cast away in a balloon, the particulars of which can never be recorded, as no trace of him has been discovered. I am able to give extracts, however, from a memorandum forwarded on the 14th June, 1883, to Prof. Tyndall at the Royal Institution by Mr. Gower as follows:—"A series of experiments which have been carried on in the neighbourhood of Paris for the past two years yielded results this afternoon which seem to me worthy of general attention, from the fact of their having included the driving of a large balloon fairly against the wind by steam power. The aërostat in question consists of an envelope of gold-beater's skin in the form of a cylinder, with rounded ends, and flattened somewhat at the sides. Its length is 30 mètres, and diameter 10 mètres, with a capacity, say, of 2,000 cubic mètres, and a lifting power when filled with hydrogen of something over two tons. A car of wickerwork, fortified with brass tubes along its length beneath, is suspended by netting in the usual manner for nearly the whole length of the balloon. At or

* Read before the Aëronautical Society, December 11.

near the central point of this car is placed a double cylinder horizontal engine of 5 H.P., made almost wholly of bronze. From this extends a shaft of steel tubing $1\frac{1}{4}$in. in diameter, and provided with knees to allow of slight deflections, straight to the forward end of the car, where it is geared to a nearly upright shaft of larger size, which serves to supply the power to an upright flywheel, or fan, about $1\frac{1}{2}$ mètre in diameter, placed exactly upon the line of the centre of the aërostat, at a right angle to its length and about 6in. from the envelope. The blades of this wheel are of wood, one centimètre in thickness, and having an area of about 0·19 of a square mètre each. They are quite flat, and set perpendicularly to their axis, which is itself as nearly horizontal as possible. The wheel is not, therefore, designed to have any propelling power as a screw, and is apparently capable of no function other than that of rarefying the air in its vicinity when turned at a high rate of speed." Here follows a detailed account of what Mr. Gower considers a successful experiment. This I omit. But I cannot avoid noticing a significant paragraph in this memorandum. He writes: "A very gentle breeze was blowing from the north, and the machine was held by the forward end (that of the fan wheel), in order that the stern might swing exactly into the line of the wind's direction. The engine was then started upon the same conditions of speed as before, and the balloon was released, *except that a man at each end walked by the car with small bags of sand, which he hung upon the car, or removed, as the slight changes in equilibrium demanded.* The machine yielded a foot or two to the slight airs, then gathered headway and moved forward directly in the 'eye of the wind,' which was blowing at from three to four kilomètres the hour." It must be understood that I have emphasised, as far as italics will allow me, all that is said about the means taken for preserving the equilibrium of this balloon, whose length is 30 mètres to 10 mètres diameter. The significance of these italics will be strengthened by what I shall have further occasion to observe. The *Morning News*, till lately published in Paris, says: "The successful experiment by Mr. Gower was made on June 14, 1883, and was witnessed by a large number of people, who have attested its success. There can be no question that, notwithstanding Frenchmen have done much in the way of invention towards this achievement, it was an American, aided in part by English capital, who first constructed and drove against the wind a large balloon, and this more than a year before the experiments at Meudon." At a lecture delivered at the United Service Institution by Mr. Gower shortly before his balloon fatality, I asked him how he maintained the shape of his balloon, seeing that it was upon its shape that he so much depended for success. He replied that there was no other stiffening but that which arose from distension by the gas. I remarked that the shape was likely to be altered by the act of propulsion against the atmosphere, and consequent compression of the gas. This he admitted. It follows, therefore, from this absence of rigidity, that the rate of progress through the air must be limited by the ability of the envelope to sustain the pressure of the compressed gas. An analogy has been attempted to be drawn between the balloon and the fish. Undoubtedly the fish can swim against a strong current: but consider the difference in the structure of the two. The body of the fish is homogeneous throughout; whereas the only substance of the balloon is that which is comprised in its thin envelope. Upon this absence of rigidity General Hutchinson comments in his article upon "Navigable Balloons," inserted in the *Broad Arrow* Sept. 12, 1885. He quotes Gaston Tissandier, whose pamphlet advocates extreme lengths, up to 1,000 yards even, and who hopes, he says, to attain "the speed of express trains, and command over nearly every wind." In fact, we are having over again the extravagant speculations of the first experimenters and writers in aëronautics. In the conclusion of his article, General Hutchinson, who is a great advocate for extension of length, naïvely remarks: "Another question is, how best to impart the requisite stiffness to the envelope, and such a constantly-preserved automatic pressure as will keep it (with its embracing net) when only partially filled with gas *constantly* stretched under all conditions of altitude and temperature?" Yes, I think the General will find the attainment of those conditions a poser; for let us see what shaped gas envelope is recommended—viz., a cylindrical form "as the best of forms," and "because," it is said, "the less its diameter the less the bursting strain"; and also that "it is the simplest form to construct when made of prepared silk—merely breadth of the material joined at the selvage." Therefore, we are free to imagine, simply as a model (because the proportions would be much greater), a sausage the length of this room, and about 3ft. thick, with both ends cut off, and two extinguishers substituted. But the outer skin of this sausage is its only substance. Its gaseous interior is subject to uncertain vagaries, depending upon temperature and pressure. As well attempt to propel a spirit level with the air-bubble maintained in the centre as propel such an apparatus against a wind. And this observation is apropos of my italics. To stiffen such an apparatus so as to make it effective would add too much weight, so that this aërial sausage might just as well be stuffed with pork. Yet the most difficult problem of all is left to the last, as one of the minor details. Alluding to Mr. Gower, and the loss of himself and balloon at sea, one is led to reflect upon the many narrow escapes from death which have occurred to aëronauts within sight of land, and their apparent helplessness under such conditions. Now it appears to me that there has been a want of mechanical devices to meet exigencies of this nature. It is evident that when an accident of this kind occurs it is seldom through a catastrophe such as a rupture, but nearly always through condensation of the gas, and the descent into the sea is gradual. The weight carried and the balloon are nearly in equilibrium, the man being a little heavier. Now these are the conditions which I should like to see carried out in a small experimental balloon without a valve, car, or ballast, the aëronaut sitting saddlewise armed with a punting pole shod with a termination fitted to push off from the surface of water, trees, houses, and land. The punter in a tideway keeps himself from shore under the influence of the stream with a pole. Is it not feasible that the aëronaut so equipped could keep his balloon under the influence of the aërial tide by pushing from whatever may be underneath him? A push of 40lb. would be equivalent to nearly 1,000ft. of gas added to his balloon; therefore, I think many a ducking would have been saved by the simple provision of a suitably-shod pole suspended from the car ready for use. A pole shod with a circular disc, the upper portion of which sloped upward, would perhaps be suitable in this case.

USEFUL AND SCIENTIFIC NOTES.

Dietetic Fallacies.—1. That there is any nutriment in beef tea made from extracts. There is none whatever. 2. That gelatine is nutritious. It will not keep a cat alive. Beef tea and gelatine, however, possess a certain reparative power, we know not what. 3. That an egg is equal to a pound of meat, and that every sick person can eat eggs. Many, especially those of nervous or bilious temperament, cannot eat them; and to such eggs are injurious. 4. That, because milk is an important article of food, it must be forced upon a patient. Food that a person cannot endure will not cure. 5. That arrowroot is nutritious. It is simply starch and water, useful as a restorative, quickly prepared. 6. That cheese is injurious in all cases. It is, as a rule, contra-indicated, being usually indigestible; but it is concentrated nutriment, and a waste repairer, and often craved. 7. That the cravings of a patient are whims, and should be denied. The stomach often needs, craves for, and digests, articles not laid down in any dietary. Such are, for example, fruit, pickles, jams, cake, ham or bacon with fat, cheese, butter, and milk. 8. That an inflexible diet may be marked out, which shall apply to every case. Choice of a given list of articles allowable in a given case must be decided by the opinion of the stomach. The stomach is right and theory wrong, and the judgment admits no appeal. A diet which would keep a healthy man healthy might kill a sick man; and a diet sufficient to sustain a sick man would not keep a well man alive. Increased quantity of food, especially of liquids, does not mean increased nutriment, rather decrease, since the digestion is overtaxed and weakened. Strive to give the food in as concentrated a form as possible. Consult the patient's stomach in preference to his tastes; and if the stomach rejects a certain article, do not force it.—*Journal of Reconstructives.*

THE production of lead in the United States in 1885 was 129,412 short tons. Total value, at an average price of 81dols. per short ton at the Atlantic coast, 10,469,431dols., a decline of 10,485 tons and 67,611dols. in value from the product of 1884. The production of white lead is estimated at 60,000 short tons, worth, at $5\frac{1}{4}$cents. per lb., 6,300,000dols.

A FRENCH inventor proposes to use electricity for bleaching paper pulp in the following manner. A solution of chloride of magnesium is used. This is of the strength of about 16° Beaumé. On passing a current through, electrolysis taking place, various chemical reactions occur, setting free divers oxychlorides, which, so it is said, effectively bleach the fibre.

AN ingenious process for giving a silver surface to iron has recently been devised in Austria. The iron is first covered with mercury, and silver is deposited upon its surface electrolytically. The iron is then heated to about 300° C., and the mercury evaporates, leaving the layer of silver on the surface of the iron.

SCIENTIFIC SOCIETIES.

ROYAL ASTRONOMICAL SOCIETY.

THE December meeting was held on Friday, the 10th, at Burlington House. J. W. L. Glaisher, Esq., in the chair. Capt. Robt. Dowling, the Rev. Robt. Sparke Hutchings, the Rev. Henry Pool Slade, and Mr. Washington Teasdale were elected Fellows of the Society. On the motion of Mr. Inwards, seconded by Sir James Cockle, Messrs. H. Sadler, R. Bryant, and R. J. Lecky were appointed auditors of the society's accounts for the past year.

Mr. Buckney described a chronograph which had been sent from Melbourne by Mr. Ellery for the purpose of being exhibited at the Colonial Exhibition. He said the principal feature worthy of remark is the parabolic pendulum controlling the clock which drives the drum of the chronograph. It is a modification of Huygens' parabolic pendulum, and was described by Mr. Ellery in the *Monthly Notices* for Dec., 1875. The pendulum revolves about a vertical axis, and as the driving power is increased, and the pendulum flies outwards, it unwraps two wires by which it is suspended from the evolute of a parabola, so that the bob of the pendulum flies outwards in a parabolic arc, and the time of revolution is always constant, however large the circle described. I believe that this chronograph was made at the Melbourne Observatory. As the drum is driven by the parabolic pendulum, a siphon pen containing aniline ink is carried along the drum making a spiral line, which is broken every second by a current from the standard clock of the Observatory—in this case the circuit is made and broken by a chronometer beating seconds. The drum goes for about two hours and a half, and the control of the parabolic pendulum is so perfect that a line may be drawn along the paper on the drum bisecting the seconds marks, and showing that there is not a variation of a tenth of a second in the driving during that time.

Mr. Ranyard asked why the driving of the drum could not be controlled by the standard clock, as well as the motion of the pen. This would insure the seconds marks being in a line, if that was considered necessary. Though the parabolic pendulum was perfect, theoretically, for a constant temperature, it cannot be compensated for heat changes, which may make a greater difference in the rate than if a circular arc were substituted for the evolute of the parabola.

Mr. Buckney said that the less work the standard clock was given to do the better. He believed that the temperature difficulty was practically got over by the whole instrument being inclosed in a glass case; in a period of two hours and a half the changes of temperature were practically inappreciable.

The Astronomer-Royal said that the object of this pendulum was not to insure uniformity of motion for a long period of time; but uniformity from second to second. It is in that respect that the parabolic pendulum is superior to any other. The regularity of the trace produced on this chronograph may be taken as evidence of the accuracy of the going of the driving-clock; but the chronograph-clock is only required to divide the seconds which are registered from the standard clock.

Col. Tupman said that this chronograph was not new: it had been in use for more than ten years. He had seen one in Adelaide, one at Melbourne, and one at the Observatory, Christchurch, New Zealand—and they all worked very well.

Mr. Common said: I think, so far as I can see, that the direction in which improvements in chronographs will be made is the direction in which the Americans are working. They get rid of the barrel altogether, and use a revolving wheel, which can be depressed at any particular moment, and registers the hundredth part of a second. The clock itself registers the whole seconds and the minutes.

Mr. Maunder read a paper on "Mr. Sherman's Observations of Bright Lines in Stellar Spectra." He said that Mr. Sherman had described the bright lines as appearing as beads on the spectrum. This was not possible, unless the spectrum of the star was a mere line; but he distinctly stated that he was using a cylindrical lens, which would have widened the bright lines as well as other parts of the spectrum. Mr. Sherman also states that he used a slit which subtended 6 minutes of arc in width, while the diffraction discs of the stars examined would be about 3 seconds in diameter; so that the slit would be 120 times as wide as the disc of the star, and the measures of the positions of the lines observed would be absolutely unreliable unless he knew where the star was with respect to the jaws of the slit.

Mr. Knobel read a paper by Dr. Copeland on the *Nova Andromedæ*. Immediately on the receipt of the telegram with respect to the change in the nebula at Dun Echt, a circular was sent out, and observations of the nebula were commenced. When the new star was first seen on the 1st Sept.

1885, it appeared to be of about the 7½ magnitude. With the spectroscope only very slight indications of bright lines could be detected. The continuous spectrum of the star resembled that of the Great Nebula. On Sept. 10th it extended from between B and C to half-way between F and G. By the 15th Sept. the Nova had fallen in magnitude, and only traces of two bright lines could be made out. On Oct. 1st those two bright lines could still be detected. On Oct. 19th the spectrum was continuous, but not uniform. The Nova then appeared as of the 8·7 magnitude. On Jan. 2nd it had fallen to the 13·5 magnitude. On Jan. 30th it was not certainly seen. On Feb. 2nd there was no trace of it to be seen with the 15in. refractor. It seems to have decreased irregularly, fading more rapidly at first than afterwards.

Capt. Noble said: There seems to be some difference as to the colour of the star. When I first examined it, after receiving the Dun Echt circular, it was in company with my wife, who is one of the rarest visitors to my observatory. To me the new star appeared to be blue, and my wife said, directly she saw it, "It is like a tiny electric light." To my eye, it remained blue for the first few days, and then afterwards certainly became reddish.

Mr. Ranyard: I can confirm Capt. Noble as to the change in the colour of the nova; it appeared to me first as decidedly blue, and afterwards, as it grew smaller, as reddish.

Mr. Bryant: Did you observe it with both eyes?—I saw it as red with my right eye, and a totally different colour with my left eye.

Mr. Knobel: I can confirm Mr. Bryant as to the colour of planets observed with the right and the left eye: they look to me of an entirely different colour.

Mr. H. Sadler: Dembowski made a similar observation with regard to the colours of double stars; viewed with the right and the left eye, the colours appeared to him entirely different.

Col. Tupman read a note on an erratic meteor observed by Mr. B. J. Hopkins. He had in a former paper described observations of several meteors whose paths were not straight. But the phenomenon was not common. Mr. Denning had informed him that out of 1,300 meteors observed by him in 1885 only four were erratic. On the 4th of December, at 18 hours, he noticed a meteor as bright as Jupiter, which appeared in Ursa Major, and after moving through some 30° it appeared to divide, and the remainder of its path was pursued in a parallel path, but at a higher level than the first portion of the path. The meteor was moving slowly, and there could be no doubt about the phenomenon—it was not an optical illusion.

Mr. Ranyard: I have never seen one of these broken-pathed meteors, but there seems to be an accumulation of evidence proving that such paths are occasionally observed. Assuming their existence, I think that they may be explained by supposing that a projecting portion which causes the meteor to *skid* to one side from its original direction of motion is suddenly broken off or burnt, so that it becomes detached. The resistance offered by the atmosphere would be entirely changed, and it would suddenly begin to skid in a new direction. If, for example, the meteor were like a ball with two projecting wings, or a mass with two crystalline spicules projecting on either side, and one of them was torn off owing to evaporation, due to heat, the body would begin immediately to skid in a new direction.

Capt. Noble: I conclude that Mr. Hopkins does not refer to the trail or streak left behind the meteor, for such streaks have frequently been observed to be curved by the wind.

Col. Tupman: Mr. Hopkins certainly does not refer to the streak left behind the meteor. Such streaks have been observed by Smith, of Athens, and others to be bent by the wind sometimes in more than one direction; and I do not think that the phenomena observed by Mr. Hopkins can be explained, as Mr. Ranyard suggests, though, no doubt, the breaking off of a projecting portion may give rise to a sudden change of path. The meteor observed by Mr. Hopkins seems to have gone on moving in a parallel path a little above its former course. I think that there must have been two meteors, and that the one appeared just as the other was disappearing.

Mr. Ranyard said: I agree with Col. Tupman, I had not properly understood Mr. Hopkins's observation. As there is time before the meeting closes, I should like to mention a matter connected with the paper I read at the last meeting, on the rich group of meteors observed on the 27th of November last year. It has been assumed by most meteor observers that on such an occasion only a small amount of matter comes into the earth's atmosphere, and that a meteor as bright as a first or second magnitude star may be caused by a minute particle of matter no larger than a mustard seed; but I think that there are some considerations which render it very probable, if not certain, that the meteoric particles which give rise to meteors visible to the naked eye are considerably larger than mustard seeds. We may take it that small meteors seldom enter the atmosphere and penetrate to a depth much below 70 miles. Therefore, with the exception of meteors which appear in the zenith. They must mostly be seen at a distance of 100 miles or more from the observer's station. We know that a standard candle seen burning at the distance of a mile appears only a little brighter than a first magnitude star. Therefore, neglecting absorption, it would take an electric lamp of nearly 10,000c.p. at a distance of 100 miles to give the light of a first magnitude star; and a lamp of nearly 100c.p. to give the light of a sixth magnitude star. Meteors giving less light than this would only appear as telescopic meteors. I think that we may pretty safely assume that a meteor which gives the light of a sixth magnitude star has a surface as large as that of the incandescent portion of the carbon in an electric arc lamp which gives the light of 100 standard candles. For the carbon used for electric lighting is a very refractory substance, which gives a greater light — that is, it needs a greater temperature of incandescence before it is driven into vapour than other substances which have been experimented with. If metal or stone rods were driven into vapour by electricity, they would not give nearly so much light as carbon rods of equal size; then, again, the carbon in the electric lamp is comparatively quiescent. It is not subject to the pressure, or torn by the bombardment of cold air, to which the meteoric surface must be subject, which would remove the incandescent matter as rapidly as it was formed. If my reasoning is correct, a much greater amount of matter enters the earth's atmosphere during a meteoric shower than has hitherto been supposed, and a great deal may enter the earth's atmosphere and be driven into vapour without ever being seen at all. Such matter would in time find its way to the earth's surface, and when we consider geological periods of time would have a sensible effect on the growth of the earth and the shape of continents.

The meeting adjourned at a quarter to ten.

WESTERN MICROSCOPICAL CLUB.

On Monday week the members, accompanied by their lady friends, responded in large numbers to the invitation of Dr. and Mrs. N. Tirard, of 28, Weymouth-street, W. After a cordial greeting by the host and hostess, and some attention to the creature comforts liberally provided, the visitors proceeded to the spacious drawing-room. Here, under more than a score of microscopes, were displayed a collection of beautiful and minute seeds and the sparkling crystals derived from these and other sources. All were in illustration of the various forms of materials from which drugs were extracted, as well as of the drugs themselves. Dr. N. Tirard, F.R.C.P., alluded to the fact that the new British Pharmacopæia almost ignored the microscope, only in eleven cases referring to it as of use in determining crystalline forms. In the case of starch, cotton-wool, yeast, lupulin, and kamala, it is noticed as being of use for observing their forms. During solution of aloes and elemi in spirit, crystals are stated to be observable by the microscope. In the ordinary forms of catechu, light carbonate of magnesia, and precipitated sulphur, it is also noted that crystals may be detected by its use. A last reference is made to the shape of the crystals of arsenious acid observable by the microscope. Nowhere does the "B. P." refer to chemical reactions in which the microscope would be of service in determining the characters &c., of the various drugs. Dr. Tirard pointed out specimens of strychnine and brucine crystallising from hot solutions in combination with reagents, such as picric acid, bichromate of potash, and auric chloride. The microscopical characters of these bodies alone, and then the distinctive characters of their compounds, were pointed out and practically exhibited. Reference was also made to other drugs, interesting either on account of their beauty or novelty. Splendid crystals of caffeine, salicylic acid, platino-cyanides, &c., kindly contributed by A. W. Gerard, Esq., F.C.S., came under the first heading; while strophanthus, hamamelis, lacnanthes, and a number of new antipyretics, hypnotics, &c., generously brought by W. Martindale, Esq., were of interest from their novelty. Amongst those contributing microscopes and objects were Messrs. Bartlett, Gwinnell, Moore, E. and R. T. Swain, Tebbs, Tirard, White, Woodward, and the hon. sec., Mr. A. W. Stokes.

The next meeting will take place on January 3rd, at the house of Mr. E. E. Halford, when Mr. B. B. Woodward, F.G.S., will introduce the subject of "The Radula of Gastropoda."

PROF. COLLETT, the well-known Norwegian zoologist, announces that the beaver is now extinct in Northern Norway, but estimates that about 100 are still in existence in the south, chiefly in the province of Nedenaes.

SCIENTIFIC NEWS.

THE comet discovered by Barnard (1886 *f*) has now passed its brightest, and by the 21st will be only 18 as compared with unity on Oct. 5. It is, however, visible in the early evening, and will no doubt be frequently observed. An ephemeris for Berlin midnight, compiled by Dr. Svedstrup, of Copenhagen, reads—

	R.A.	N. Dec.
Dec. 21.	18h. 34m. 18s.	10° 32·2′
26.	19 6 32	7 13·7

Finlay's comet (1886 *e*) is also decreasing in brightness, and on Dec. 22 Berlin midnight is in R.A. 23h. 6m., S. Dec. 6° 16·7′.

One of the two small planets discovered by Dr. J. Palisa on the 31st of last March he named Augusta (254); he has now named the other (255) Oppavia. No. 257 which he discovered on April 5 he has named Silesia, and No. 260 (Oct. 30) Huberta.

The deaths are announced of M. Jules Lichtenstein, whose investigations in connection with the phylloxera are well-known in France; and of Prof. M. Websky, a distinguished German mineralogist.

Babu Prasanna Kumar Sarvadhikari, for many years principal of the Sanskrit College, Calcutta, and author of several mathematical treatises in Bengali, is also dead.

The opening meeting of the 104th session of the Royal Society of Edinburgh was held last week, when the president, Dr. John Murray, delivered an address. In the course of his remarks he said that, with a total and increasing membership of 507, the question was beginning to be raised whether they had not arrived at a time when only a limited number of Fellows should be elected each year. He discouraged this idea. The time had passed when it was possible to number the elect either in science or literature. Every energetic scientific man able to assist in the discovery of new facts, new principles, new processess, and new knowledge was a new strength to the Society, and ought to be welcomed. One of the best evidences of the prosperity of the Society was to be found in the great increase in its publications, which during the past three years probably surpassed in size and importance those of any other society in the United Kingdom; and he emphasised the importance of keeping the illustration of these transactions up to a high standard of artistic merit. Dr. Murray also urged the importance of founding a national library for Scotland; of having a bathymetrical survey of the fresh-water lochs; and of securing a Government grant for the Ben Nevis Observatory, which he described as "certainly the most important meteorological observatory in the kingdom." It appears that out of the £15,300 annually voted by Parliament for meteorological purposes, Ben Nevis receives no more than £100, which is a bare equivalent for the mere clerk-work necessary to supply the office at Westminster with a complete set of the observations.

The following are the arrangements for the lectures before Easter at the Royal Institution:—Prof. Dewar six lectures (adapted to a juvenile auditory) on "The Chemistry of Light and Photography;" Prof. Gamgee, eleven lectures on "The Function of Respiration;" Prof. Rücker, five lectures on "Molecular Forces;" Prof. Max Müller, three lectures on "The Science of Thought;" Mr. Carl Armbruster, five lectures on "Modern Composers of Classical Song;" and Lord Rayleigh, six lectures on "Sound." The following are the probable arrangements for the Friday evening meetings before Easter:—Sir William Thomson, on "The Probable Origin, the Total Amount, and the Possible Duration of the Sun's Heat;" Mr. W. Baldwin Spencer, on "The Pineal Eye in Lizards;" Mr. Edwin Freshfield, on "Some Unpublished Records of the City of London;" Mr. E. B. Poulton, on "Gilded Chrysalides;" Mr. W. Crookes, on "Genesis of Elements;" Capt. Abney, on "Sunlight Colours;" Mr. V. Horsley, on "Brain Surgery in the Stone Ages;" Archdeacon Farrar, on "Society in the Fourth Century A.D.;" Mr. G. J. Romanes, on "Mental Differences between Men and Women;" and Lord Rayleigh, on "Colours of Thin Plates."

At the annual general meeting of the Society

of Telegraph Engineers and Electricians, Sir Charles T. Bright was elected president, the new vice-president being Mr. W. Crookes, F.R.S., and the new Members of Council, Major C. F. C. Beresford, Dr. J. H. Gladstone, Mr. H. R. Kempe, Sir D. Salomons, Bart., Messrs. J. Brockie, Colin Brodie, and C. H. B. Patey.

In the course of the discussion which followed the reading of Major-General Webber's paper on "Glow-lamps, their Use and Manufacture" at the Society of Arts last week, Mr. W. H. Preece said that the term "glow-lamp" ought to be generally adopted; but Prof. Ayrton thought one reason why the name "glow" had been slow in coming into use was because it suggested a feeble sort of light as compared with incandescence, which suggested a bright light. Mr. Preece complained that the lamps are too long-lived, and stated that after 500 hours a 16-candle lamp descends as a rule to about 8. He prefers a lamp which maintains constancy, and there is no mode of attaining that more effective than the use of secondary batteries.

The *Electrical World* expresses the belief that, as regards expense, cars equipped with accumulators can be run, at least, at two-thirds the cost of cars on cable roads, and there is moreover the immense advantage that each car carrying its own power is an independent unit, whereas the slightest accident to a cable paralyses the whole service. The London *Electrical Review*, however, contains a paragraph which, if the statements are borne out in practice, removes the question from electrical accumulators, as compared with steam-driven ropes or cables, for our contemporary says:—"We have just had submitted to our inspection a system of underground conductors for electrical tramways which bids fair to effect quite a revolution in the present methods of conveying the current to the motor. We can only at present say that the conductor is entirely inclosed, so as to be quite unaffected by any external influences. There is no central channel, no slots; the contacts, which are not of the rubbing kind, are out of sight and reach, they cannot wear out, and we have no hesitation in saying that it is by far the best thing of the kind which has ever been brought before our notice."

At the meeting of the Bristol Naturalists' Society last week, Mr. W. P. Mendham read a paper on the deposition of dust and smoke by electricity, in which he stated that in lead works a large part of the smoke consists of a very fine oxide and other compounds of lead, and in order to save this it has been customary to make the smoke pass through miles of flues. But lately experiments on a large scale have been made to test the value of electricity in causing a rapid subsidence of the lead-dust, and have met with some success. It is probable that the same results may be obtained in other dusty manufacturing processes. By the aid of the limelight and magic-lantern, and some ingenious apparatus specially constructed for the occasion, Mr. Mendham was enabled to illustrate his lecture very fully. In the discussion which ensued, Mr. T. Morgans remarked that in flour-mills and coal-mines it would be unwise to attempt to use electricity for precipitating the dust on account of its very inflammable nature. Mr. W. Shenstone suggested the use in such cases of water containing some hygroscopic substance, such as glycerine or treacle, to retain the dust and prevent it rising again into the air. Prof. Ramsay, the president, alluded to the fact that water containing deliquescent salts had been tried. Thus, in Paris, some years ago, a solution of calcium chloride had been used to water the roads, in the hope that the salt would remain moist and prevent dust being formed. But it was found that in very hot weather the salt became dry, and itself formed a dust so irritating that its use had to be abandoned. He further stated that in Hall's leadworks at Shirehampton the lead dust is most effectually retained by causing the smoke to pass through thick flannel bags—a process much less expensive than the use of electricity would be.

Mr. Harold B. Dixon, F.R.S., Fellow of Balliol College, Oxford, has been appointed Professor of Chemistry and Director of the Chemical Laboratories in Owens College, Manchester.

Mr. W. Fawcett having been appointed director of the public gardens and plantations in Jamaica, a vacancy has been occasioned in the botanical staff of the British Museum.

The Minister of French Postal Telegraphy has sent to Brussels a delegate to arrange for establishing a telephonic line between Paris and that city. The price for the use of the telephone will be 5f. for a period of five minutes. It is the first step on record towards an international telephonic system.

The purity of Alpine air has been demonstrated by Prof. Tyndall and others, and a similar claim has been made for the air of the Mid-Atlantic. Lecturing recently on the action of micro-organisms on surgical wounds, Prof. F. S. Dennis, of New York, stated that during his last trip across the Atlantic he made some experiments to test the purity of the air about 1,000 miles from land. He employed capsules of sterilised gelatine, and exposed them for fifteen minutes. One capsule was exposed in the state room upon the main deck of the steamer. Within eighteen hours over 500 points of infection had developed. Two capsules exposed in a similar manner in a cabin on the promenade deck, where the circulation of air was free, showed five or six points of infection each ten days afterwards. A capsule exposed over the bow of the ship was found to be entirely uncontaminated.

A meeting was held at University College, Liverpool, last week to consider the proposed rules for the Liverpool Biological Society, which were adopted after a little discussion. The annual subscription will be one guinea, with an entrance fee of 10s. 6d.; student members or associates paying 5s. per annum. The meetings will probably be held on Saturday evenings, in University College; tea at 6.30; chair to be taken at 7 o'clock. The first meeting will take place on the third Saturday in January (15th), and it will be open to the public. There will then be delivered the presidential address, and the night for future meetings will be ultimately settled. No entrance fee will be charged until October, 1887, when the second year begins, for the sessions of the society will run along with the terms of the university, as the meetings are to be held in the college building and the university professors form an important part of the society. The scope of the society is very wide, including zoology, botany, palæontology, anatomy, physiology, and embryology; and the members who have already joined fairly represent these various branches of biological investigation. It is proposed to hold meetings fortnightly during the session from October to March, and then prosecute outdoor researches during the summer months.

In announcing the list of papers to be read at the autumn meeting of the Iron and Steel Institute on p. 60, we included one "On the Treatment of High-class Tool Steel," by Mr. A. Jacobs, of Sheffield. That paper was not read, because the "editing committee" did not think it suitable. Mr. Jacobs has accordingly published it (Sheffield: Pawson and Brailsford) with the correspondence that passed between him and the secretary of the Institute.

FROM a study of 32 years' observations of thunderstorms in the Vienna region, Dr. Hann finds that there is a double maximum of frequency. The greatest number occur in the first half of June, the second smaller maximum is in the end of July; between these is a secondary minimum. (Thunderstorms hardly ever occur in winter.) This agrees with observations in Munich. In Brussels most thunderstorms occur in the second halves of June and July. The daily period in Vienna shows a chief maximum about 3.20 p.m., and a secondary one at 1.2 a.m. The spring and summer storms come mostly from the east and south-east, and seem to belong to Mediterranean depressions, coming up from the Adriatic, as those of late summer seem to be on the south or south-east border of Atlantic depressions.

Jumbo's Measures.—The "mighty heart" of this deceased elephant weighed 40lb., and he measured from the sole of the forefoot to the top of the back between the shoulders 12ft.; his greatest circumference was 18ft.; his head, behind the eyes, had a circumference of 10ft. 4in.; the circumference of the forefoot was 5ft. 7in.; the length of trunk 5ft. 11in.; and the greatest width of ear 5ft. 5in.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the EDITOR *of he* ENGLISH MECHANIC, *332, Strand, W.C.*

All Cheques and Post-office Orders to be made payable to J. PASSMORE EDWARDS.

*** *In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks, a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

STELLAR AND NEBULAR PHOTOGRAPHS—"THE COMPANION TO THE OBSERVATORY" FOR 1887 — THE REAL WORK OF AN ASTRONOMER—EDIBLE VERMIN—KEEPING PIGS IN TOWNS—SYMPATHETIC VIBRATION —PHOSPHORESCENT INSECT—RULES OF GRAMMAR — STARS VISIBLE FROM THE BOTTOM OF A WELL—RANGE OF THE BAROMETER—THE RISING AND SETTING OF A STAR AS SEEN FROM POINTS ON THE EQUATOR DISTANT 180° — AXIAL ROTATION OF A BUILDING ON THE EARTH—DOES IT BOIL ?

[26591.]—SINCE writing the second paragraph of letter 26544 (p. 300), I have had an opportunity of inspecting two cyanotypes by M. E. von Gothard, from stellar photographs which he has taken, and, as one of them represents the glorious "Sword-handle in Perseus" (H 33 and 34), of comparing it with the photograph by the MM. Henry Frères of the same region. M. von Gothard's print is, as nearly as may be, on a scale of one half of that of the MM. Henry; but it is curious and instructive to note how numerous are the extremely minute stars identifiable upon them. Small, however, as M. von Gothard's star discs are, they lack that extraordinary approach to perfect circularity which forms such a distinguishing characteristic in the marvellous Parisian charts. The second cyanotype of which I have spoken is a very remarkable one, representing as it does the Ring Nebula in Lyra (M 57). Its major axis in the print measures just ·08in.; but it shows that the light of the ring is far from being equable, while the minute star following it is most distinctly imprinted on the plate. This power of rendering extremely minute points of light visible appears to me to be one of the most valuable which celestial photography has conferred upon us.

I spoke in letter 25330 (Vol. XLII. p. 489) of a new calendar and ephemeris for the astronomical amateur, which had just come out under the title of a *Companion to the Observatory*. As I write, the second issue of this really valuable little book lies before me; and I can only extend to it all the commendation which I bestowed upon the first annual part. It contains every one of the excellences which distinguished that, and exhibits one or two improvements besides. Imprimis, the Longitude of the Moon's Terminator is given for each day—a boon to the young selenographer—for whose benefit, too, the co-ordinates of about 100 of the principal lunar formations are given. Next, the whole of the phenomena of Jupiter's satellites are tabulated, and not merely the eclipses. These additions have involved the suppression of the lists of "Remarkable Nebulæ" and "Noteworthy Double Stars," a matter of very little moment to any one who has Clark and Sadler's "Star Guide" to refer to. Last, but not least, the editors have introduced a most sensible innovation in their table of Occultations of the Stars by the Moon by reckoning the angles of disappearance and reappearance from the *true* north point of the Moon round the E., S., and W., just as in measuring the position angle of a double star. Why such last-named angle should be measured from the bottom of the circle of reference in a direction contrary to that in which the hands of a watch travel, and that of a point on the Moon's limb from the top of the circle in the same way that watch hands go round the watch-face, it is simply impossible to say;—nothing but the pig-headed scientific Toryism of the institution in Verulam-buildings affording the slightest explanation of the difference. Perhaps now that this improvement has been initiated by Messrs. Maunder, Downing, and Lewis, it may find its way into the *Nautical Almanac*—whoever lives to see it.

The mention of the *Observatory* suggests to me to recommend the perusal, in the current number of that serial, of a report of an address delivered at the laying of the corner-stone of the new Astronomical Observatory at Carleton College, Northfield, U.S., by Miss Mary Bird, the assistant in mathematics and astronomy. I would especially advise all those to read it who picture to themselves astronomers lying luxuriously on their backs on handsomely upholstered sofas of the last degree of mechanical refinement and ingenuity, and gazing on Lunar detail, the wonders of the Saturnian system, or the clusters in Perseus, Cygnus, and Lyra, in a warm, comfortable, and convenient apartment. A better or more truthful description of the mere "grind" of ordinary observatory work it would be difficult to find anywhere.

As Mr. Stanley Smith (letter 26561, p. 304), does not seem to be, in American parlance, "nasty particular" what he eats, he might, I think, try squirrel with advantage. I had one, which I had shot, cooked one day; albeit, I had not the pluck to taste it. A gentleman more courageous in this respect than myself did, however, eat some, and his verdict was that it was "as delicate as any chicken" he had ever tasted. Gipsies cook hedgehogs by rolling them up just as they are in clay and inserting this in their camp fire. When cooked, the spines, skin, and all come off in the clay, leaving the white meat perfectly clean and free from all impurity.

The friend of "One Willing to Learn" (query 61050, p. 311) only spoke the bald literal truth when he told him that he could at any time obtain the removal of pigs kept in a town under such circumstances as your correspondent describes—always supposing that the swine are a nuisance; and this complainant must prove. But local boards have large powers in the way of making by-laws, and it was held in the case of the Wanstead Local Board v. Wooster that a by-law prohibiting any occupier of a house in a populous town keeping pigs within *one hundred yards* from a dwelling-house was reasonable and valid. The inspector of nuisances, or his employers, would proceed under 38 and 39 Vict. c. 55, s. 47 summarily before a magistrate. If he refused or neglected to take steps, and the neighbours suffered from the presence of the pigs, then I think that their owner would be indictable at common law for misdemeanour in creating a public nuisance. If "One Willing to Learn" is resident within the jurisdiction of an urban or rural sanitary authority, he had better get a copy of their by-laws and study it.

In reply to query 61077 (p. 312), a great deal depends upon the material of which the wall is composed. He would be a long time, for example, in starting a clock in beat by the aid of a synchronously-going one, were both attached to a wall of damp clay or sand.

The insect—or more accurately, myriapod—seen by "W. E. D." (query 61091, p. 312) was the familiar Scolopendra electrica. As it generally lives in holes its light is not so often seen as that of the common glow-worm: but it may be sometimes found in potting-sheds and such places. Generally, when it crawls along a path it leaves a phosphorescent trail behind it. Some of the foreign sorts of Scolopendra are poisonous; but our little British species is quite harmless, though not very inviting to look at.

As "Doctor Medicinæ" (query 61099, p. 313) invites the opinion of your readers generally as to the correctness or incorrectness of such a phrase as "It is me," I, as one of them, would merely say humbly that it seems to me not only ungrammatical, but positively cacophanous. I would certainly join issue with him on the question of this solecism being a "custom." That, I would venture to assert, depends largely upon the social rank of the utterers. I can only speak for people in the position of those among whom I live and mix, and assuredly they do *not* say "It is me," but invariably "It is I." See Matthew xiv. 27, Mark vi. 50, John vi. 20, &c. I should like "D. M.'s" authority for the assertion that the best authors employed the expression "You was," "in the latter part of the 18th century," save as putting it into the mouths of characters in plays and novels. A single example from either Johnson or Goldsmith will suffice. Having said which, I may add, however, that with the concluding clause of your correspondent's query I am entirely in accord; believing that grammar was made for man—certainly not man for grammar.

Query 61101 (p. 313) is rather vague, because the only stars visible from the bottom of a well would be the bright ones which in these latitudes are near the zenith at their meridian transit, such as α Cassiopeiæ, α Persei, Capella, γ Ursæ Majoris, γ Draconis, or α Cygni; while in the case of a total solar eclipse probably every star of the first magnitude—and even conceivably a few of the second—which happened to be above the horizon might be discerned. What stars these would be would, *ex necessitate*, depend upon the time of year at which the eclipse happened.

In reply to the first question contained in letter 26583 (p. 325), I have had the mercury in a standard barometer in my hall as high as 30·672in. (this was on Jan. 17, 1882), while on Wednesday night last, at 12 o'clock, it registered 28·210in., and was even then sinking. It stood at 30·466in. at 9 a.m. on Nov. 24 ult. Between 9 p.m. on Dec. 7 and 9 a.m. on Dec. 8 (i.e., in 12 hours) it fell 0·958in. "M. C. B." will probably read something of the disastrous gale which accompanied and followed this.

With reference to query No. 2, of course a star which would be rising to an observer on the Equator, would be setting to another man removed from the first by 180° of longitude; and equally, of course, refraction would, so to speak, cause such rising and setting to overlap—in other words, calling the first observer A, and the second B, A will see the star some 2m. 19s. before it is above his geometrical horizon, and B for the same time after it has sunk below his. Hence, it will be visible to both simultaneously for 4min. 38sec., or thereabouts.

The third question put by "M. C. B." is not a very easy one to answer definitely; but, of course, a building situated in latitude 45° would describe a mean path about the earth's axis, between one situated at the Equator and another on the Pole. This is a type of query eminently calculated to "let in" those gentlemen who insist that the moon has no axial rotation at all.

"Weald" (query 61145, p. 333) is labouring under a slight misapprehension. Vapour is given off by water at all temperatures between its freezing and boiling-points. Say that it is heated to 65° Fahrenheit, and the vessel containing it is taken into a room of which the temperature is 34°; then will the invisible vapour become converted into minute vesicles of water by condensation, and the water will "steam." Perhaps a very simple experiment may suffice to convince "Weald" that water is always giving off vapour in a gaseous form. It is simply to fill a teacup with it, and place the cup out in the middle of a field on a fine summer day. He will find that the contents of the cup have very materially shrunk by eventide.

A Fellow of the Royal Astronomical Society.

SIRIUS.

[26592.]—As the report in the ENGLISH MECHANIC for November 19th of Mr. Gore's interesting paper did not give either the value of the parallax he used, or the elements of the orbit of Sirius employed, I was unable to account for the discrepancy between Auwers and himself. Since then I have, of course, read his paper, and equally, of course, I have found his figures correct, assuming the parallax, semi-axis-major, and period which he gives. I would remark, however, that Henderson does *not* give a parallax of 0·150″, but 0·23″; while Abbe gives from Maclear's much more numerous and trustworthy observations from 1856 to 1863 with the Cape Transit circle (nearly a facsimile of that at Greenwich) 0·27″. With this parallax, if the mean distance of the *comes* is not greater than 8·31″, the mass of the system is not above twelve times the solar mass. Henderson's observations were made with the old mural circle. Gyldén's parallax of 0·193″ (*Bulletin de l'Acad. de St. Pétersbourg*, VII. p. 365) is the result of a discussion of the observations of Maclear and his assistant from August, 1836, to January, 1838. Auwers' orbit is founded on the observed irregularities of R.A. and Decl., and with Dunér's correction to the angles it seems to satisfy the observations from 1862 to 1882 fairly well. I give the elements obtained by Auwers, Plummer, Colbert, and Mann for comparison. There is an interesting note by Mr. Plummer on the "Motion of the Companion of Sirius" in *Monthly Notices* XLII. p. 56.

	Auwers.	Plummer. (Elements A)	Colbert.	Mann.
T	1843·275	1891·51		1898·182
☊ (1825·0)	61° 57·8′	48° 46′	42·4°	10·2°

i	47° 8·7′	55° 0′	57·1°	53°
e	0·6148	0·5046	0·58	0·7515
a	2·3307″	8·32″	8·41″	8·31″
P.	49·399yrs.	50yrs.	49·6yrs.	49·46yrs.

$\mu = 7{\cdot}26°$

Mr. Gore will find Auwers's elaborate investigation in *Publicationen der Ast. Gesell.* No. VII. The pos. angle of the *comes* is probably now about 24°, and the distance 6·5″. It will soon be getting a very difficult object, even with the great refractors of the present day; but in 1882 it is said to have been seen at Baltimore with only a $4\frac{1}{10}$in. refractor, and in 1883 with a 5in. On the 2nd of December, 1882, the companion was seen by Mr. Todd with the 12in. refractor at Mount Hamilton "as readily as a satellite of Jupiter."

December 11. **H. Sadler.**

V CYGNI.

[26593.]—In answer to Mr. I. W. Ward's letter (26570, p. 322), I herewith send the additional observations of Mr. Birmingham, taken from his MS., and those of my own up to the present date:—

1882.	May 28	8·0 +	Birmingham
	29	8·0 +	"
	June 4	8·0	"
	Nov. 6	10 – 10·5	"
	13	Larger	"
	Dec. 6	8·8 – 9·0	"
	29	Smaller, not over 11	"
1883.	Jan. 7	10·0	"
	Feb. 3	10·2	"
	Nov. 13	8·0	"
	Dec. 6	9 – 9·5	"
1885.	Dec. 1	8·5	Espin $17\frac{1}{4}$in. equatorial
	15	8·7	"
	25	8·3	"
1886.	Jan. 4	8·2	"
	15	8·3	"
	18	8·0	"
1886.	May 6	10·0	"
	Sept. 14	11·5	"
	Nov. 17	11·0	"

Mr. Ward's suspicion that there are are two maxima would seem to be the actual fact. I should have placed the maximum either at 1886, Jan. 1st, or 1886, Jan. 18th. We may certainly fix a maximum on 1882, May 29, and allowing three maxima to have taken place, we should have from 1882, May 29th, to 1886, Jan. 1st.

$$P = 440 \text{ days} \pm$$
$$V \quad 8{\cdot}0 - 12{\cdot}0$$
Epoch 1886, Jan. 1st.

We should thus have for the next maximum the middle of March next, or March 18, with a smaller maximum a month previously. Mr. Baxendell's estimate of maximum magnitude is evidently a whole magnitude at least too small.

T. E. Espin.

ASTRONOMICAL—α ARIETIS—CORRECTION—A CLEFT.

[26594.]—My sketch of this group is wrong. D is to be brought ¼th of the distance nearer to α, and G half the distance. It is nearly on the same parallel with D. C, F, D form an isosceles triangle, having C D for its base. Line 8, after "C" a "full stop." Line 13, for "G" read "C." A fine cleft was seen the 10th inst., crossing from N. to S. A ring plain near Vasco da Gama on the N.W., which seems to answer to *e* of Beer and Mädler. Good libration is necessary to see it well.

C. M. Gaudibert.

COMET *f*, 1886.

[26595.]—I am very pleased to see that my letter on p. 301 has resulted in the publication of "Excelsior's" interesting description (letter 26572, p. 322) of his observation of this comet on Dec. 6th. I would like, however, to point out that your correspondent, in attributing to me a mistake I have not made, himself falls into error. The shorter of the two tails was, and, of course, still is, on the *preceding* side of the nucleus, as seen with the inverting eyepiece usually employed with an astronomical telescope. "Excelsior" probably made use of a terrestrial eyepiece to view the comet with.

With regard to his second point of difference with me, I would just remark that, as is well known to all observers of comets, these bodies frequently undergo striking and rapid changes of form as they approach the sun; getting brighter as they near that luminary, details of structure previously invisible or non-existent, begin to be seen. It thus follows that a description of a comet having reference to a particular date does not as a rule hold good for its appearance as seen on some other day. For instance, in my description of this comet as seen by me on Nov. 22, I particularly mention that no nebulosity was visible with my instrument, in the space between the two tails; but on the occasion of my last observing the comet with the same telescope, viz., Dec. 5, I found the space between the tails filled up with very faint cometary matter. Therefore, as "Excelsior's" remarks apply to the comet as seen by him on Dec. 6, he will at once see that he had very good reason for not seeing it as I described it in my last letter.

B. J. Hopkins.

Forest Gate, E., Dec. 14.

L. A. S. CIRCULAR No. 11—METEORS WITH CURVED PATHS—M 31—M 32—COMET BARNARD—B 277—U CYGNI —V CYGNI.

[26596.]—In your reproduction upon p. 258 of the L. A. S. Circular No. 11, I observe that the epoch of the places is given as "1885." This is a misprint for 1855. This misprint indicates that other copies of these Circulars are like those that come to myself—so faint as only to be deciphered with considerable difficulty. I take notice of this matter in order to draw attention to the difficulty

of making out the Circulars with certainty, and of suggesting that copies be printed a little more plainly.

I notice that Mr. Ranyard spoke at the recent meeting of the R. A. S. about meteors with *curved* paths. I have seen several of these. One was a Perseid, seen on Aug. 10, 1881. It was a very fine meteor. To my note is added, "Path somewhat curved at termination." My notes contain mention of several other meteors with similarly abnormal paths, perhaps seven or eight altogether. The most curious case was one in which a slightly curved path was terminated by a sharp turn, so that the line indicating the path in my sketch looks as though it were ended by a little hook. In a third case, I have a note to the effect that the path, a short one, was curved in the manner of a scimitar. There could be no mistake here, for the meteor, which was a brilliant one, travelled slowly, and left a trail which marked its course. The radiant of the former would appear to be that near Polaris, belonging to the stream mentioned under dates Sept. 21 to 25 in the list of meteor dates under September in the *Companion to the Observatory*.

In connection with the reported continued change in M. 31, I may say that the few times recently when I have seen this object, I have never been able to detect anything the least like the *Nova*. The suggestion, however, which the asserted reappearance conveys is well worth attending to, and it is to be hoped that the nebula will be watched to discover if any changes are really occurring. On November 1st I made this note of its appearance: "Beautiful; filmy. Central condensation not at all marked. Could be traced a great way *n.f.* in finder." It seemed to me on this occasion that the nebula was more *filmy* than before.

As to M. 32, I see that a correspondent in the *L. A. S. Journal* has been drawing attention to "a stellar appearance in it," which he had not noticed before. In a letter in "Ours" about the Nova Andromedæ, I mentioned that on Sept. 17, 1885, M. 32 seemed to be very bright. The following are some observations of this nebula, made with my 3¼in. Wray.

1884, Oct. 11.—E.p. 45. Small; round; very bright; cometary in aspect. Air pretty clear.

1885, Sept. —12. E.p's. 45 and 145. As before. Small; round; bright; definite. Equally condensed in centre. Air very clear.

Sept. 17.—E.p's. 45 and 145. With both powers nucleus seems unusually bright and definite. Moonlight. Conditions poor.

Sept. 26.—Ep. 45. The nucleus again seemed very bright. Conditions poor.

Sept. 30.—45 and 145. This nebula was seen to be bright in the centre. Def. good; but air not clear.

1886, January 5.—45. Very bright and definite. Conditions fairly good.

Nov. 1.—145. Small; bright; definite. Conditions fairly good.

If the nucleus of this nebula should turn out to be variable in distinctness, it would be a very remarkable fact. It is, of course, excessively improbable that the nucleus of a star cluster should be variable in brightness; for this would imply, either, that there was *one* star within it so much brighter than its companions that variation in it affected the magnitude of the united light, or that a number of the component stars were variable; and in a similar range and period: and neither supposition is very probable. But the conjecture might well be hazarded that the nucleus of such a cluster as M 32 might well be variable in *distinctness*, for it is plain from the spectrum that the light from the cluster has to pass through an absorbing medium; and if this medium should vary in thickness or in absorbing power, the visibility of the nebula, and consequently the distinctness of the nucleus, would naturally be affected. In this way, we might learn something about the phenomena and changes of the dark, absorbing, masses which may exist in space.

Comet Barnard has been an exceedingly fine object, and I do not think it speaks altogether well for the enterprise of some of "ours" that it has not been more fully commented upon. It cannot have been much seen, for I noticed that the *Athenæum* announced it as being visible to the naked eye (of the 5th mag., I think it was said) at a time when it was really very bright. I have found the longer tail at least 12° long, and the head large and very luminous, and fully as bright as a 3rd mag. star. I will communicate further on this matter; but meanwhile would inquire if the spectrum has been observed?

B 277 has been at a maximum, and is at present a magnificent object. Its colour is full scarlet. On the 17th ult. it was full 7th mag. and a striking object. Since that date it has decreased.

I am much obliged to "F.R.A.S." for the trouble he has taken to try and answer my question about U Cygni; but I am not surprised that nothing is to be found in the authorities he names, seeing that Birmingham speaks of having "discovered" this object. The stars are in the *Durchmusterung*, therefore they must have been there to have been observed; and it is thus made clearer how strange a thing it is that so very splendid a pair should have escaped detection so long. It is not likely that searches in the region were *always* made at a date of *minimum* of the red star; and yet it appears difficult to account for so strange an overlook, for it is hazardous to assume that the exceeding richness of the tints is only of recent date. I hope we may hear more of the matter; and hope, too, that more observations will be forthcoming.

As to V Cygni, I am much obliged to Mr. Maunder for his remarks, and will certainly try to get the observations he speaks of as being useful. There is a valuable letter *re* V Cygni, by Mr. Ward, in "Ours" for Nov. 6, 1885. I am obliged, too, for the information as to the spectrum of U Cygni. It seems difficult to get specific information as to the spectra of individual stars. Is there any work giving anything like a complete list? Perhaps Mr. Maunder would be kind enough to tell me the spectra of R Boötis, R Arietis, T Cancri, R Sculptoris, and S Orionis, and also of Messier 15. I wish them, in order to add to some comparative tables.

S. Maitland Baird Gemmill.

HORIZONTAL WIND POWER.

[26597.]—SEEING on page 267, Vol. XLIV., a favourable notice of my horizontal wind power, it occurs to me that this would be just the thing to drive a dynamo to store up electricity for power or light, as the machine may be made cheaply, and safe in any storm, with very little attendance; and as I think I did not give any description of the stationary engine, but only of the portable ones used for ploughing, &c., I will endeavour to describe one which will be safe, cheap, and of considerable power.

The principle of the machine is this: that each sail is placed at a right angle to the arm that carries it, and if moved from that position it presses a spring that acts to restore it to its former position. The larger and wider the sail, the more powerful the spring required, and the larger the sweep of the end of the sail; therefore, for handiness and safety, the narrower and more numerous the sails the better.

For a cheap and strong power for driving dynamos, &c.—for the shaft I would have a long balk of deal timber, square, and tapering to the top, as they are imported. The bottom end should be rounded for 6in. up it, but left the full size it will be when the corners are rounded off—and this shall be the bearing on which it shall turn—in an iron socket made fast in brickwork. On the lower end, and temporarily fixed at 3ft. or 4ft. from the bottom, should be placed a wheel, which is to give off the power of the machine. Above this, and at a convenient height, should be fixed a casting of iron having twelve sockets, to hold the ends of twelve arms; and above this, and at a proper height to receive the sails, should be fixed a second casting to hold the ends of twelve other arms, and above this and on the top of the shaft a socket in which the shaft should turn, it being rounded off as at the bottom for that purpose. The lower arms should be of yellow deal, 3 by 4½, and 14ft. long. Directly over these should be twelve lighter arms of the same length, to carry the tops of the sails, the bottom ends of which turn on the lower arms.

The lower arms should be supported near their outer ends by tension rods of strong galvanised wire, such as is used for fencing, made fast to the shaft; the top arms, in like manner, by tension rods to the shaft above them. On the top side of the lower arms, and on the underside of the upper ones should be bored holes to receive the spindles in which the sails turn. The arms are to have their deep sides perpendicular. Between the outer ends of each two arms should be a rail, 4½ by 3, to connect them together, and also to carry sails. These rails are also supported by tension rods, like the arms; and above them should be other rails to carry the upper ends of the sails. The sails, of which there are to be 60, are made of half a 14ft. yellow deal, cut diagonally from ½n. on one side to ½in. on the other, which will make two sails 2½in. thick at one side, and ½in. thick at the other, and 9in. wide. The top and bottom ends of each sail should be sawn off from the thin side to 2½in. of the thick side, leaving a piece to form a spindle on which the sail is to turn.

Holes in the end of each arm, and also in the rails between the arms, are made to receive these spindles, and pieces of sheet-iron placed in them for the spindles to turn on. The spindles on the top of the sails should be shorter than those on the bottom, as the springs will be fixed to the sails at the bottom, and they have more strain on them there.

As the sails will turn on their thick sides, the wind will have more power to turn them from their positions than if they turned on a spindle near the middle, so that the spring must be strong; they may be made of ash fixed to the lower end and on the outside of the sail, and just so long as to turn without touching the next sail; this will be about 27in. long, and by being fixed to the sail, 18in. will be the length of the active part of the spring.

To support the other part of the spring a second rail must be fixed inside the outer one, much slighter than the outer rail, as it will only carry the springs. This second part of the spring will be just so long as for its end to meet the end of the first when the sail is in its proper position of a right angle to the arm.

A cord to run through the end of the second spring will be made fast to the end of the first spring, and tie the two together when the cord is tight; but set the sail at liberty to turn any way when the cord is slack; and if the cord is brought to a pulley on the shaft, and then down it, the sails may be put into action, or released to turn edge to wind by tightening or loosening this cord. If the cords of the 60 sails are fixed to a ring to slide on the shaft, all the sails may be released or fixed to the springs at once.

Five sails will be placed in each division, one on the arm and the four others on the rails between them, and will turn one between the arms, and the other four between the bottom rail and the other rail fixed between the upper arms to carry the tops of the sails. Each sail will have springs as described, and cords from them to the shaft.

The shaft, which will be so long as to be considerably above the tops of the sails, will be supported by tension rods, from the top socket in which it turns to the ground around it. If not long enough for the tension rods to clear the upper arms, they may be carried over poles fixed in the ground just outside the lower arms, and thence to the ground.

As the 60 sails will have a surface of nearly 600ft., a very considerable power will be obtained at small expense. For the 60 sails, will require:

	30	deals 14ft.			
The lower arm	6	,,			
The upper (3 by 3)........	4	,,			
The lower rail	3	,,			
The upper rail	2	,,			
The stays for upper arm	1	,,			
	—		£	s.	d.
	46 at 2s..............		4	12	0
The balk, say			1	0	0
Iron work (except wheel)			4	8	0
			£10	0	0

Say, an equal sum for workmanship, and about £20 for the whole.

A great source of power in these engines is that each sail coming up to the wind is pressed inside the circle described by its spindle, and flies outside of it when going down the wind, and is in the best position for the wind to drive it as well as having increased leverage on the arm and shaft, and as it presses harder on the spring the spring yields more in that position, and the sail exposes greater surface to the wind than when coming up to it.

If machines of this sort were placed on hills and waste places, such as commons, &c., I think we should get our towns lighted cheaply.

Seeing the inquiry of Mr. Browne on page 303 of the 3rd December, as to the power, &c., of the horizontal wind power referred to by Mr. Collingridge, I will supplement my letter by saying that the mill I describe will give a power of ten horses when the wind presses 2lb. per foot on the sails. The best total width of sail I found after experiment was about one-third more than the diameter of the circle described by the sails, so that the 60 sails, 9in. wide, will be 45ft., and the diameter of the circle 30ft.

In the portable mills I used for ploughing, the sails were six in number, each being 6ft. wide and 12ft. high, and the arms 12ft. long, and I have had seven ploughs on the rope at one and the same time, the rope being drawn by two mills, and as the soil was stiff and heavy, three horses were always used on one plough, so that the two mills gave off 20 H.P. at that time; but the wind was a good stiff breeze. Our usual number was two ploughs to each mill.

Philip Vallance.

[26598.]—AFTER Mr. Raymond Browne had made sundry criticisms (letter 26557) on my reply to query 60817, he says, "And there he leaves us." If Mr. B. would kindly refer to the original query he will find that it was not my business to go further than answer the several points raised, which I submit I have done.

With respect to the inquiries Mr. B. has favoured me with, I may say the largest model I have made on this horizontal plan was ½H.P., given on friction brake on its vertical axle (not having the room to put up a large mill, I have to be contented with steam-power, its cost of fuel, and its attendance). Experiments show that a fair proportion is: Length of arms, 8ft. from centre; sails, 7ft. high and 6ft. wide, kept by a spiral spring at right angles to the arm, when not acted on by the wind: such a size will give in a wind of 2lb. to the square foot 4H.P.

If anyone interested in wind-power will refer to

Mr. P. Vallance's description of his patent (ENGLISH MECHANIC, Vol. X. p. 631), it will save much unnecessary description, as the chief improvement I have made is to adapt the louvre boards of the modern vertical mill, controlled by a governor, to Mr. Vallance's solid sail form, and thereby getting nearly the same steady speed, whatever work, and whatever wind.

Albert Collingridge.

CUTTER BAR.

[26599.]—I REPLY to letter 26584. The small steel which is rolled to suit the Haydon tool-holders is easily tempered, after it has been shaped, either filed or ground. A blowpipe and an ordinary gas-burner suffice for this purpose.

As these small tools are so portable, it is a good plan to sharpen several at a time. Mushet's steel cannot be filed, and this will to many be an objection. The experiment shall be tried with Mushet; and perhaps "Evod" will give the result of his test, as it will interest many.

M. A. Bear.

Britannia Works, Colchester.

MOVEMENTS OF DIATOMS.

[26600.]—IN answer to "Londiniensis" (26590), I beg to say that, whilst disclaiming any title to be regarded as an authority on the subject, no theory as to the source of motion of diatoms that I have met with seems satisfactory. Although I have studied the living forms for years, I am quite unable to account for the marvellous phenomenon.

By Prof. W. Smith it is referred to forces operating within each frustule and originating in the vital operations of growth which may cause the surrounding fluid to be drawn through one set of apertures and expelled through another.

The existence of apertures is clearly established, and is exemplified in the mineralised forms I had the good fortune to find in the London clay; but granting this, if the motion be the result of aqueous currents, how is it that one does not see some evidence of this outside the diatom? If anyone with better apparatus than mine has seen small particles influenced by the supposed endosmose and exosmose, I shall be glad to receive information.

Some diatom motion that I have observed has been clearly attributable to the superior attractive force of an associated group lying near, and I have sometimes thought that the molecular movement first observed by Dr. Robert Brown in 1827 should be taken into account.

Still, as far as I know, the problem as to the motive power has yet to be solved. The movements certainly are wonderful, and when watching the more active forms, it is hard to disposses oneself of the idea that they are sentient organisms. Especially is this the case with *Bacillaria paradoxa*, which, being well known, need not be described.

In conclusion, I would point out that the power of motion seems to be largely dependent upon form. The discoidal and triangular diatoms are generally, if not always, immobile; those that are boat-shaped move freely, and the most active are those of linear outline.

I may briefly add that I have quite recently met with some of these last-mentioned in the London clay, all that I had previously found in that formation having been either discoidal or triangular.

W. H. Shrubsole.

INCANDESCENT LAMPS—TO MR. SHIPPEY.

[26601.]—PRESSURE of business has prevented me replying to the questions asked by "Iota" on page 285 ere this. I may now say in answer to question (1) That there is as yet no scientific discussion as to the real cause of the "halo" effects which sometimes surround a carbon filament, but to create which the lamp must be considerably over-incandesced; but even then this photospheric effect does not occur in all carbon conductors alike, even when run at the same pressure of E.M.F.

Filaments made of cotton threads, felt, or carbonised paper, if not properly baked, are apt to show this optical delusion far more than filaments made from bamboo, Mexican fibre, rhea grass, gold-beater's skin, or the cellulose materials used in lamp manufacture, simply because filaments made from the latter materials are less porous, and therefore can be made more dense during preparation, and by the several improved methods and secret processes now applied in the manufacture of carbon conductors used in incandescent lamps, this to a great extent is overcome.

My own opinion is that the term "scintillation," as used by "Iota," is not a correct word, as no carbon conductor (wrongly described by some inventors as a filament) ever emits any sparks whatever; it being simply a photospheric or "halo" effect caused by the resistance and brought about by the nature of the carbon conductors used, which effect I have noticed shows itself more plainly in a lamp with a bad vacuum, probably caused by the minute molecules floating about in the bulb, which are being absorbed, and again emitted according to the temperature, whereas in lamps of very high resistance made with cotton or paper filaments, I think the effect is then caused by the unevenness of the materials used, which emit something from the innumerable points of fluff thereon, also by any surplus flow of current through the materials above described, all of which slightly expand when the lamp is overrun or strained beyond the actual voltage or normal candle-power. There are probably other causes, which is a subject well worthy of research. My own experiments have taught me that a properly-baked carbon when treated by the bisulphide of carbon process is less porous, far more dense, and stronger than filaments made by and under the so-called flashing processes adopted by Edison and Swan. I find that when made under the bisulphide treatment they are more refractory, will stand a higher pressure, consequently, being harder, will allow a greater flow of current to pass through the carbon conductor, and this without producing the "halo" effect frequently noticed in lamps when overrun. Many beautiful lamps are suddenly destroyed by inexperienced electricians switching on the full current, which, I may mention, is very detrimental to a cold filament inclosed in vacuum. I have always advised, where batteries are used, in order to prolong the life of a lamp, that it is better to arrange the cells so as to switch in an extra cell if required after the lamps have been run a short time under their normal voltage, as by this means the lamps are gently warmed, and proper expansion takes place; they are then better able to bear the full force and pressure of current flowing through the leads.

Many amateurs have also a habit of unduly switching on and off the lights merely for show, forgetting that by so doing they are damaging their lamps. This should be avoided as much as possible, as such a course is detrimental to the lamps in use. When a dynamo is used, a little resistance should always be used in the circuit, which is easily cut out when the lamps have run a short time, and are giving the full light required.

As to question (2): If the 12-volt low-resistance lamp alluded to was one of our battery lamps, it would be made according to our patent of Mexican fibre, whereas the 25-volt 10c.p. lamp, containing a fine conductor, would probably be made from "rhea grass," as used for our Standard lamps, but specially made to run 2 or 4 in series on 50 or 100-volt circuits in combination with lamps of high resistance. Candle-power is candle-power, whether produced from a 12 or 25-volt lamp; but voltage and resistance is another matter—the higher the voltage the less the ampères absorbed. It may be mentioned that some types of lamps are good for one thing but not suitable for another; for instance, the Edison lamp is of high resistance, and specially suited for central station lighting, being made of 100 to 500 ohms resistance, according to requirements, whereas the lamps manufactured and sold by my firm (under recent discussion) are of specially low resistance, say, from 3 to 20 ohms resistance according to voltage, and, consequently, would not be suitable for central station lighting, but for battery work, where a few ampères, more or less, is of no object, or for separate domestic lighting, where one has to resort to a small gas-engine to run a few lights only, either direct or by accumulators, then for these purposes I do not hesitate to say, from an economical point of view, there is nothing better than a low-resistance lamp, which, of the two, is far more difficult to make, especially when even resistances and a given voltage are required to produce same effect.

I have not made photometric measurements as to the difference of light produced from a short thick carbon conductor over that of a long, thin one of same voltage and power, but will do so when I can spare time, and will, with the Editor's permission, report the result of my tests in the pages of the "E. M."

Arthur Shippey.

PAVY'S AMMONIACAL CUPRIC SOLUTION.

[26602.]—ALL your chemical readers owe a debt of gratitude to Mr. A. H. Allen for the generous way in which he gives most valuable information. In his reply, however, to inquirers on sugar titration (letter 26549) he, unwittingly I am sure, does injustice to one of the most delicate and exact processes of sugar estimation.

Mr. Allen states that in the case of diabetic urine containing but little glucose the Pavy blue liquid cannot be employed. Yet on page 229, Vol. I., of his latest edition of "Commercial Organic Analysis" Mr. Allen shows that 1cc. of the Pavy solution equals ·0005 glucose, while in the ordinary Fehling selution 1cc. = ·005 glucose. So that, in fact, you can deal with solutions by the Pavy method that are ten times as dilute as those that the ordinary Fehling solution is used for.

I frequently use it for diabetic urine, diluting this to 10 or 20 times its volume and running it into 10 or 20cc. of the Pavy solution. It is not necessary to precipitate the albumen, since this only forms a little more ammonia (fatal to ordinary Fehling solution) and does not influence the result. It is, however, too delicate for qualitative use, for it shows the minute proportion of glucose normal to all urines.

A preliminary trial is made in a test tube with Fehling's solution, and if glucose be indicated the Pavy solution can be used for its estimation. The Pavy ammoniacal cupric solution will show ·05 per cent. of glucose in a urine, that is, half the amount quoted by Mr. Allen as the lowest indicated by any other process. The advantage of the Pavy fluid in use is that the fluid remains always transparent and clear, passing gradually from a blue to a colourless state. In the ordinary Fehling method you look through a cloud of steam at a more or less blue fluid that gets thicker and muddier each moment with red particles so that it is almost impossible to say when the blue colour disappears. Pavy solution will keep; Fehling will not. It is to be regretted that Mr. Allen, usually so exact, has in one or two other points mistaken the Pavy process in his otherwise admirable work. Particulars of the method of working, apparatus, calculation, &c., of this process, I should be happy to supply if required.

Alf. W. Stokes, Public Analyst.

TRICYCLE MATTERS.

[26603.]—THE difference in weight between 40in. and 50in. wheels is, of course, something, but not much, and I cannot assent to the assumption made by Mr. R. G. Bennett (No. 26555), p. 303, of current volume, that "the tricycle can be made so much lighter" with small wheels. The axle and framework generally to be as strong must be as heavy *cæteris paribus* in both cases—size of wheels excepted. If the increased ease of propulsion arises from the larger diameter of the steering wheel, clearly that is not in consequence, but in spite of, the smaller diameter of the driving wheels.

I thank "Doctor Medicinæ" for his suggestion, but fear that he has forgotten the impolicy of prescribing for his patient without a personal interview. Now I am old and heavy, and could no more "step off my horse without allowing it to stop" than I could "go in for" a race—my movements are more like those of the bear than the antelope. Again, I presume "D. M." would find it easier to walk up the hill without his tricycle, than to drag it up after him. Certainly I should; but pushing it up before me is quite another matter. I would rather do that than walk up without it; it is something to bear upon, and it takes my weight off my legs. Here is another instance of one man's meat being another man's poison.

Gamma Sigma.

NASMYTH'S BRASS FOUNDRY.

[26604.]—APROPOS of my article on Brass Foundry in the "Amateur Workshop," the following extract from James Nasmyth's admirable autobiography may be of interest to many of your readers:—

"I got up early in the mornings to work at my father's lathe, and I sat up late at night to do the brass castings in my bedroom. Some of this, however, I did during the day time, when not attending the university classes. The way in which I converted my bedroom into a brass foundry was as follows: I took up the carpet so that there might be nothing but the bare boards to be injured by the heat. My furnace in the grate was made of four plates of stout sheet-iron build with fire-brick corner to corner. To get the requisite sharp draught I bricked up with single bricks the front of the fireplace, leaving a hole at the back of the furnace for the short pipe just to fit into. The fuel was generally gas coke and cinders saved from the kitchen. The heat I raised was superb—a white heat, sufficient to melt in a crucible six or eight pounds of brass.

"Then I had a box of moulding sand, where the moulds were gently rammed in around the pattern previous to casting. But how did I get my brass? All the old brass works in my father's workshop drawers and boxes were laid under contribution. This brass being for the most part soft and yellow, I made it extra hard by the addition of a due proportion of tin; it was then capable of taking a pure finished edge. When I had exhausted the stock of old brass, I had to buy old copper or new in the form of ingot or tile copper; and when melted I added to it one-seventh of its weight of pure tin, which yielded the strongest alloy of the two metals. When cast into any required form this was a treat to work, so sound and close was the grain, and so durable in resisting wear and tear. This is the true bronze or gunmetal.

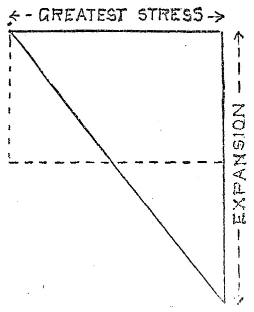
"When melted the liquid brass was let into the openings until the whole of the moulds were filled. After the metal cooled it was taken out, and when the room was sorted up no one could have known that my foundry operations had been carried on in

my bedroom. My brass foundry was right over my father's bedroom. He had forbidden me to work late at night as I did occasionally on the sly. Sometimes when I ought to have been asleep I was detected by the sound of the ramming in of the sand of the moulding boxes. On such occasions my father let me know that I was disobeying his orders, by rapping on the ceiling of his bedroom with a slight wooden rod of ten feet that he kept for measuring purposes. But I got over that difficulty by placing a bit of old carpet under my moulding boxes as a non-conductor of sound, so that no ramming could afterwards be heard. My dear mother also was afraid that I should damage my health by working so continuously" (p. 115).

J. H.

ON THE MODULUS OF ELASTICITY.

[26605.]—THE modulus of elasticity is sometimes obtained by noting the elongation produced in a rod of the material by a given tensile stress.



In this method let L = original length of the rod, l = the elongation produced by a stress of $p$lb. per square inch, then modulus of elasticity = E = $\frac{Lp}{l}$.

But as the stress p can be produced by heat as well as by mechanical force, another means of obtaining E suggests itself.

It is obvious that when a bar of metal is heated say 1°F., and first prevented from expanding in the direction of its length, and then suddenly allowed to expand, the work done by the heat can be represented by the area of a triangle as in sketch; also that it can be as well expressed as: Greatest stress × half expansion, as per dotted lines.

Again, as the linear expansion of a body is $\frac{1}{3}$ of its cubical expansion, only $\frac{1}{3}$ of the heat energy is available for doing the work of linear expansion.

Taking a bar of wrought iron, 1ft. long × 1 square inch in section to weigh 3·3703lb., specific heat of wrought iron = ·113, and expansion per degree Fahr. = ·00000676, then

$$E = \frac{3{\cdot}3703 \times {\cdot}113 \times 772 \times 2}{3 \times {\cdot}00000676} = 29{,}000{,}000\text{lb. per sq. in.}$$

nearly, which is the value usually given.

On trying the same formula with other metals, I found some to agree very well indeed with the tables; but others, lead for instance, were very far from coinciding.

By the way, E for lead is generally given as 720,000lb.; but from a table in "Ganot's Physics," it appears to be about 2,560,000lb.—much the same value as obtained by the above method.

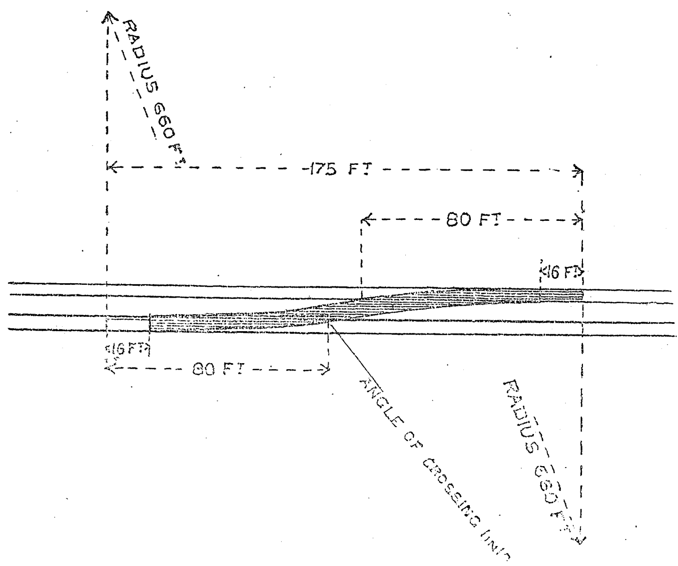
I should be glad if any reader will explain why this method does not appear to be universally true.

C. N. P.

DOUBLE-ENGINE RUNNING.

[26606.]—MR. STRETTON (p. 286, let. 26542) has done good service by writing you about the empty trains that are dragged about, particularly Scotch trains; and I hope those in authority will see the letter and act upon it. How we shall get on this winter if they don't reduce the loads I cannot tell; but we shall not be able to keep time. There is no mistake, the 800 class are a fine engine, and I don't wonder that Mr. Stretton speaks well of them; but he is rather hard on the 1667 lot. They are the only failures we have had, and when they get the new boilers, they will be all right. All our old drivers say there is nothing like an 800; but there is something in being used to an engine. Mr. Stretton was a pupil at the time when Mr. Kirtley brought out the 110, 170, and 800 classes eighteen or twenty years ago; and, although I don't think either our old drivers or Mr. Stretton are partial to them yet, we know that what one learns in early days often sticks in one's ideas. I admit that we have got ten failures; but I think we ought to set against them the number of good engines Mr. Johnson has put on our road. I have looked over the ENGLISH MECHANIC for many years back in the hope of finding a diagram of 800 class, but there is not one in your columns. Would any correspondent oblige by sending one?

Midland.



POINTS AND CROSSINGS.

[26607.]—MR. T. ATKINS (p. 329) has given us a very highly theoretical rule to lay out a cross-over-road, which he himself says would be no use to anyone without a good knowledge of mathematics.

As the reader who asked the question was a "Platelayer," I presume he will quite fail to obtain the few simple figures he wants, so I will help him as follows:—

(1) Decide where you wish one pair of points to be; (2) measure 175ft., which will give opposite end of cross-over road; (3) measure 80ft. from each point, which will give you the position of the crossings. Put in your crossings with an angle of 1 in 10, and your reverse curves with a radius of 10 chains or 660ft. Use switches 16ft. long, and you will have no trouble.

Theory is very good in its way; but "Platelayer" wants a few simple figures to enable him to perform his work, and I trust the rough drawing will assist him.

A Practical Man.

PASSENGER TRAINS AND PARTING COUPLINGS.

[26608.]—THE daily papers of Dec. 9th contained particulars of an accident in the Farringdon-street and King's-cross tunnel of the Midland Railway, which might have resulted in serious loss of life.

Accidents arising from the parting of couplings are of frequent occurrence; but so far as I am aware, no attempt has as yet been made to advise the driver when this has happened.

Happily a means, inexpensive, automatic in action, and reliable, is at hand in the coupling system now universally employed, both in passenger and luggage trains. All that is needed is a small battery in the guard's van, and a polarised magnet operating a disc fixed in some conspicuous place on the engine footplate. So long as the waggons or carriages are properly coupled up, the disc would show "All right," as a small current flowing round the polarised magnet would prevent its attracting the armature carrying the disc; but should severance of the couplings take place, the circuit completed through them would be broken, and the magnet at once pull the armature, carrying the disc to "danger," and give warning to the driver by ringing the bell.

The weight of the couplings would always insure electrical contact; but if objection be raised to this method of forming a line, any waggon or carriage could be fitted with the needful connections for, say, 2s. each, and since the return circuit would be completed through the rails, the total cost of fitting a train would not exceed 40s.

It becomes a question for serious consideration, whether upon our crowded underground and suburban lines, over which mixed trains follow each other in rapid succession, some such system should not be insisted upon. Labour would not be increased, but saved, and the driver would at once know when his waggons or carriages were properly coupled.

I am in no way interested pecuniarily in the adoption of this or any other system having the same end in view, but merely make the suggestion in order that the travelling public may know that a remedy for this very frequent class of accident exists.

Francis M. Rogers, F.C.S.

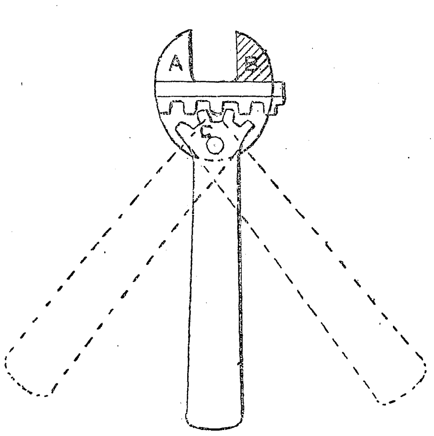
RANGE OF BAROMETER.

[26609.]—IN reply to "M. C. B." (letter 26583), I offer a few observations from my meteorological records of the last six years. During this period the highest point attained by my barometer (corrected for temperature and height above sea-level) was 30·87in. at 9 a.m. on Jan. 18, 1882; whilst the lowest, registered on the 8th of the present month at 11 p.m., was 28·02in. (similarly corrected for temperature and height). Taking this period as representative, the extreme range of the barometer in this locality amounts to about 3in. Frequently this range during 24 hours exceeds an inch, as representative of which I may mention that in the interval between 10.30 a.m. on Oct. 25, 1885, and 9.30 a.m. on the succeeding day (a period of 23 hours) the mercury fell from 30·08 to 28·97. The height of my station above sea-level is 525ft., and I may add, for the information of "M. C. B.," that its latitude and longitude are respectively 52° 30′ 23″ N. and 1° 56′ 38″ W.

Handsworth. B. A.

ADJUSTABLE SPANNERS.

[26610.]—AS you have illustrated three kinds of adjustable spanners lately in the "E. M.," we beg to send you a sketch of our patent adjustable spanner, which consists of a toothed jaw A sliding



in B, and worked by a toothed handle C. One of its chief advantages over other spanners is "that the handle can be placed almost at any angle with the jaws when they are placed at any size," by turning the handle out of gear, then placing the handle in the required position, and gearing up the jaws again. The advantage of this is obvious where nuts are awkward to get at.

Chas. Martin (pro Moore and Martin).

CONCERNING CHAMBER ORGANS.

[26611.]—IT is matter of great satisfaction to me that Mr. Audsley is able to speak as he does of my work upon the Mustel organ. I fear, however, time and distance must have lent no inconsiderable "enchantment to the view." I think, however, it is only right that I should say something as to the alleged great difficulty in playing the Mustel organ. Our friend, Mr. Audsley, much exaggerates it. I should think that it is quite as easy to play the Mustel organ with effect as his own chamber pipe organ. After a long experience of pianos, harmoniums, American organs, and pipe organs, of many sorts and conditions, I am satisfied that, instrument for instrument, the harmonium is the most difficult

of all to play really satisfactorily. But of all the harmoniums I have ever played upon, I have no hesitation whatever in saying that the Mustel is by far the easiest to play *effectively*.

Although until I saw the one I ultimately purchased I had scarcely ever seen a Mustel organ, yet, directly I put my hands upon it, I took to it as readily and as easily almost as the proverbial duckling to its water, and I fancy the experience of anyone who had the slightest musical capacity would be the same. There is nothing like the Mustel organ for *drawing out* one's musical capacity. Let those of your readers who contemplate the purchase of a Mustel organ first learn the rudiments and fingering upon any common instrument, and look forward to the Mustel when they have achieved some measure of capacity upon the smaller instrument suggested. They will then be in a better position to appreciate its marvellous beauties.

I heard the other day of a very good definition of the distinction between an American organ and a Mustel organ. I may be forgiven for repeating it. It is this: Upon the Mustel organ you may pray, sing, laugh, and, if need be, *swear*. Upon the American organ you can *pray only*.

I have regretted more than once that in reply to one of your correspondents I did not suggest to her that she should procure all the numbers of Mr. J. M. Coward's *American Organ Journal* (Metzlers). I know of no better arrangements either for the American organ or the harmonium. The selection of pieces, too, is far removed from the type so common in ordinary books of "voluntaries."

Country Solicitor.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[60432.]—**Architecture.**—If what is meant by Classic architecture be not generally understood, it would be well to explain it here. Classic, when applied to architecture, signifies, just as it does when applied to literature, what appertains to ancient Greece and Rome, and the chief characteristic of Classic architecture is the horizontal principle of construction, as opposed to the vertical tendencies of the lines in the Gothic arches and gables. We may succinctly distinguish between Gothic and Classic by describing them as what is Gothic and what is not, since whatever is not included in these two terms is very rarely practised in this country. Gothic architecture is particularly advocated and enforced amongst us by the clerical parties, and particularly by the so-called Architectural Societies of Oxford and Cambridge; but these are really archæological societies, which greatly bar the progress of architecture as a true art. There can be no doubt, however, that Gothic for secular buildings is detested and execrated by the great majority of the English people. The great bulk of Englishmen must, no doubt, loathe to contemplate the expression of monastic austerity, the hideous deformity and mortifying meanness presented to their view by those forms of Gothic which constitute what its advocates, with unblushing audacity, have designated the "national style." No one should venture to foist this ghastly architecture of the cloister and of the tomb as being most in accordance with the national taste of the English people. With all the Gothic deformities and tomb-like vaults which have sprung up of latter years amongst us, we should be quite dead-sick of the style by this time. Instead of such revolting features, we would require that our eyes should rest on buildings presenting dignity of mass in their regularity of form, artistic proportions and longitudinal extension. In point of practical requirements it would be nonsense to deny, with regard to Gothic, that the narrow lancet window is quite unsuitable for this climate; that the tower and steeple are altogether useless; that such high-pitched roofs are extravagantly expensive; and that the staircase turret with its newel staircase is a most miserable make-shift for its purpose, and even a very dangerous structure for the aged and infirm. What a contrast between the Classic entrance portico approached by a wide-spreading flight of steps, and the unutterable meanness of the entrance to the new Law Courts. The style of architecture to be adopted should always be capable of presenting the building as a whole; but this is what Gothic is altogether unable to do if the building consists of a number of halls and chambers. In such cases Gothic can only present a patchwork appearance, which is always a dilapidated appearance, and just the same as if the building were made by addition to addition at different periods of time. The Americans are a very practical people, and to America indeed we can look for exquisite examples of modern design. Now, Classic is the favourite style with the Americans. Their great Capitol at Washington — built of white marble, and covering five acres of ground—is in the Roman Corinthian style, and is modelled after the Pantheon of Rome. With regard to the very important matter of colour in architecture, it is the case that a red or deep-brown colour in the walling takes away all architectural effect from the buildings. This colour should be avoided as much as possible, if it were only to afford some variety from the constant glare of the red brickwork. It is very desirable, then, that building materials in terracotta should be made in considerable quantities in imitation of white stone, and not so much like red bricks in colour. But what is the style of the new Law Courts? Well, to be sure, a new name had to be found in order to designate this phenomenal architecture. It was termed "Muscular" Gothic and also "Eclectic," and its different parts were made purposely all vieing with one another in deformity. The style was in defiance of all principles of art and of all regard for the purpose of the building, and it bore some relation to what was known in painting as "Pre-Raphaelism." An explanation of Muscular Gothic as applied to the Law Courts will be found in the *Architect*, September 2, 1871. This journal stated that the number of Muscular architects was so small that they might be counted on the fingers and thumb; and, as an instance of the corrupt system of selecting Government designs, it stated that a single individual, whom it named, so manœuvred matters as to insure the selection of a Muscular Gothic design for the Law Courts. In order to make architecture flourish, we should have an artistically competent and sufficiently representative body of judges to select the designs, particularly for Government buildings; and we should be particular to prevent any interference from those Mediæval lunatics, the Muscular Goths.—W. H.

[60523.]—**Battery.**—After Messrs. Shippey's letter and Mr. Bottone's answer to 61039, I am like a donkey between two haystacks. I rather lean, after what has been said, to the cell described by Mr. Bottone on page 561 of the last volume. Will that gentleman kindly tell me the size of carbons and zincs, and proportions of solution and number of cells required for the necessary lamps required, of Messrs. Shippey's make, for a room of the size mentioned? One great advantage I see in the above cell is that there are no porous pots, which are expensive and a constant source of trouble. Will Mr. Bottone please say if I am to couple up in parallel or series, and what size leads to use?—NEMO.

[60530.]—**Lens Grinding (U.Q.)**—If J. H. Wheat, whose query did not catch the eye of Mr. Lancaster, will take such information as an amateur can give, he is welcome to it. The finest emery will not polish a lens; it will only prepare it for that operation. Use putty powder. A "lead tool" may be the proper thing—I don't know; but I polish lenses up to an inch in a compound of beeswax and putty powder; melting the wax in a small clean iron spoon, then adding the powder till pretty thick, and pouring into a hollow turned in a piece of wood stuck into a bell-chuck. I am not aware if this is the way of the "trade"; but I get my glass that a ½in. magnifying lens will not detect a mark on it.—JAS. A. CAMPBELL.

[60700.]—**To Draughtsmen, &c.**—The method on p. 306 is just as correct as mine, given in the first reply, but surely is not so simple. The lines are in as many directions as you require parts, instead of in only two. Moreover, as the point E has to be found by prolonging so short a line as C A, it is certainly far less correct in practice (though as Euclidean in theory). That a "finite right line can be produced" is the weakest of Euclid's postulates, and by no means to be granted without limitation—indeed, practically, very much limitation.—E. L. G.

[60814.] — **Modified Leclanche Battery.**— Should not this querist give more information about this battery, or, at least, the date of the patent? Where did he find any mention of it?—NUN. DOR.

[60814.] — **Modified Leclanche Battery (March's Patent).** — The initial E.M.F. of this is 1·4 volt per cell; but this falls off in working to about 1 volt, so that it is necessary for lighting purposes to be able to switch on some spare cells. The resistance varies, of course, with the size of the cells, but as these have no porous pots in them it is low, being about ·03 ohm in the largest size. They are intended for intermittent lighting, cauterising, &c.—BARKER AND CO.

[60818.] — **Coil.**—I would recommend this querist to read up the many excellent descriptions of coils which have appeared in your paper, and to rebuild his coil. What does he mean by a coat of pitch and resin between the layers of the secondary?—J. W. B.

[60819.]—**Portable Electric Lamp.**—The battery inquired about under the name "Regent," was illustrated in No. 1112, as the "Maquay," the name of the patentee; and on p. 569, No. 1118, there is an account of an exhibition of portable and other lamps on this principle. It seems rather singular that the querist should not have looked in the index of the last volume; but I presume he really wants to know whether any of your readers have had personal experience with the lamp and battery.—NUN. DOR.

[60823.]—**Redecorating Harp.**—"Arpa" may as well clean off the paint and start afresh. Black paint rarely dries thoroughly hard when mixed as described; but if by cream "Arpa" means a paint made of white lead, it ought to have dried hard at least, especially as he rubbed each coat down with sandpaper. He should procure some best pale copal or amber varnish, and mix his prepared and ground colour with that, and he should take care to apply it in a room at a temperature of not less than 60°, free from draughts or dust. As to the gilt, trace the design in gold size, or paint in orange first, then apply gold size, and when the latter is tacky, lay on the leaf gold.—SAML. RAY.

[60825.]—**Draw-Vice.**—Wire of ·121 or ·171in. is suitable for short lines. As to sketches of the tools, you can find them in any catalogue of telegraph materials.—LINEMAN.

[60845.]—**Polishing Silvered Goods.**—This question has been answered several times since Mr. Sprague's articles a good while back. The "bobs" are made of leather discs—walrus hide, for instance, when single; but bull-neck leather when they are made of several clamped together. Felt, cloth, and calico are also used; but for silver-plated work most polishers use wooden bobs, covered with hard and soft leathers, and circular brushes, with dollies made of swansdown. Rottenstone, tripoli, crocus, and rouge are the chief polishing materials. With these the real black polish can be obtained.—NUN. DOR.

[60851.]—**Sheet Wax.**—Melt the wax, stir in some lampblack or other suitable pigment, and pour out on slabs of glass, marble, or other material capable of taking and retaining a good surface impermeable to the wax.—NUN. DOR.

[60911.]—**Steam Engine.**—I have not your original query by me, so forget if you gave particulars as to lap, if any. But from width of ports and travel now given, I expect it is ¾in., and you may increase this by pinning on ½in. at end of valve. This will enable you to cut off at about ¾ stroke if you give valve $\frac{1}{10}$in. lead. Of course you must set eccentric forward to give the requisite lead; this will not only open exhaust port earlier, but at same time also cushions earlier, and to that extent also saves steam, and if an engine running at a good speed is essential to smooth running.—T. C., Bristol.

[60936.]—**Oxygen.**—In preparing oxygen from potassium chlorate mixed with black oxide of manganese it is often a great inconvenience that the gas is given off in sudden rushes, and does not directly stop when the light is removed. To obtain this result the following mixture should be used—

Potassium chlorate	8	weights
Black oxide of manganese ...	2	„
Ordinary kitchen salt	1·5	„

All to be properly mixed and powdered. By this mixture the gas is given off at a uniform rate, which lessens directly when the gas is turned lower, and immediately stops when the light is taken away.—HOLLAND.

[60983.] — **Chloride Battery.** — If by "strength," this querist (p. 328) means E.M.F., there is no battery which has about three times the strength of the Leclanché per cell. If there were, it would surely be the subject of a patent. It puzzles me why such a request should be made, when a reference to Mr. Sprague's book, or, for that matter, any textbook of electricity—not to speak of back volumes—would show that a cell having an electromotive force much over two volts is unknown. I calculate we must invent some new elements before we get that. Perhaps by "strength" the querist means something else. If so, he will, no doubt, explain.—NUN. DOR.

[60985.]—**Tides.**—As no one has yet replied to the query of "E. F. S." in your issue of Nov. 26, I may say that by De La Rue's tables high water at Simon's Bay, on the Atlantic coast, is always 1 hour 6min. earlier than at Panama, on the Pacific coast. These two points are (as "E. F. S." is probably aware) at the extremities of the proposed ship canal across the isthmus.—B. A., Handsworth.

[60993.]—**Permanent Way.**—The stone-block sleepers were first used by Barnes in 1797. To go fully into the matter would take much space, and not be of general interest; and besides, it is all to be found in Stretton's "Railway Safe Working," to which your correspondent, "Permanent-Way Man," should refer for details."—PRACTICAL.

[61000.] — **Pipe Moulding.** — Thanks to "J. H." for his reply; I have received No. 985,

other numbers being out of print. Can you give me a sketch how they are done with a core-box, and if hot-water pipe cores are dried, and how the saddle (with stud) is fixed in core, as they are done in Glasgow? and oblige—H. S. H.

[61002.]—**Dynamo and Storage Battery.**—To EDWARD CONRY.—I observe, and will presently give you the details you require.—EDWARD CONRY.

[61012.]—**Annealed Zinc.**—Your correspondent "Dens" is certainly mistaken when he says zinc cannot be softened. Ordinary commercial zinc is quite malleable and ductile at a temperature a little below that of boiling water, and can be bent, folded, rolled, or hammered out with ease, although it is hard and brittle at ordinary temperatures. "Dens" is most probably a dentist, and unacquainted with zinc in any condition except as it appears when cold or when melted. If he will treat one of his zinc dies to about the temperature of boiling water, he will find it not much harder than lead, and he will be able to flatten one of his dies out on his anvil without cracking, if his zinc is clean.—THOS. FLETCHER.

[61019.]—**Brazing.**—A good "shop wrinkle" in brazing band-saws is—after filing the ends down to a proper scarf joint, ram a raw potato on to each end of the saw, just allowing the part to protrude that is intended to be heated. This keeps the saw cool, and before the potato gets cooked through the slit the joint should be complete, unless the operator has been too long over his job.—T. F. S. T.

[61048.]—**Electric Conductors.**—The information you furnish is not sufficiently definite to enable a practical answer to be given, for the following reasons:—(1) You do not say the minimum current and E.M.F. that will be required all along the 25 mile stretch. (2) You do not say what dynamos you mean to use; so that it is impossible to reckon what will be the loss of power by transmission through the dynamo—a quantity which, with different machines, varies from eight to forty per cent., and which varies also with the price; the most efficient machines costing, naturally, the highest price. Are you prepared to pay a good price for your plant? Your loss by leakage would depend entirely on how the cables were laid, the surrounding soil, and the particular time of year, as in dry summer weather it would probably be almost nil, while in wet winter weather it might be nearly 50 per cent. of your power, especially considering the length of your line. Even on a two-mile line at Blackpool, from 30 to 40 per cent. of the power is at times lost by leakage (when the weather is wet and stormy) and resistance in the jointings of the rails. In view of this, and of the great fact that you have water-power at command, and so have not to pay for coal and steam machinery, I should most strongly advise you to dispense with the main conductor along the line, and get your power from accumulators carried on the car; but that is your affair. The following items may possibly be of some use, but are of necessity only rough approximations, owing to the want of the definite information I have asked for above. If you cannot give this, as it is purely technical, then, if you will say what weight you want to carry or draw, e.g., a train of electric engine and five ordinary railway goods trucks, each truck carrying so much, or electric engine and three passenger cars, like an ordinary tramcar, each carrying so many passengers, and the trains required to move at such-and-such a rate, I may be able to assist you, and if you seriously contemplate forming such a line, and care to communicate with me by advertising your address, may be able to put you in the way of getting more substantial aid to your enterprise. I find, on going into the figures, it is impossible to give you a reliable answer without knowing more particularly the particulars of the trains to be run, the speed, and the number of trains that would be run at once. I presume you refer to a single line. Assuming that your electromotors would not take more than 100 volts as a maximum, your 170 H.P. would give you roughly, through the dynamos, about 100 volts and 1,000 ampères; but without the data asked for above it is impossible to say what amount of current you would require, and how much of the 1,000 ampères you could afford to sacrifice to the E.M.F. If you could do with 200 ampères, and could devote the H.P. represented by the remainder to the production of a much higher E.M.F. than 100 volts, you could afford a much smaller and less costly cable than if you required 800 ampères out of the 1,000, because the higher E.M.F. would enable you to maintain a minimum of 100 volts at all points along the 25 mile stretch. (This is by way of illustration only, and not by actual figures.) Another consideration is that with the continual wear of the travelling contacts on your overhead line, this being necessarily of soft metal, would rapidly wear out, and get thinner, and thus every week would require a slightly greater force to drive your trains than the one before, because your travelling contacts must press moderately hard on the overhead conductor to break through the resistance caused by oxidation of the bare wire in the air, and this pressure means wear and tear. Considering all things, and especially the fact that you get your power from water, and therefore probably for nothing, I should strongly advise your using accumulators carried on the car, like coals in an ordinary tender. These you could make for yourself, while as a counter-item saving not only the first cost of the overhead conductor and specially-jointed rails, but also the wear and tear of the first (unlike which the accumulators would improve with use), and everlasting trouble and expense in keeping good electrical contacts all along the rails over 25 miles of line. You can reckon for yourself how many joints there would be in such a length. An overhead conductor line that may be very practicable for two miles becomes a very different thing for 25, because you do not carry your power with you, as in the case of accumulators or steam. Where are your sources of power placed? Grouped at one end, or scattered along the 25-mile stretch?—EDWARD CONRY.

[61049.]—**Dynamo.**—We suppose you mean how can you avoid a complete breakdown? The only way we know is to short-circuit the faulty section by soldering a wire from one end of it on to the other. The bad section will then become charred right through, but the machine will work. We ran a Gramme A exciter in this state for a fortnight at an exhibition without any noticeable result, and we know that a flat ring machine was also working in the same state.—BARKER AND CO.

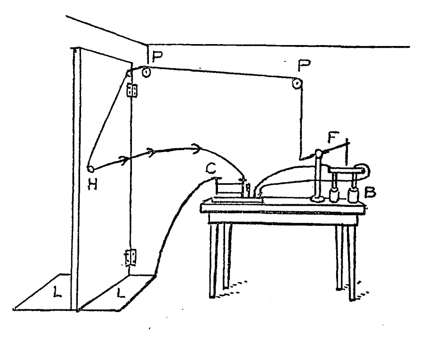
[61051.]—**Lens Shutter.**—If "Photographer" removes the hood of his lens, he will admit extraneous diffused light, which will tend to reduce definition, and consequently the picture may be partly lost in haze, owing to this cause. Of course, the hood must be removed if he wants this unscientific flap shutter to be of any reasonable size, which may be replaced by a large diaphragm rigidly fixed in front of the lens; then apply the flap shutter. I have been thinking myself of having an arrangement under electrical control, so that by simply pressing a push the exposure can be made, and on releasing it (the push) the lens is recovered. This may be effected by an electro-magnet and some convenient source of current, such as a bottle bichromate battery, and a disc revolving in front of the lens, as the rotating diaphragms only having one hole, instead of three or four, as generally. I leave it to others to devise further; perhaps Mr. Bottone will say something in this photo-electrical departure. I am well aware of the electric snap shutters that have been invented; but not of one that prolongs exposure, as the operator requires, and manipulated by electrical arrangements. There is a pneumatic one that fulfils this latter purpose, and may be of use to querist, only I believe it is rather expensive.—A. TREYER EVANS, Newport, Mon.

[61053.]—**Preparation for Mixing Bronze Powders.**—Seeing no one has answered this query, I venture to suggest "gold size," which can be obtained from any carriage builder.—A. TREYER EVANS, Newport, Mon.

[61054.]—**Magnets and the North Pole.**—Some years ago, when a boy, I remember reading of a vessel which sailed round some point of magnetic attraction, termed "The Magnetic Pole." It was stated that the needle of the ship's compass pointed towards the said point as the ship neared it, and, turning aside as the ship passed, continued to point in the same direction; and after the ship had passed, what appeared to be the centre of some great attraction, the needle of the compass was pointing nearly south, just the opposite to what it was a short time previous. I do not recollect in what particular book this statement occurs, as I have read several accounts of Arctic expeditions; probably some one of your many readers may have read the same account. Further, in support of this, I have an atlas with the "Magnetic pole" marked on it, the author giving its position as about 70° 20' North latitude, and 96° West longitude.—SIMPLEX.

[61055.]—**Varnish for Bright Parts of Bicycles.**—Rub the bright parts of bicycle with a little vaseline; that will prevent it from rusting, and is better than any varnish for the bright parts.—J. C.

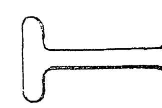
[61056.]—**Door Connection for Giving Shocks.**—Let a square of sheet lead be nailed on the floor outside the door instead of a mat. At some point near the door place a 1in. spark induction coil, with a two-celled lifting bichromate battery connected to its primary terminals. Let one of the secondary terminals of the coil be in electric contact with square of lead, while the other is similarly connected with the hasp and staple. Contrive, by a suitable length of string passing over a pulley, that the plates of the battery shall be lowered into the liquid directly the hasp is moved. The annexed sketch gives general idea of arrangement. C the coil, L L the leaden sheet, B the battery, F the lever to allow lowering of plates when the hasp is pulled. Of course, you will



require a check-string to prevent the battery being lowered when you yourself go in.—S. BOTTONE.

[61057.]—**Steam Launch.**—In answer to this query, I may mention to "Itchen" that his yacht, if yacht it may be called, is sadly out of proportion; in fact, I should call it a small barge. Surely there must be a mistake: 8ft. beam for a 22ft. 8in. boat! Why, this is considered to be a fair beam for a 40ft. boat. There are many boats built now 45ft. long with a beam of 8ft.; 5ft. beam for a 23ft. boat is ample. However, taking your boat as having a beam of 8ft., it will take much more power to drive it, as the lines must be very full in the boat you describe; and to drive her 7 knots an hour you will require an engine having a cylinder of not less than 6in. diam. by 6in. stroke, and having a boiler at least 4ft. in diameter. You may reckon that the engine and boiler will occupy 9ft. of the length, 23ft. I should have been pleased to go further into the question with you, but I think there has been a mistake. Anyway, write again, and I shall be pleased to assist you.—ENGINEERING MANCHESTER.

[61060.]—**Gut v. Leather Bands.**—From my experience, I certainly would prefer the 1in. leather belt to the two ⅜in. gut bands, as the latter are very apt to pull away at the thread of the hook and eye; as, if the hook or eye internal thread be sharp, it soon cuts away the gut, and if they be blunt there is no holding power. Also, two gut bands would be bad, even supposing you could adjust them to equal tension, as, if one came in two, you would have to shorten both. If you do use catgut, I should use one band of a larger size.



If anything tends to develop bad language, I think the breaking of a catgut band does. In a small steam lathe, you can pack the lathe up if you have to shorten the belt; but in a foot lathe you will have to put an extra piece in (with another hook and eye), or get another band. As regards the latter part of your query, there are several mechanical fastenings for uniting the ends of leather bands in the market; but for small bands perhaps as good a one as any is the brass one of this shape.—SEVERN TUNNEL.

[61061.]—**Engine and Boiler.**—If p is the pressure per square inch in the boiler, *above that of the atmosphere*, f the working load per sq. inch, t the thickness of the plates in inches, and r the radius of the shell *in inches*, then $p = \frac{f\,t}{r}$ Knowing f, t, and r, you can find the safe pressure. The f per square inch differs for different joints. For a single-riveted lap-joint it is 31,000lb., for other joints it is usually more. Thus, for a scarf-welded joint it is 46,000lb. The length need not be taken into account, as is seen from the formula.—A. E. RICHARDSON.

[61064.]—**Vertical Engine.**—The steam pipe requires clothing with non-conducting material, and probably it has many bends from boiler to engine. Your condenser is shut off too soon in both top and bottom of cylinder. The supply of steam in the up stroke is insufficient, either through defect in throttle valve or contraction in steam passage. The air-pump requires to be 12in. diam. and 12in. stroke.—S. M. S.

[61068.]—**Ramsbottom Safety-Valve.**—Is not W. H. Thurlow confused by taking the *centre* of hole A as the point where the spring acts, instead of the bottom of said hole? The *bottom* of the hole A should be level with the bottom of holes (or cups) B for the line of pressure to be a straight line. This would make it appear as if the hole were half its diameter too high up. If any

thing, I should think point A would be better a little below the level of B B to prevent any tendency of the lever to cant.—T. F. S. T.

[61071.]—**Planing Machine Tools.**—Probably because the feed is put on at the end of the cut (before the back stroke begins), instead of just before the fresh cut begins.—T. F. S. T.

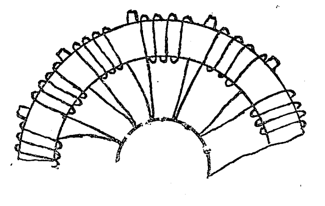
[61076.]—**Type-writing Ribbons.**—In negotiating for purchase of type-writers, I have understood that the ribbons could be renewed "at home" by getting similar webbing, and coating it with aniline dye and glycerine.—T. F. S. T.

[61078.]—**Red Rust from Sheet Tin.**—Ordinary "sheet tin" is only thin iron coated; most likely your "tin" has its coating injured, and the iron within yields the rust. Try brick-dust, or rottenstone and oil, and a good rub.—T. F. S. T.

[61079.]—**Lathe.**—I have found the same fault when the tool is blunt and round on the edge. It refuses to cut till sufficient pressure is put on with the slide-rest screw to force the blunt edge through the glazed surface it has formed; then it digs in and makes a groove. Keep your tools hard enough and thoroughly sharp.—S. F. S. T.

[61087.]—**Metallic Fire Alarms.**—The two best metals to use are silver and platinum. Very thin plates, of course, bend more readily than thick ones. A ribbon of each of the above metals united together by hard solder makes a good fire signal, if placed near the ceiling of a room, and joined with a battery and electric bell. Brass or copper and steel might act fairly well, but will not last so long. —A. E. RICHARDSON.

[61088.]—**Dynamo.**—You will not need to drive quite so fast, say, 1,400 revs. But you must not expect to get 60c.p. from the machine half the size figured. It will only give about 25c.p. The annexed illustration shows the mode of winding



and connecting to commutator strips. In words, it is "the end of one section forms the starting point of the next."—S. BOTTONE.

[61091.]—**Curious Phosphorescent Insect.**—"W. E. D.'s" "insect" is not an insect, but just an ordinary glow-worm.—GAMMA SIGMA.

[61092.]—**Hot-Air Motor.**—TO MR. SEAL.—To obtain ½-man power you will require working cylinder to be of 60 cubic inches capacity. The heater will have to contain about 100 cubic inches (when displacer is in it.) The displacer should not have more than 1½in. stroke. I have made these motors of the same design as given in "Ours" of April last to give out about 250 foot-pounds per minute. I have a new design for engines of ¼-man power and upwards, drawings to scale, of which I will give in these columns if you or any other reader of "Ours" would like to have them, and the Editor has no objection.—J. SEAL.

[61099.]—**A Rule of Grammar.**—Will Mr. Hall kindly say who made the "rules of syntax," one of which he thinks has not been grasped by a fellow correspondent?—G. W. M.

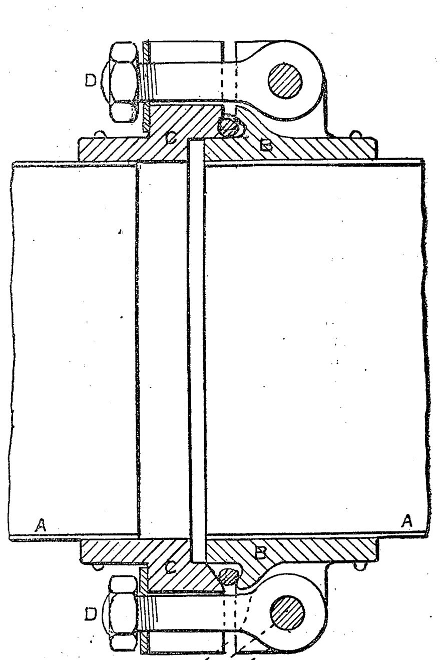
[61099.]—**A Rule of Grammar.**—"Weald" must forgive me if, for others' sake, I correct his answer to above on page 332. His French is all right, but his German example, "Es ist mich," is not only grammatically wrong, but a barbarism. Wrong in grammar because the German tongue, like all others I am acquainted with, *does* require the same case after as before the verb to be, and were a German given his choice between Es ist mich (it is me) and Es ist ich (it is I) he would undoubtedly choose the latter. And a barbarism because he would unfortunately never think of using either form, but say Das bin ich (it am I) or Ich bin es (I am it), accordingly as he wished to emphasise the *it* or the *I*. But this example does not clearly show the rule of grammar, because the neuter pronoun *Es* is the same in all cases: let us therefore substitute "He is I" or "I am he." Here we must avoid using the personal pronoun "He" (Er, nom.: Ihn, acc.) and substitute the masculine definite article (Der, nom.: Den, acc.:). The German would say, Der bin ich (*not* Den bin ich) for "he am I," and ich bin der (*not* den) for "I am he." Were I to construct this sentence according to "Weald's" faulty instructions, "he is I" would read "Er ist mich," and a German hearing this would infallibly understand him to mean "Er *isst* mich"—*i.e., he eats me*, which reminds me of my old master's favourite puzzle—viz.,—PES EST CAPUT.

[61099.]—**A Rule of Grammar.** — Unless "Doctor Medicinæ" wishes to be considered an uneducated man, I should certainly advise him to say "It is I," in place of "It is me." At the same time, however, I must say it is my firm belief that originally everyone, educated or not, used to make use of the latter expression until a lot of grammatical pedants ordered otherwise. We must not lose sight of what our language is derived from. It seems from "Weald's" reply that the German idiom, "Es ist mich," is the exact equivalent of "It is me," and I can add that the same idiom is also found in the Danish language, where this phrase is "det er mig" and not "det er jeg." I note Mr. Bottone's argument about "It" and "I" being really one and the same, and are, therefore, obliged to be both in the same case; true, so far as it goes, and it is also true that the nominative precedes the verb, from which circumstance he is quite at liberty to argue that the verb "to be" requires the nominative case to follow. But there is yet another way of arguing this matter—viz., that it is a rule that verbs govern the accusative case, so that it is quite correct to say "It is me," and, bearing in mind Mr. Bottone's argument, may we not fairly contend that in this sentence the word "it" should be considered as being in the accusative case the same as "me."—WHAT IS SAUCE FOR THE GOOSE IS SAUCE FOR THE GANDER.

[61099.]—**A Rule of Grammar.**—I think the views of "Doctor Medicinæ" must be admitted by reflecting persons to be absolutely true. Horace, who was certainly a man of sense, said, "usus quem penes arbitrium est, et jus, et norma loquendi." Language is like a world, and the so-called rules of grammar are, at best, like lines of latitude and longitude drawn across the face of it. When a pedant wants to regulate our speech to suit his views of what ought to be, he is like a man who would shift the position of towns to suit the convenience of geographers. Rome, for instance, is in lat. 41° 54′ N.; lon. 12° 28′ E. How much nicer it would be to move it to lat. 42 and lon. 12. When questions are in dispute, however, the votes of those who have studied grammar may fairly count for a little more, *ceteris paribus*, than the votes of those who have not. "It is me," "it is him," is still sub-judice. The only reason for the usual rule about the verb "to be" is that it is so in Latin and some other languages; but surely if we reflect we shall admit that there is no need for the word following "to be" to be in any "case" at all. If there were an absolute form of the word, a "stem," then surely that "absolute form" would follow the verb "to be." Where there is no absolute form there is no particular reason for taking any case but that which is the simplest and easiest to pronounce. In English the accusative case is that which comes most naturally at the end of a sentence; hence we might naturally expect people to say, "it is me," and "it is him." To say "it is I," is like galloping your horse to a precipice and pulling it up sharp at the edge; a feat (if you could perform it) well calculated to show off your horsemanship, and therefore "it is I" is highly favoured by those who despise the ignorant herd. I am of opinion that in some cases the multitude will prevail, and in some the few. As to votes, I am for "it is me," but I cannot vote for "it is him." Logic has very little to do with such matters. I stoutly stand up for "than him," though "than he" is not exactly wrong: this is a question of the same class.—X. Y. Z.

[61099.]—**A Rule of Grammar.**—As "Weald" and S. Bottone practically agree with me, I need only refer to the reply of W. C. Hall. As he surmises, I am tolerably familiar with the grammar of our Anglo-Saxon forefathers, having as an undergraduate gone in for honours in English literature, and I am also tolerably conversant with modern English grammar; but that does not blind me to the fact that such a thing as a hard and fast rule of grammar does not exist—in other words, there is no law of grammar. Custom makes it, and if custom changes, grammar must accommodate itself to the change, or become obsolete and pedantic. My reason for inserting my query was to ascertain, through the medium of probably the most widely-circulated scientific paper in the world, whether custom has, or has not, yet sanctioned any exceptions to the rule of syntax I quoted, and which I "thoroughly grasped" (W. C. Hall to the contrary notwithstanding) twenty-five or thirty years ago. The only authority I have ever seen mention this matter is Dean Alford, in "A Plea for the Queen's English." He says: "*It is me.* Now, this is an expression which everyone uses. Grammarians (of the smaller order) protest; schoolmasters (of the lower kind) prohibit and chastise; but English men, women, and children go on saying it, and will go on saying it as long as the English language is spoken. Here is a phenomenon worth accounting for. 'Not at all so,' say our censors, 'don't trouble yourself about it; it is a mere vulgarism. Leave it off yourself, and try to persuade everyone else to leave it off. But, my good censors, I cannot. I did what I could. I wrote a letter inviting the chief of you to come to Canterbury and hear my third lecture. I wrote in some fear and trembling. All my adverbs were (what I should call) misplaced, that I might not offend him. But at last I was obliged to transgress, in spite of my good resolutions. I was promising to meet him at the station, and I was going to write, 'If you see on the platform an old party in a shovel hat, that will be I.' But my pen refused to sanction (to 'indorse,' I believe I ought to say, but I cannot) the construction. '*That will be me*' came from it, in spite, as I said, of my resolve of the best possible behaviour." Further on he quotes Dr. Latham's "History of the English Language"—a book I have not by me—who says: "We may call the word *me* a secondary nominative, inasmuch as such phrases as *it is me* = *it is I* are common. To call such expressions incorrect English is to assume the point. However, Dr. Latham, though approving of "*it is me*" as good English, and asking "Is there any real custom in favour of '*it is I*,' except so far as the grammarians have made one," sticks at "*it is him, it is her*," though why he should accept the one and reject the other, which is equally customary, is not apparent. In my first communication I did not mention the French form "*C'est moi*," because I did not consider it an equivalent expression, and what we have to do with is what is, or is not, good English, irrespective of the idioms of any other languages or the idiosyncrasies of grammarians, who, in respect of the rule of syntax in question, appear to have been mere plagiarists copying blindly the rules laid down by their predecessors, without the smallest consideration for the usages of society at large.—DOCTOR MEDICINÆ.

[61100.]—**Thin Steel Pipes.**—I cannot say whether they are used to any great extent, but have seen some hundreds made. They are riveted up lengthways, the steel being about $\frac{1}{16}$in. thick, caulked with a caulking iron, and connected by means of flanges and bolts as shown in sketch. A,



steel pipe; B, male flange; C, female ditto; D, eyebolt; E, indiarubber ring washer. The flanges embrace the steel pipes, and are riveted circumferentially. To detach the lengths of pipe, the eye bolts are thrown back, the lugs being open to allow the bolts to clear in the direction of the dotted line F.—J. H.

[61100.]—**Thin Steel Pipes.**—I got a beautiful sample some years ago, I think from the Weldless Steel Tube Company, Icknield Pool-road, Birmingham. No doubt they could give the information "F. H. S." wants.—T. F. S. T.

[61101.]—**Stars Visible from Bottom of Well.**—Will "R. E. F." explain why the "only star likely to be visible in the daytime in the latitude of London is Gamma Draconis"? "R. E. F." seems to have an idea that 8½° of latitude is an enormous distance viewed from the stars. I suppose if a star could peep down a well, it would also be possible to see the star from the well. To the querist I would recommend a study of some of the star maps, which will show him what stars come overhead in the course of the year.—E. D.

[61101.]—**Stars Visible from Bottom of Well.**—Any bright star whose Northern Declination approximates to the observer's latitude so as to approach his zenith would be visible during part of the year at a certain, though of course not constant, hour in the daytime. So far as I am aware, no catalogue of the actual stars visible in such a position as "Faciebat" puts, has ever been compiled. There are, however, many lists of stars visible during an eclipse. Sir G. B. Airy, observing the solar eclipse of 1860 in Spain, records the following nine stars as seen by his assistants during totality—viz., Regulus, Saturn, Mercury, Procyon, Jupiter, Venus, Castor or Pollux (not accurately ascertained), Capella, and Arcturus. Clouds obscured Sirius and α Orionis, which otherwise would doubtless have been visible. Halley records of the eclipse of 1715 that there were no fewer than 22 stars visible in a particular direction where the sky was darkest. This number, however, would seem to be exceptional. In general stars only of the first magnitude are actually seen, though the obscurity is often such that second and third magnitude stars should theoretically be visible. The explanation of this fact given by M. Belli seems to be the most plausible, though others have been offered. He says that during the short interval of totality the eye has not sufficient time to recover from the dazzling effects of the sun's rays, and so take advantage of the actual darkness which prevails.—B.A., Handsworth.

[61105.]—**Exhaust Pipe.**—Replace bend into chimney by a T-piece, and run a pipe down to outside over a gully, and govern the exit of condensed steam by a valve.—S. M. S.

[61108.]—**Oil for Cycles.**—A very old hand in the machine shop has more than once declared there is no better lubricant for cycles than Neat's-foot oil. Personally, I use Avilla Tringham's oil.—GAMMA SIGMA.

[61108.]—**Oil for Cycles.**—Some time ago I saw a suggestion to use vaseline dissolved by heat, and having 10 to 12 parts of petroleum added. I have used it on my machine ever since, and find it superior to any oil.—DOCTOR MEDICINÆ.

[61108.]—**Oil for Cycles.**—I don't know how to remove the disgusting smell from sperm oil; but I got "machine oil" from Messrs. Johnson's, Church-street, Liverpool, two years ago, almost odourless, and what is left in the bottom of a gallon tin is sweet yet, and perfectly good for use. I don't know its composition, but it is far better than any "odorous" sperm or any other kind I ever saw. I understand it is a mixture.—T. F. S. T.

[61108.]—**Oil for Cycles.**—Why not try a mixture of equal parts of washed lard and finely-powdered blacklead? In cycles it sticks longer *in situ* than oil, and on most of the bearings you can fit a little reservoir with a screw cap so as to force a supply down to the journal or axle from time to time. No gumming, no odour, no mess, while the plumbago keeps a beautiful surface on all the wearing parts. Try it and report results for the benefit of others. If you must have oil, use neatsfoot which has been kept in a glass bottle exposed to the light in contact with strips of clean lead; and if you object to odours that are not perfumes, put a bit of camphor in, or, if you prefer, a little otto of roses.—ESSAR.

[61111.]—**Hand Saw.**—The difference is as you say, that Englishmen *thrust* their saws, Orientals *pull* them for the cutting strokes. Bending and buckling are not so likely to occur when pulling as when thrusting, hence Oriental saws are also thinner than those of English make, and less material is wasted in sawdust. The Japanese sit when sawing, and place their feet against the wood.—J. H.

[61111.]—**Hand Saw.**—Some years ago three was a discussion in these pages about using keyhole saws with the teeth reversed so as to make the cut with a pulling stroke—a method which at least avoids all risk of buckling the saw. A little time ago, wanting to cut out a lot of thick wood from an old vine, and not having a keyhole saw-blade, I inserted a metal or "hack" saw in the handle with the teeth reversed, and accomplished the work with ease and despatch. Any attempt to thrust such a saw through damp wood, unless it was held taut in a proper frame, would have inevitably produced buckling or breakage. I should prefer a saw with a thrust action if I had to take a cut through a 12ft. plank; but there are circumstances in which a saw with the teeth reversed is an advantage, especially when you have no more suitable tool.—SAML. RAY.

[61113.]—**White Enamel Paint.**—Some time ago I was in a similar difficulty; but overcame it by rubbing with a smooth block of the whitest pumice-stone procurable.—W. C. HALL, Newport, Mon.

[61115.]—**Gas Engine.**—The valve actions of a gas-engine are rather complicated, as it is not a case of one single action like steam, but a triple combination of gas, air, and flame. I do not know that a verbal description would convey much information, so will send you drawings of the valves, &c., next week (Dec. 24). I shall not have time to get them out for the next number (Dec. 17).—EDWARD CONRY.

[61116.]—**Iron Boot Used in Junod's Vacuum Treatment** (Hæmospasia).—"J. H. M." will require to get this apparatus made to order; it is so little used that I am afraid no surgical instrument-maker keeps it in stock. Underneath is Junod's description: "Moyen thérapeutique qui consiste à faire le vide sur de larges surfaces sur un ou deux membres, même sur la moitié du corps à l'aide d'appareils particulier. L'hémospasie a pour but d'attirer en peu d'instants une masse de sang et de fluides plus ou moins considerable sur une partie saine et de soulager d'autant les organes qui sont le siège d'une congestion morbide."—B.SC., Plymouth.

[61118.]—**Electro-Magnet.**—Have two limbs ½in. in diameter, 3in. long. Wind with No. 24 s.c. wire until their diameter becomes 1½in. Thus wound, you will be easily able to pull the ounce with 1 cell Daniell or Leclanché.—S. BOTTONE.

[61120.]—**Ferrous Oxalate Developer.**—The result is a perfect developer, and requires no further addition.—S. BOTTONE.

[61120.]—**Ferrous Oxalate Developer.**—The developer is ready for use after exposure, and if not energetic enough, a few crystals of clean $FeSO_4$ may be added at the same time; carefully observing the precautions necessary when preparing the strong developer.—A. TREYER EVANS, Newport, Mon.

[61121.]—**Wax or Paraffin Stains.**—Use benzole or methylated chloroform.—DOCTOR MEDICINÆ.

[61121.]—**Wax or Paraffin Stains.**—Benzole, commonly known as benzine or benzoline, may be used.—A. TREYER EVANS, Newport, Mon.

[61121.]—**Wax or Paraffin Stains.**—The droppings from wax or paraffin candles are very easy of removal from carpet or cloth. Place a piece of thick blotting-paper over the spot, and pass a hot iron over it; this repeated two or three times, all trace of grease disappears.—W. H. C.

[61121.]—**Wax or Paraffin Stains.**—Place a sheet of blotting-paper over the stain, make a common sad-iron pretty hot, lay it on the paper, and replace the paper from time to time, until it has sopped up all the wax. If any mark remains, a few drops of benzine collas will remove it.—S. BOTTONE.

[61121.]—**Wax or Paraffin Stains.**—(1) Lay a piece of blotting-paper on the stain and then press on it a flat iron, as hot as possible, without scorching the paper or the material under it; (2) wet the material all round the stain with benzine (which you can get at a druggist's, or perhaps at an oilship) so as to prevent the stain from spreading, and then rub with benzine.—EDWARD CONRY.

[61122.]—**Magic Lantern Slides for Boys' Lantern.**—Buy a small bottle of liquid Indian ink from any vendor of drawing materials; use a fine pen, and draw or write what you like on the glass. I have made many lantern slides in this way. See that the glass is clean, dry, and free from grease.—UMBRA.

[61122.]—**Magic Lantern Slides.**—Dissolve a bit of Indian or China ink in water, and use one of the lithographic steel pens (sold by most stationers). Any of the outlines which may be too thick thin down by scraping on either side with the sharp point of a penknife blade. The outline of high-class pictures may be done this way by those who have not the ability to draw and paint with the brushes as they go along.—DENS.

[61122.]—**Magic Lantern Slides.**—I have used the ordinary moist black paint sold in tins, mixed with water and a little bichromate of potash. This latter body prevents the paint from being tacky after being exposed to light, and only a small portion of it is necessary. An ordinary fine steel pen, a clean glass plate, and the (thick) solution is all I use. Walter Woodbury invented a varnish, prepared by the mixing of a few drops of a solution of indiarubber with a solution of gum dammar in benzole, which he previously coated the plate with, and traced the design in Indian ink.—A. TREYER EVANS, Newport, Mon.

[61123.]—**Analysis of Kainit.**—Water, 2¾ parts in a hundred by weight (at boiling point); sulphuric acid, 23¾ parts in a hundred by weight (at boiling point); chlorine, $32\frac{1}{10}$ parts in a hundred by weight (at boiling point).—A. TREYER EVANS, Newport, Mon.

[61129.]—**"Loeb" Battery for Electric Light.**—This query seems to be identical with 61039 which appeared on p. 293, and the querist, having seen these wonderful batteries, ought to know more about them than any one except those who showed them. Will any one guarantee 70 hours with once charging? If the querist will take the trouble to look in Mr. Sprague's book or search the indices, he will find abundant information, and can then make his choice of understanding for himself or accepting what he is told.—NUN. DOR.

[61131.]—**Electric Cautery.**—This query cannot possibly be answered from the data given. Current is the only thing required in heating a cautery, and the heat = $C^2 \times R$; but ·06 ohm may mean anything as regards length and sectional area of conductor. Please say what diameter your cautery is, and is the ·06 ohm R when cold; it will, of course, be very different when hot. We presume you use platinum wire. The easiest way you could measure the current flowing would, of course, be with an ampère-meter; but you could perhaps more easily arrange a large surface voltameter, and collect the mixed gases liberated. An ampère flowing for one hour liberates about 40 cubic inches of mixed gases; or if a copper voltameter is used, the same current would in one hour deposit about 18¼ grains of copper.—OHM.

[61131.]—**Electric Cautery.**—TO MR. E. CONRY.—The most economic and satisfactory way that I know of would be by two or three single-fluid bichromate of potash cells. The agency required to raise any conductor (i.e., the piece of cauterising wire) to red or white heat is a certain amount of current forced through it, and this forcing requires a certain E.M.F. directly proportional to the resistance of the conductor, i.e., the greater the resistance the greater the E.M.F. required. There are, I think, tables published in some book of the amount of current required to raise wires of various gauges and conductivity to particular heats; but I have not got them by me, so will look up the matter and write you next week. To exactly measure the small amount of current required for the resistance you mentioned, you would require a very delicate ammeter—like Sir Wm. Thomson's, or Mr. Sprague's differential galvanometer—something that will measure from about the $\frac{1}{100}$th of an ampère to 4 or 5 ampères. I do not think you could yourself make a neat and permanent instrument of sufficient delicacy unless you have good tools and appliances, and some skill in instrument-making.—EDWARD CONRY.

[61133.]—**Adiabatic Curve.**—"A. J. W." does not seem to know what an adiabatic curve is. It is a curve showing the expansion of gases under varying temperatures due to expansion. These curves are obtained by ordinates, which are calculated by a formula having a different coefficient for each gas, according to its specific heat. I am sorry I cannot give "A. J. W." the formula, as all my books have been destroyed by fire; but I will try to obtain it by next issue. It is given in Rankine.—NEMO.

[61133.]—**Adiabatic Curve.**—If a gas be kept at a constant temperature while the pressure on it is varied, the volume will vary according to the well-known law of Gay Lussac. If volumes are taken for abscissæ and pressures for ordinates, then the resulting curve is termed an isothermal curve, and in the case of a perfect gas such a curve is a rectangular hyperbola. If, however, the gas be inclosed in a vessel perfectly impervious to heat, then the volume for a given pressure will no longer obey the law of Gay Lussac, and the curve in this case is called an adiabatic curve. I do not think such a curve could be described mechanically; but it is possible to draw one from their equation, which is $p v^x = R$, where p = pressure, v = volume, x = ratio of specific heat at constant pressure to specific heat at constant volume, and R = some constant.—WM. JOHN GREY, F.C.S., Analytical Chemist, Newcastle-on-Tyne.

[61133.]—**Adiabatic Curve.**—To "A. J. W."—I know of no method of describing this curve; but its ordinates can be calculated by the formula $\frac{P}{P_1} = \left(\frac{V}{V_1}\right)^r$ where PP_1 are the pressures, VV_1 the volumes, and r the ratio of the specific heats for constant pressure and constant volume of the gas he is dealing with.—GFYUNG.

[61136.]—**Screw Cutting.**—If "One in a Fix" will only think, he will find that for every four threads of his leading screw, there will be eleven threads on the one he is cutting, and will gear only every four threads. You can only gear at every thread of the leading screw, when the thread to be cut is a multiple of the pitch of the leading screw.—HELIX.

[61136.]—**Screw-Cutting.**—I do not quite understand your difficulty. If you bring your saddle back to starting mark, and also have marks on face-plate, and change-wheel in same starting position, the saddle will, of course, gear with screw, and you can put the cut on before starting, if you take notice of position of handle of cross-slide before you draw slide back. The nut of saddle will drop in at every inch, if face-plate and change-

wheel marks are in starting position. Is this what you require?—T. C., Bristol.

[61136.]—**Screw-Cutting.**—"One in a Fix" can scarcely have followed exactly the directions given, or he would succeed with a screw of four threads as easily as with one of two threads. Let him see that his marks are correctly made when the carriage is in gear with the leading screw and all ready for first cut. And in setting for second cut be sure that all the marks are exactly followed, and that the leading screw wheel is not one-eleventh too early or too late. If it is, turn till the marks are exactly right, when the nut drops into the screw-thread at once. If the leading screw wheel is one-eleventh too forward, eight turns will bring it right. If one-eleventh behind, three turns of mandrel are needed.—NEPHESH.

[61136.] — **Screw-Cutting.**—If the pitch of leading screw is equal to, or a multiple of, pitch of screw being cut, its pitch (leading screw) is the least distance. If pitch of screw being cut is a multiple of pitch of leading screw, its pitch (screw being cut) is least distance; and if the one is not a multiple of the other, their least common multiple is the least distance carriage must be traversed for succeeding cuts. Taking 11 threads, the least common multiple of $\frac{1}{4}$in. and $\frac{1}{11}$in. is 1in., so that 1in. is least distance in this case; but "J. H.'s" plan is quite correct so long as the pitch of leading screw is a measure of 1in., and the carriage is to be traversed 1in. or some multiple thereof. In the foregoing, pitch must not be confounded with number of threads per inch.—WORKMAN.

[61136.]—**Screw-Cutting.**—Whether you have two threads or four in your leading screw matters not in this case, since each are aliquot divisions of the inch, and if your pitch is $\frac{1}{11}$ of an inch your nut must gear at every inch with either two or four threads in the leading screw. This is self-evident, since $\frac{1}{11}$ pitch simply means that the space of 1in. is divided into 11 equal parts. The nut once set could not gear at anything less than 1in., because you could not divide two or four threads into 11 without a remainder. But every 11th thread will coincide with 1in. of the leading screw, and therefore whether you have two or four threads, the nut should gear at every successive inch, *beginning* at the point from which you started. That is really the important matter—to commence at one spot for each successive cut: hence the chalking of the bed and wheels. If the nut will not fall into gear at each successive inch, the lathe must be at fault, probably slack screws causing backlash, which in that case you must take up. Let us go through the process. The change wheels are on, nut in gear, and saddle in a certain position relatively to the headstock or poppet, or bed, as you may choose to take. Before starting the cut, mark two teeth of any pair of change wheels which are in actual contact, flank to flank, preferably starting from the one in the leading screw, and on the side facing the rest, so as to be seen from the rest. Mark the position of saddle on bed, or measure or gauge its distance from headstock or poppet, and then enter your thread. When at the end of cut run back the tool-holder slide, release the clasp nut, and rack the saddle back to its previous position, as shown by the chalk-mark on bed, or by measurement from headstock to poppet. The lathe continues running the while, and now set the tool a trifle forwards for next cut, and watch the change wheels revolve until the chalk marks on the teeth come round towards each other. When they coincide, throw in the clasp nut instantly, and allow the cut to go on again. Repeat this until the thread is of the proper depth.—J. H.

[61137.]—**Regulating Current.**—Run your dynamo a little slower, or, if that be not possible, put an adjustable resistance into the F.M. circuit, or a similar resistance in the lamp circuit, so adjusted as to raise the lamp circuit when a 10c.p. lamp is on to the same resistance as when a 20c.p. lamp is on. This you can find quickest and easiest by actual experiment, starting with, say, 10 ohms—e.g., a field of arc lamp carbon. The first, however, is the proper way. See my answer, No. 61110, in the current number (Dec. 10). —EDWARD CONRY.

[61139.]—**Chromic Acid v. Bichromate.**— "W. W. N." is mistaken on two points. Chromic acid is not a better depolariser than potassic bichromate; but it is cheaper to use, inasmuch as 201 parts CrO_3 at $7\frac{1}{2}$d. per lb. do the work of 295 $K_2Cr_2O_7$ at 6d. per lb. I have recently concluded a series of experiments upon this very subject, and my results will be published in next month's *Analyst*. I find that a solution containing 8 per cent. CrO_3 gives the same resistance, E.M.F., and galvanometer gradient, whether it be made from the anhydride or the salt. In the latter case more sulphuric acid is used up, thus:—

(1.) $Zn + 4H_2SO_3 + 2\,CrO_3 = Zn\,SO_4 + Cr_23SO_4 + 4H_2O + O_2$

(2.) $Zn + 5H_2SO_4 + K_2Cr_2O_7 = Zn\,SO_4 + KCr2SO_4 + 5H_2O + O_2$.

It is true that CrO_3 is ten times more soluble than $K_2Cr_2O_7$ in diluted acid; but it must be remembered that, as you increase the amount of CrO_3, so likewise must you increase the amount of acid. For 8 per cent. CrO_3, 15·7 per cent. (by weight) H_2SO_4 is required by theory. I use generally 20 per cent. I consider that more than this is unwise. I have myself entirely discarded the use of $K_2Cr_2O_7$, as the CrO_3 is cheaper and handier to use, and does not deposit crystals of chrome alum. Further, the reduced solution being bright green, it is easier to see when it is used up than when $K_2Cr_2O_7$ is employed.—H. PERCY SMITH.

[61140.]—**Grey Stains on Black Marble.**— If you have a method of polishing black marble, you certainly have also a method of removing stains. To what are the stains due? Some are removed by means of a cloth wetted with paraffin oil; but a useful recipe for most stains is one I noticed given in the Answers to Correspondents on p. 334.—OBERHOF.

[61141.]—**Screw-Cutting.**—You can see what you require in the "E. M." of October 15th, pages 146-7.—WALLACE NEWLAND.

[61141.]—**Leading Screw.**—Set down 2 for mandrel (being number of threads per inch leading-screw) and 13 (threads required) on leading-screw. Intermediates, 10 each. Now multiply first pair by 10 and second pair by 5, and we have

Mandrel
20 — 100
‖
50 — 65 leading-screw.

For threads of 15 or 19 to inch, use 75 or 95 on leading-screw.—NEPHESH.

[61141.]—**Screw-Cutting.**—The ratio of gearing in the cases you give are $\frac{2}{13}$, $\frac{2}{15}$, $\frac{2}{19}$, and so on, for any number of threads—viz., thread of leading screw at top, and of required screw of bottom. You can now split up as you please, if you remember to multiply both numbers by the same number you choose (which should be some multiple of 5)—thus $\frac{20}{130}$, $\frac{20}{150}$, $\frac{20}{190}$. You could use following double trains, say, $\frac{20}{65} \times \frac{30}{60}$, $\frac{20}{50} \times \frac{30}{90}$, $\frac{20}{95} \times \frac{30}{60}$; the only difficulty being in the last, as you may not have a 95 wheel.—T. C., Bristol.

[61141.]—**Screw-Cutting.**—To cut screws with four wheels or compound gear—

Lathe spindle wheel	A
Gearing with stud wheel	B
Second stud wheel	C
Gearing with screw wheel	D

Example: Required set of compound wheels to cut 13 threads to the inch. Chalk down the number of threads on your leading screw 2, and the number you want to cut 13. Annex cipher to each, and we have 20 and 130; divide 130 by 2 gives 65. Now suppose a number, and multiply by the same. You divide by, say, $30 \times 2 = 60$; this will give—

	A	B	C	D
13 Threads	20 ...	60 ...	30 ...	65
15 "	20 ...	60 ...	30 ...	75
19 "	20 ...	60 ...	30 ...	95

—H. H.

[61141.]—**Screw-cutting.**—Place the number of threads in the guide-screw for a numerator, and that in the screw to be cut for a denominator; add ciphers to obtain the wheels for a simple train, find suitable factors, and add ciphers to these for a compound train. Thus, guide-screw two threads per inch, and threads to be cut 13, 15, 19 per inch—

(1) $\frac{\text{Guide screw}}{\text{Screw to be cut}}\ \frac{2}{13} = \frac{20}{130}$ for single train; for double train say $\frac{2}{13} \times 5 = \frac{10}{65} = \frac{2 \times 5}{10 \times 6{\cdot}5} \times 10 = \frac{20 \times 50 \text{ drivers}}{100 \times 65 \text{ driven.}}$

(2) $\frac{\text{Guide screw}}{\text{Screw to be cut}}\ \frac{2}{15} \times 4 = \frac{8}{60} = \frac{2 \times 4}{5 \times 12} \times 10 = \frac{20 \times 40 \text{ drivers}}{50 \times 120 \text{ driven.}}$

(3) $\frac{\text{Guide screw}}{\text{Screw to be cut}}\ \frac{2}{19} = \frac{2 \times 1}{19 \times 1}$ say $\frac{20 \times 100}{190 \times 100}$ substituting $\frac{20 \times 50 \text{ drivers}}{95 \times 100 \text{ driven.}}$

By a process of halving, doubling, or taking aliquot parts, you can obtain a vast number of changes, only remembering to preserve the ratio between the drivers and driven.—J. H.

[61141.]—**Screw Cutting.**—If "Chaser" will divide the nnmber per inch of the threads of his leading screw by the number of threads to be cut, he will obtain the ratio of the driving to the driven wheels. Taking his examples $\frac{\text{Driving wheels}}{\text{Driven wheels}} = \frac{2}{13} = \frac{20}{130}$. If we have these two wheels, we can cut the thread for a double train, then, $\frac{20}{130} = \frac{20 \times 1}{65 \times 2}$. Now we want two wheels; one twice the other. Take a wheel of 30 teeth, then the second must have 60 teeth. Now we have $\frac{\text{driving wheels}}{\text{driven wheels}} = \frac{20 \times 30}{65 \times 60}$ The other examples will be $\frac{20 \times 30}{75 \times 60}$ and $\frac{20 \times 30}{95 \times 60}$.—HELIX.

[61141.]—**Screw-Cutting.** — The product of numbers of teeth in driving-wheels must be to product of numbers in driven wheels as the number of threads per inch in leading-screw is to number to be cut. Write down number of threads per inch in leading-screw, below it number to be cut, and alongside each write down number of teeth of wheel of which you have two in your set (for the lathe I run they are forties) with the multiplication sign between, thus— $\frac{2 \times 40 \text{ drivers}}{13 \times 40 \text{ drivens}}$. Now these are in the proper ratio; but you don't have wheels of 2 and 13 teeth, so you must multiply or divide until you get four numbers corresponding to four of your wheels, always bearing in mind you must multiply or divide a driven by the same number, to preserve the proportion; thus multiplying the 2 and 13 by 5 you get the train $\frac{10 \times 40}{65 \times 40}$; but you don't have a 10; but multiply the 10 and driven 40 by 2, you have $\frac{20 \times 40}{65 \times 80}$, wheels you will likely have, and which will cut 13 per inch. Precisely the same method will give $\frac{20 \times 40}{75 \times 80}$ to cut 15, and $\frac{20 \times 40}{95 \times 80}$ to cut 19 per inch.—WORKMAN.

[61142.]—**The Wimshurst Machine.**—"Shock Spark" is probably working with his Leyden jars not coated with shellac varnish, hence the free surface of the glass has a thin film of moisture upon it, up which the electricity creeps in the form of thin tree-like sparks when the jars are highly charged. The shortness of spark is, no doubt, due to some pointed surface, or other imperfection in the machine, from which the electricity leaks off. Examine it when working in a dark room, and see if it is so. Remedy any defect, and coat the Leyden jars with varnish, and you will most likely get better results; 17in. glasses suitably mounted are capable of giving sparks 8in. length.—J. W.

[61144.] — **Lathe.** — One-sixteenth of feed is heavy for a foot lathe, and it would, therefore, be preferable to take off two cuts of $\frac{1}{32}$ each.—J. H.

[61144.]—**Lathe Feed.**—The feed is not too much if it is a short length, or if well supported by a travelling stay. At the same time, if the piece is much out of truth, it is far better, and will make truer work, if the $\frac{1}{8}$in. is removed in two roughing cuts.—T. C., Bristol.

[61145.] — **Does it Boil?** — Dictionaries are cheap nowadays, and I believe they all contain definitions of the word "boil." I think our friend "Weald" will find that all liquids, even liquid metals, give off vapour long before they begin to boil, which is simply the state of ebullition, and can occur at considerable differences of temperature according to the air pressure on the liquids. Even a cup of comparatively cold water held in the hand and taken out into the frosty air, will "steam" as he puts it, because the vapours then become visible. Is the question put quite bonâ fide? I ask because there seems some hint that answers are not to urge that visible steam is not gaseous water. Steam is certainly not a gas in the true sense of the term, although superheated steam may approach very near to the conditions of a true gas; but then that requires temperatures very much higher than that of boiling water, whatever that may be.—NUN. DOR.

[61145.]—**Does it Boil?**—It seems to me you are making a slight confusion between vaporisation and ebullition. Water will vaporise at all sorts of temperatures, even below freezing point, this vaporisation depending directly on the dryness of the atmosphere, and only indirectly on its heat. The boiling point of water is a certain point on the thermometer at which, when the pressure of the atmosphere is at a certain figure, water will begin to assume the state of complete ebullition, and this point varies with atmospheric conditions, being very different at the top of a mountain from what it is in the valley below. 212° F. or 100° C. are the recognised boiling points, a certain atmospheric pressure being inferred. I believe 15lb. on the square inch, and at or about the sea level (i.e., under all ordinary circumstances), the boiling point will not vary very much above or below this, probably not more than one or two degrees either way; but it is possible to have water boiling at 180° F. on the one hand, or not boiling at 300° F. on the other.—EDWARD CONRY.

[61146.] — **Battery.** — TO MR. BOTTONE. — I have just tried one of Mr. Shippey's 5c.p. lamps marked 7 volts with the battery described at p. 561, Vol. XLIII., with the following results:—

2 cells, 1c.p.; 3 cells, 3c.p.; 4 cells, over 5c.p. Thickness of wire required will depend on distance: anything under 10 yards, No. 16 will do; over 10 up to 20, No. 14; over 20 up to 40, No. 12; over 40 up to 80, No. 10, &c.—S. BOTTONE.

[61147.]—**Red Steam.**—The red hue in this steam is "very like a tinge of angry sunset sky preceding rain," from exactly the same cause—aqueous particles in the air. The "rainbow colours" are easily seen in a spray of water produced by an atomiser. "Weald" saw the red because the watery vapour allows only the red rays to pass. Looking on a spray brightly illuminated, he would see the rainbow colours from diffraction, which may possibly also have some effect on the steam from his cup of hot boiling coffee. Mem. for the 'Xmas dinner table: to take special notice of the colour of the steam from the turkey and the goose, and the pudding.—NUN. DOR.

[61148.]—**Screw-Cutting.**—One turn moves 5-20ths, or $\frac{1}{4}$ of 3in., pitch is therefore $\frac{3}{4}$in., other screw $\frac{3}{5}$in. If leading screw is $\frac{1}{4}$in. pitch, write $\frac{3}{4}$ for mandrel, 1 for intermediate $\frac{1}{4}$ for leading screw, multiply first pair by 40, second by 80. Thus, mandrel, $\frac{3}{4}$ of 40; intermediates, 40 and 80; leading screw, $\frac{1}{4}$ of 80 (*i.e.*, 30—40, 80—20); for second screw, 30—50, 80—20; or, single gearing, 60—20 for one, 60—25 for another.—NEPHESH.

[61148.]—**Screw-Cutting.**—To cut a screw that will traverse a nut the 20th part of 3in. at the 5th of a revolution. Assuming that your leading screw is $\frac{1}{2}$ pitch, the wheels will be: lathe spindle, 60; leading screw, 40; the intermediate wheel may be any convenient size. The pitch will be $\frac{3}{4}$, 2nd 20th part of 3in. at 4th of revolution; lathe spindle, 60; leading screw, 50. Pitch will be $\frac{3}{5}$.—H. H.

[61148.]—**Screw-Cutting.**—If the screw traverses $\frac{3}{20}$in. in $\frac{1}{5}$th of a turn, then we have $\frac{15}{20}$ in one turn = $\frac{3}{4}$in., and the threads per inch will will be $\frac{4}{3}$; if the leading screw has two per inch, then $\frac{\text{driving wheels}}{\text{driven wheels}} = 2 \div \frac{4}{3} = \frac{3}{2}$ and $\frac{30}{20}$, or any two wheels having these proportions. In the other example, $\frac{3}{20} \times 4 = \frac{3}{5}$, and the rev. per inch be $\frac{5}{3}$, then $\frac{6}{5} = \frac{\text{driving wheels}}{\text{driven wheels}}$; $\therefore \frac{60}{50}$ or $\frac{30}{25}$ will cut the thread.—HELIX.

[61148.]—**Screw-Cutting.**—The first nut moves $\frac{5}{20}$ of 3, $\frac{3}{4}$in. per revolution, that is $\frac{3}{4}$ pitch, and the second nut $\frac{4}{20}$ of $3 = \frac{12}{20} = \frac{3}{5}$in. pitch. You do not give thread of leading screw, so I will suppose 2. The wheels must be $2 \times \frac{3}{4} = \frac{6}{4}$ or $\frac{60}{40}$ for first, and $2 \times \frac{3}{5} = \frac{60}{50}$ for second. You can use double train $\frac{30}{20} \times \frac{40}{40}$ for first, and $\frac{30}{25} \times \frac{40}{40}$ for second. If leading screw 4 to inch, use 60 for 40 wheel at top.—T. C., Bristol.

[61148.]—**Screw-Cutting.**—The following is the method for finding the pitch of screw you require to cut: $\frac{1}{20}$ of $\frac{3}{1} = \frac{3}{20}$ = what it travels in $\frac{1}{5}$ of a revolution. Therefore, if it travels $\frac{3}{20}$ of an inch in $\frac{1}{5}$ of a revolution, what would it travel in $\frac{5}{5}$ revolution? $\frac{1}{5} :: \frac{5}{5} : \frac{3}{20}$.

$$\frac{3}{\underset{4}{20^*}} \times \frac{5^*}{5^*} \times \frac{5^*}{1} = \frac{3}{4}$$

$\frac{3}{4}$ being the pitch of screw wanted to be cut, and exactly the same with the other $\frac{1}{20}$ of $\frac{3}{1} = \frac{3}{20}$ what it travels in $\frac{1}{4}$ of a revolution. Therefore, if it travels $\frac{3}{20}$ of an inch in $\frac{1}{4}$ of a revolution, what would it travel in $\frac{4}{4}$ revolution $\frac{1}{4} :: \frac{4}{4} : \frac{3}{20}$

$$\frac{3}{\underset{5}{20^*}} \times \frac{4^*}{4^*} \times \frac{4^*}{1} = \frac{3}{5}$$

$\frac{3}{5}$ being the pitch of screw wanted to be cut. You cannot expect to know what wheels to put on when you do not give the pitch of your leading screw.—WALLACE NEWLAND.

[* Cancelled figures.]

[61148.]—**Screw-Cutting.**—$\frac{1}{20}$ of 3in. is $\frac{3}{20}$in., which multiplied by 5 gives traverse for one revolution, which is, of course, the pitch. Now, $\frac{3}{20}$in. $\times 5 = \frac{3}{4}$in. pitch of first mentioned screw; and $\frac{3}{20}$in. $\times 4 = \frac{3}{5}$in. pitch of other. Now, the driving-wheel or wheels must be to the driven wheel or wheels as the pitch to be cut is to pitch of leading-screw (don't confound the pitch spoken of here with the number per inch); hence, supposing your leading-screw to have two threads per inch, then $\frac{\frac{3}{4}}{\frac{1}{2}} = \frac{30 \text{ driver}}{20 \text{ driven}}$ or $\frac{60}{40}$ or $\frac{120}{80}$ any of which gears will cut $\frac{3}{4}$in. pitch. Again—

$\frac{\frac{3}{5}}{\frac{1}{2}} = \frac{30 \text{ driver}}{25 \text{ driven}}$ or $\frac{60}{50}$ or $\frac{120}{100}$ any of which will cut $\frac{3}{5}$in. pitch.—WORKMAN.

[61148.]—**Screw-Cutting.**—Traversing one-twentieth part of 3in. in the fifth of a revolution, in one revolution the traverse will be five-twentieths, or $\frac{1}{4}$ of 3in. = $\frac{3}{4}$in. = $\frac{3}{4}$in. pitch, or four threads in 3in. In the second case a traverse of one-twentieth part of 3in. in the fourth of a revolution means that in one revolution the traverse will be four-twentieths, or one-fifth of 3in. = five threads in 3in. In each case 3in. contains a complete number of threads. Taking the first case, and assuming a leading screw of two threads per inch (you do not state the number), you have the ratio—

Leading screw = 6 threads in 3in.
Screw to be cut = 4 " "

Hence, $\frac{6}{4} = \frac{60}{40}$ or $\frac{30}{20}$ or $\frac{120}{80}$ drivers. driven.

In the second case—

Leading screw = 6 threads in 3in.
Screw to be cut = 5 " "

Hence, $\frac{6}{5} = \frac{60}{50}$ or $\frac{120}{100}$ or $\frac{30}{25}$ drivers. driven.

—J. H.

[61148.]—**Screw-Cutting.**—To cut a screw that will traverse the 20th part of 3in. in one-fifth of a revolution:

20th part of 3in.
5th part of 1 revolution.
3in.
5 whole revolution
—
20)15
4 = $\frac{1}{4}$
—
60($\frac{3}{4}$in.
$\frac{3}{4}$ pitch $4 \times \frac{3}{4} = 3$in.
Leading-screw 4 to 1in. × 3 = 12.

$$\frac{4}{12} = \frac{40}{120} = \frac{5 \times 8}{10 \times 12} = \frac{50 \times 80}{100 \times 120} = \frac{50 \quad 40}{100 \quad 60}$$

To cut a screw that will traverse the 20th part of 3in. in one-fourth of a revolution:

20th part of 3in.
4th part of 1 revolution.
3in.
4 whole revolution.
—
20th)12
5 rev.
—
60(3in. long 5 rev.
5 threads in 3in.
Leading-screw 4 threads to 1in. × 3 = 12.

$$\frac{5}{12} = \frac{50}{120}$$

$$\frac{5 \times 10}{10 \times 12} = \frac{50 \quad 100}{100 \quad 120} = \frac{25 \quad 100}{50 \quad 120}$$

$$\frac{5}{12} = \frac{5 \times 5}{5 \times 12} = \frac{25}{60} = \frac{\overset{25}{50^*} \quad 50}{\underset{30}{60^*} \quad 100}$$

* Cancelled figures.

—WESTWOOD.

[61149.]—**Dynamo.**—Detach the coil that heats from its neighbour, if a Gramme ring armature, and join these two by a short bit of wire of larger gauge than that of the armature wire. If the armature be drum-wound—i.e., each coil separate from the rest—separate the offending coil from its sections of the commutator at each end, and run without it. If this causes the machine to spark too much (which depend greatly on the current and E.M.F. it was giving), join the two commutator bars to which the coil was attached by a piece of wire of larger gauge, as in the Gramme ring case. A piece of the armature gauge, doubled, will do very well. If you have leisure, you might design a couple of little plug connections, so as to plug the coil in or out at pleasure, or else do it by connecting through a ferrule joint with screws at each end, one end of the wire to be connected always and the other at pleasure.—EDWARD CONRY.

[61156.]—**Battery for Lamps.**—I should suggest your continuing the double fluid, with sulphuric acid and water in outer, and saturated solution of bichromate of potash in inner cell. I have used this cell greatly, and have found it clean and convenient, and not wasting to any material extent by the solutions being left standing. In this respect I prefer it to chromic acid solutions. Have a look at the cells now and again to see that the sulphuric solution is never lower than the other, as, if this happens, the bichromate may leak through the porous pot and soil the zincs, which last should always be amalgamated, otherwise the cells will waste their strength in local action. I will send you next week a datum from which you will be able to calculate pretty nearly how much you would get out of any sized cell as above.—EDWARD CONRY.

[61157.]—**Condensing and Non-Condensing.**—If you have 10lb. pressure in exhaust-pipe you are crippling engine very much indeed. But I suppose this is purely a coal question with you; if so, an experiment will suit you best. You could, for example, notice nearly exactly how much fuel it takes to keep steam and fires exactly in same state for one or two hours, and then how much it takes in same time when engine is running. Again, it is dependent on number of hours engine and heating apparatus are working per week. Some five years ago I had a similar case, and it was rather a nice point as to whether it should be a new condensing or non-condensing engine, and I decided under the special circumstances on non-condensing. There is nearly the same heating power in steam at 5lb. as at 10lb.—T. C., Bristol.

[61158.]—**White Enamel or Paint.**—Use the white glazed tiles where you can, and cover other parts with zinc oxide paint ground in best stoving copal.—NUN. DOR.

[61159.]—**Electrical.**—"Elm" will find the Nicholson's revolving doubler fully described in the *Phil. Trans.*, Vol. LXXVIII., page 405. Bennet had the electrophorus only, and so used them by hand as to increase the charge.—J. W.

[61160.]—**Herbs.**—There is no tisane in the "Formulaire Magistral" called "tisane aux quatre herbes." Probably "Uranos" means the very common "tisane aux quatre fleurs," which is much used for cough soothing. Here is a recipe:—Fleurs de guimauve (flowers of marsh mallow), fleurs de pied de chat (flowers of catsfoot or everlasting), fleurs de pas d'âne (flowers of coltsfoot), fleurs de coquelicot (flowers of wild poppy). Take equal quantities, dry, mix, break up small, and infuse as we do common tea, using about the same quantity; the proportion given in the Pharmacopœia is 12 to 1,000 of boiling water.—B.SC., Plymouth.

[61162.]—**Sewing Machine.**—Is the "Pestered Man" using same tensions for thick work as for thin? It seems (by his query) that the hook takes fresh thread from the reel instead of pulling up the old loop. His thread should be well oiled, and the work slightly soaped. Then tighten up the tension till the loops disappear, and the bottom thread pulls well up into the work.—NEPHESH.

[61162.]—**Sewing Machine.**—Probably the loop is left because the spring box or thread check through which the cotton passes prior to tension pulley has become clogged, and does not put sufficient strain on cotton to prevent it slipping round tension pulley instead of turning the pulley. If by turning the thread three times round tension the machine works, this the cause certain. Remedy—clean out thread check, take out screw in end spring, and two discs, clean and replace. It must put enough strain on the thread to prevent it slipping over the tension pulley without turning said pulley.—ROBERT ROYCE.

[61163.]—**Faulty Dynamo.**—TO MR. BOTTONE.—The proportions of your wire on armature and F.M.'s are wrong, hence your partial failure. Put about $\frac{3}{4}$lb. No. 20 on the armature and 5lb. No. 18 on the field, or 7lb. No. 16, and you will be nearer the mark. As it stands at present, the resistance of your single Swan lamps is too high. Try two or three in parallel; or get one of one-third the resistance; or look at the last page of my book, "The Dynamo," as to the mode of coupling up in shunt.—S. BOTTONE.

[61164.]—**Observatory.**—A "gun-tackle purchase" is generally composed of two single blocks. If "Observer's" roof is not too heavy, I don't see where he will need them, if his sash rollers are large enough. My own Berthon roof is 12ft. diameter; it is fitted with 2in. sash rollers and stout galvanised plate, and can be easily turned by thumb and forefinger; it has been up more than two years. Keep all rollers well oiled at bearings. "Observer" should have stated size of his roof, as much depends upon this. If he and "C. T." will write to 28, East Claremont-street, Edinburgh, I shall be pleased to help them in any way I can. It is difficult at times to reply to queries from lack of knowing what is really required.—H. A.

[61165.]—**Diffraction.**—I cannot do better than refer F. Bennett to Prof. Tyndall's most useful little book, "Notes on Light." Its price is only a shilling, yet I think it contains all that an ordinary reader requires. Here he will find the phenomenon of diffraction fully explained.—H. A.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last, Jas. A. Campbell has replied to 60530.

QUERIES.

[61171.]—**Electric Railway Signals.**—Wanted, some account of the new electric block system that is being fitted up through the Severn Tunnel.—ELECTRIC.

[61172.]—**Engines.**—Will any reader favour us with details of one of the Midland heavy mineral train engines with the small wheels?—LOCO.

[61173.]—**Varnishing Fishing-rods.**—I am trying to varnish some fishing rods, but I cannot succeed to my satisfaction. After applying the varnish, which is made of rectified spirit and best shellac, I find that a multitude of very small bubbles breaks out all over the rod, and instead of feeling smooth there is an unpleasant roughness. Will a kind reader help me out of my difficulty?—SHELLAC.

[61174.]—**Cane-Splitting Machine.**—I shall feel obliged if any of your readers will give a description of a machine for splitting cane.—R. G. M.

[61175.]—**Sugar for Removing Boiler Scale.**—A short time ago, there appeared in your columns a paragraph describing some experiments made (I think by an Italian engineer) with sugar as a means of removing and preventing the formation of scale in steam-boilers, and asking subscribers who might try it to give the results of their experience. I have charge of a 4-horse vertical boiler which, through neglect, had become badly scaled. During the last four or five weeks I have put in about $\frac{1}{2}$lb. of common brewer's sugar at intervals of seven days, and blown off a couple of gallons or so of water twice a day while working. On breaking man-lid and mud-door joints last Saturday, I was agreeably surprised to find that a considerable detachment of scale had taken place, so much so that I had some difficulty in removing mud doors, pieces of scale as large as my hand having been loosened and fallen into the narrow space between boiler shell and firebox. We use only town (Birmingham) water, which is hard. If I continue the use of sugar to the effectual removal of all scale (which I anticipate), would some of our scientific contributors say if it would be safe to use it as a detergent, or whether it would be likely to injure the plates? I had hoped to see some experiences on this question in "Ours" before now, as it is of considerable importance.—OMPAX.

[61176.]—**The Wimshurst Machine.**—I have nearly completed my 12in. influence machine, and have met with an unfortunate mishap. I mounted the plates about a week ago by cementing them to ordinary deal bosses with Prout's elastic glue, then varnished and placed on the sectors, and put away in a cupboard to dry. On taking them out, I found a large crack on one from the boss to the edge, and the other was cracked wedge shape. Though the glass did not cost much, I do not wish to do away with them, as it has cost me time and trouble by varnishing, placing on the sectors, and mounting. Would they do if I cemented the edges with Prout's glue? This will hold them firmly, as well as the bosses. In the next plates I mount, would cementing a thin washer between the boss and glass prevent cracking? Does one always get the same sign of electricity from each terminal, or does it vary? In the Voss, the sign of electricity we get depends which paper disc on the stationary plate has the greatest initial charge, and so the increasing quantity of the charge starts from this disc. Does the Wimshurst machine act like this by starting its charge from the plate whose sectors have the greatest residual charge, and so get electricity of various signs at different times, or is it constant whenever used? What is the theory and advantage of two different-size discharging balls? Are large or small Leyden jars the best for good sparks? Will the machine work if the plates are $\frac{3}{8}$in. apart?—ELECTRICITY STUDENT.

[61177.]—**Plate Machine.**—Can I make a good small frictional machine with a 5-16in. plate-glass disc 8in. in diam? Also the proper sizes for the combs, rubbers, bosses, conductors? Also a simple way of mounting a plate machine disc with and without a central aperture?—ELECTRICITY STUDENT.

[61178.]—**Electric Lamp.**—Will someone kindly advise me as to whether small lamps, say of 5c.p., can be repaired when the platinum terminals are broken off flush with the glass, and, if so, how?—S. M. S.

[61179.]—**Concrete and Cement Plastering.**—Will some engineering reader who has a knowledge of the above kindly state if it is a fact that salt (or sea) water is not suitable for mixing with cement, sand, gravel, &c., to form concrete or cement plaster? It is stated by many that it is not, and I should like to know why, if it is so?—IRISH CONTRACTOR.

[61180.]—**Dynamo.**—I have a small set of castings, which I have made. I want to make them into a dynamo to supply six lamps 45 volts. Please give me size and weight of wire for magnets and armature for series winding—that is, if castings are large enough: Armature, $3\frac{3}{8}$in. diam., 2in. wide; magnets, 3in. long, 1in. diam.; four limbs to magnets.—AMATEUR.

[61181.]—**To Mr. Bottone.**—Is this the proper proportion of resistances for a compound Gramme machine, E type, to maintain 120 lamps, 110 volts: R. armature, 1-20 ohm; R. magnet, series coil, 1-30 ohm; R. shuntcoil, 50 ohms. If not right, please put me right.—AMATEUR.

[61182.]—**Lead Hammers.**—Can any reader inform me how to mix antimony with lead for the purpose of hardening the lead for making lead hammers? I have tried melting the antimony with the lead; but it appears to burn on the top of the molten lead and will not mix with it.—W. M.

[61183.]—**Engine Details.**—Would any of our fellow-readers please give me size of slide-valve and throw of eccentric to cut steam off at half-stroke for cylinder, diam., $3\frac{1}{2}$; length of stroke, 5in.; size of ports, steam 5-16 by $1\frac{3}{4}$, exhaust $\frac{5}{8}$ by $1\frac{3}{4}$; bars between, 5-16? Also, please show how to get size of slide valves and eccentrics for any cylinder, or recommend book on same?—GREEN LAD.

[61184.]—**Sheep Dip.**—I understand that undiluted oil made from coal-tar is used for this purpose, although sold under some fancy name. Could any reader of "Ours" inform me as to this, and if not used without the addition of water, hot or cold—how many gallons is used per 100 sheep? The oil contains carbolic acid.—WOOL.

[61185.]—**Twin Screw and Paddle Engines.**—Will any of your correspondents kindly give me information (as fully as possible) as to the advantage possessed by twin screw and paddle engines (disconnecting or otherwise) over the ordinary type?—TWIN SCREW.

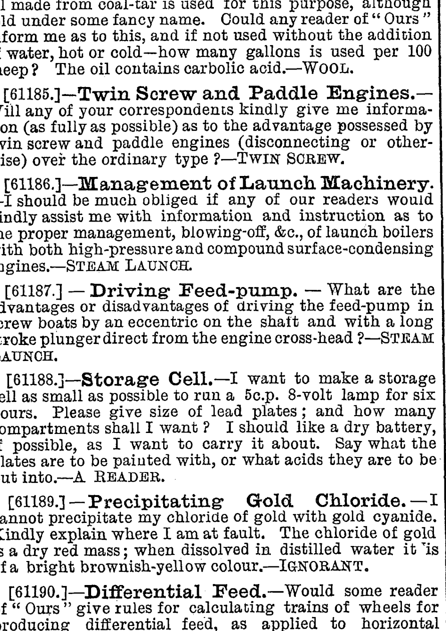
[61186.]—**Management of Launch Machinery.**—I should be much obliged if any of our readers would kindly assist me with information and instruction as to the proper management, blowing-off, &c., of launch boilers with both high-pressure and compound surface-condensing engines.—STEAM LAUNCH.

[61187.]—**Driving Feed-pump.**—What are the advantages or disadvantages of driving the feed-pump in screw boats by an eccentric on the shaft and with a long stroke plunger direct from the engine cross-head?—STEAM LAUNCH.

[61188.]—**Storage Cell.**—I want to make a storage cell as small as possible to run a 5c.p. 8-volt lamp for six hours. Please give size of lead plates; and how many compartments shall I want? I should like a dry battery, if possible, as I want to carry it about. Say what the plates are to be painted with, or what acids they are to be put into.—A READER.

[61189.]—**Precipitating Gold Chloride.**—I cannot precipitate my chloride of gold with gold cyanide. Kindly explain where I am at fault. The chloride of gold is a dry red mass; when dissolved in distilled water it is of a bright brownish-yellow colour.—IGNORANT.

[61190.]—**Differential Feed.**—Would some reader of "Ours" give rules for calculating trains of wheels for producing differential feed, as applied to horizontal boring machines? A is wheel keyed on mandrel driving B (B and G are keyed on a sleeve, which revolves on spindle C), G drives D, which is keyed on screw S. If



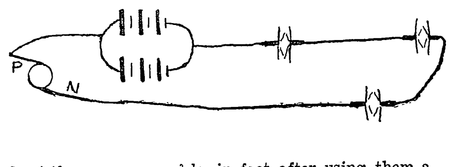
pitch of screw = 3 threads per inch, what trains of wheels would produce 35·8 and 3 threads per inch respectively? Will the introduction of intermediate wheels produce different results? As "Goodeve's" and other textbooks are in no way exhaustive on this subject, perhaps some of our able correspondents will oblige—A BELATED FOREMAN.

[61191.]—**To Mr. Wimshurst.**—I have a 12in. plate machine, with combs on glass tubes and 12 brass sectors, 2 3-16 by 7-16 by $\frac{1}{8}$, on each plate; but I cannot get it to excite itself, though if a charge is given to it, it gives a brush discharge about 3in. long. What size of jars should I also use for same?—LES DENTS.

[61192.]—**Colouring Stock Fittings.**—To "ARMOURER."—Many thanks for your kindness in answering my query. I shall be glad to avail myself of your kind offer of lending me the tool; and now there is one thing more I should like to know: How to colour the stock fittings. I have tried two or three ways, but cannot manage it properly.—J. BEARDSHALL.

[61193.]—**Poisonous Alkaloids.**—Balland about two years ago recorded in *Jour. de Pharm. et de Chem.* that poisonous alkaloids existed in old flour. Has this been verified, and to what extent? Mr. Allen would probably oblige—ARMY HOSPITAL COMPOUNDER.

[61194.]—**E.P.S. Secondary Batteries.**—Will some reader of our journal inform me the best plan of recharging the above batteries from a series-wound dynamo, running three arc lights in series, with a C of 15 ampères at 185 volts? The batteries are 8in. by 10in. by $2\frac{1}{2}$in. I have tried to charge them repeatedly by connecting them in multiple arc with lights, as per sketch,



and yet they are very weak—in fact, after using them a few seconds they appear to lose all traces of charge. Should I charge them by connecting them in series with the lamps? I don't think the cells are in any way defective, and they are comparatively new. Does the solution require changing, or how am I to know when to do this?—OWEDA.

[61195.]—**Damage by Woodworms.**—Certain pieces of my furniture in daily use have been attacked by woodworms, and it appears to be spreading over the rest, new and old. In some instances the wood has been riddled to the consistence of sponge. Could any correspondent tell me what will stop this, and whether a bad piece of wood will infect another? I have tried rubbing cayenne pepper into the holes and flooding them with turpentine, but without avail.—F. K.

[61196.]—**Staining Leather.**—What will stain new sheep skin leather to the various shades of dark-brown and dark olive, so as to match old calf binding, as I wish to re-back certain old volumes? Also how to stain light-coloured leather into scarlet suitable for labels? Any hints would greatly oblige—F. K.

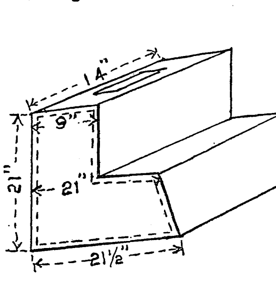
[61197.]—**Motor and Coil.**—Kindly inform me what is the average cost of working motor and electric motors from $\frac{1}{4}$ to 3H.P. Will No. 26 s.c. wire do for induction coil, secondary, and what quantity to get 1in. spark? What are the advantages of coils made in section, and details to make one? What size platinum points are best for contact breaker, and if it requires more primary than an ordinary one?—J. L.

[61198.]—**Induction Coil.**—What length of spark will an induction coil (with condenser) give of the following dimensions? It measures 3 by $1\frac{3}{4}$, is wound with two layers of No. 18 cotton-covered wire for primary, and 6oz. of No. 40 silk-covered for secondary (in sections).—F. DAWSON.

[61199.]—**Fan.**—Would "Rouge Gorge" kindly send description of fan mentioned by him in his reply to query 61019?—H. E. SMITH.

[61200.]—**The Work of the Heart.**—Can any of our readers tell me (1) the average weight of food consumed by an adult, and its heat value, (2) and average work done by one man in 24 hours? It seems to me the food consumed must give an extraordinary duty if the heart does work = raising 125 tons 1ft. in 24 hours, to which I suppose must be added the work done by the man himself.—H. E. SMITH.

[61201.]—**Range Boiler.**—Will someone kindly give a sketch how range boilers are moulded in greensand?



No chaplets are to be used for steadying the cores. This sketch will show what is wanted to have only one opening on the top, 8in. by 6in.—H. S. H.

[61202.]—**Fret Saws Breaking.**—I have a fretarm fitted to my 3in. lathe, driven as usual by a pin in the face-plate. The saw is held between one arm of wood and a vertical sliding bar, working in guides below the platform. The action is easy, and apparently all is as it should be; but I break saws, sometimes every few minutes, and even in a straight cut in $\frac{1}{4}$ stuff. Can any reader suggest the reason? I am a novice; but I take great care, and endeavour only to press the wood straight forward. I strain the saw fairly tight, till it just twangs if tried like a harp string. I fancy it is better to strain the saw between two arms like a Roger fret machine, as there is no sliding bar needing lubrication, and the driving power is not communicated to the oscillating arm by making a connecting link of the saw itself; but hundreds are made as mine is, and I suppose they are found to answer. One of Churchill's machines is advertised to cut 3in. stuff, so that a fret saw must be capable of standing a deal more strain than $\frac{1}{4}$ stuff can bring upon it. The saws appear to be fairly tough if tried by bending and purposely breaking one. Someone please assist.—O. J. L.

[61203.] — **Porous Pots.** — To "EVELINE, NEWPORT," OR OTHERS.—In the "E.M." for April 16th last, p. 154, you say it makes porous pots act better to bake them over a clear coke fire. Would a clear coal (or anthracite, perhaps) do as well? Also how to bake them? Am I to cover entirely with coal, or merely rest them on the top and turn them? Is there any other method?—LONDINIENSIS.

[61204.]—**Photographic.**—What distance should the stop be placed in front of a view lens? Also, is the Rectilinear the quickest for instantaneous work?—LENS.

[61205.]—**Mechanics.**—Would any of our mechanical friends kindly help in the following questions? A vertical bar, moving in guides, is driven by a circular cam plate, having a centre of motion in the line of direction of the bar. The distance from the centre of motion to the centre of plate is 2in., and the bar exerts a pressure of 10lb. when rising, but falls by its own weight. What would be the work done in 100 revs. of the plate? (2) A horse drawing a cart along a level road at the rate of two miles per hour performs 29,216 foot-pounds of work in three minutes. Would anyone tell me what pull in pounds the horse exerts in drawing the cart?—NOVICE.

[61206.]—**Clothing.**—Would some kind fellow English Mechanic, or his wife, help a mother who likes to keep her boys and girls well clothed? I can manage to make up the garments; but it is such a puzzle to me to cut them out. Father and the boys are able to measure and draw all the various parts of their work, and it goes together the first time. Isn't there some method whereby I could measure them up, take the dimensions of the young "urchins," and then develop it on paper, so that I could feel that I was going to work scientific? "Draw a correct line and then work to it," as Ned says. A little instruction on the above would greatly oblige many a mother, as well as—JANE CONSARCINATION.

[61207.]—**Paper Doors.**—Will any of our readers kindly inform me if they know of paper doors and mantel pieces being made? If so, how?—JOINER.

[61208.]—**Watch.**—(1) What do watch-makers use to restore the dull crystallised appearance on the works of watches that have been handled with hot fingers? (2) Does a slightly bent balance wheel make any difference to the time-keeping qualities of a watch?—A. C. J.

[61209.] — **Psychological.** — To "GARRISON GUNNER."—I have a friend wholly given up to "drink." He is the father of a respectable family, and is very anxious to reform, but has lost all control over himself. I have just been reading an account of a case of mesmeric treatment of a desperate criminal, thoroughly bad and unmanageable in prison, who had it impressed upon her while in the mesmeric sleep that on recovering her normal state she was to become a reformed character. A course of this treatment had the desired effect, and she is now a hospital nurse. When I read the above, I could not help but wish that my friend could be treated in a similar way. Does "Garrison Gunner" know of any similar case, and would he advise my friend to try it?—T. EDGE.

[61210.] — **Mean Pressure.** — Referring to the ENGLISH MECHANIC, dated April 23, I should be much obliged to "Fizgers, Belfast," if he would kindly explain a little matter in his description of "Rankine's diagram for mean pressure" on page 173, and the 35th line from the bottom in the third column, it states: "take $BM_3 = \frac{1}{2}$ BM + the back pressure." The question is: How is the back pressure to be taken into account, as BM_3 is, of course, larger than $\frac{1}{2}$ BM by itself, and $\frac{1}{2}$ BM alone would bring that point inside the triangle instead of in the sector of the circular arc? I also notice in Rankine that the length of AX is decided by taking CI as a radius, and describing the arc from the centre C and cutting the line AX.—ASAPH.

[61211.]—**Planing Machine.**—To "T. C., Bristol," AND OTHERS.—I am making a small planing machine. Could you give information of how to drive it with one pulley or by treadle to get a quick return motion? There is one (The Eureka) that does this. Any information on this subject will oblige—PLANING.

[61212.]—**Oilcloth.**—Would any kind reader inform me what the blocks are made of for printing oilcloth, and what kind of paint is used for same, and kindly state if there is a book published on the above subject?—NOVICE.

[61213.]—**Engine Query.**—To "T. C., BRISTOL."—Kindly let me know this: We have a winding engine here. When she is working in back gear, if we will put a drop of oil on bottom bars, it won't be touched until steam is shut off. The blocks keep up to the top bars, and keep to the bottom bars when working in forward gear. It is a double engine, working first motion—slide valves.—ENGINEMAN.

[61214.]—**Pumping Set.**—Would any reader give me any information about a set hanging her column? I understand it is a quantity of air between the bucket and clack, and cannot get rid of it. Is a bad clack the cause of it?—CLACK PIECE.

[61215.]—**To Mr. Bottone.**—(26559, No. 1132.) Can you supply more lamps like the one you describe as only requiring 4·7 of an ampère, or tell me where I could procure them? Any information would oblige. What was the c.p. of the lamp, and how many volts did it require?—HARRY FRIVOLI.

[61216.]—**A Good Battery.**—Can anyone tell me where "Cato" has answered "Peregrinus" (60889)? I have looked very carefully, but have seen nothing as yet. If he has not answered, is it not rather cruel to keep many (no doubt) in suspense after raising our expectations as he did? If this comes under "Cato's" notice, I hope he will, at any rate, satisfy my curiosity, which has been fully aroused.—HARRY FRIVOLI.

[61217.]—**Pocket Barometer.**—In your issue of Dec. 4th is a diagram of an aneroid barometer, which, on the face of it, appears to give an immense amount of information; but which, nevertheless, in principle appears to me to answer a want I have felt, but which I had not the ingenuity or speculation to overcome. I have been living near Sydenham-hill, and come to the City every day to satisfy the stern necessities of life, and I carry a small aneroid in my pocket. I take the readings of barometer at home each evening and morning, and during the day generally inspect it also; but the result of these mid-day inspections is frequently to mislead me. My barometer hand points where it did when I left home. I say "Yes, steady—promises fair;—arrange accordingly for the evening's pastimes; but to my annoyance the instrument plays me false at the moment I have forgotten the change of altitude, and the apparently unmoved hand really means a fall of, say, 1-10in. in a few hours, which is a very different warning to steady. I know the difference of height; but it is not convenient to go into an elaborate calculation of three points of decimals at any moment one may desire to look at the barometer before you can tell what it means. Now, with the plan described by your correspondent "Montmartre," it appears to me we have only to set one of the motions, say A, for the diurnal change, and another, say B, with the altitude on it just 75ft., 100ft., or whatever may be necessary below it; then I know that in the City I always read changes from B, at home from A. Now, there are one or two points I would like to ask your correspondent "Montmartre"—viz., are these motions independent of each other. Also, to a person who has no intention of travelling on the continent of Europe, and therefore would only require English measurements, whether it would be necessary to have more than two of the motions? The size shown is excellent for reading; but your correspondent does not say anything about thickness. All the aneroid barometers I have seen of such a size seem to have been designed more to fix in one's hat than to carry in the waistcoat pocket.—TOWERS.

[61218.] — **Lighting Lantern.** — Will any reader kindly help me with the following? I want to light up my magic-lantern with the most powerful incandescent light possible; space about 4in. sq. Can I get one lamp of 40 or more c.p, or must I have, say, three 25c.p.? If so, how many cells shall I want, and will ordinary bichromate arrangement with chromic acid be most efficient and economical? Also, how many hours such a battery will run with one charge, say two hours each night?—MAHMOUDIE.

[61219.]—**Gold Solutions.**—Will any of "ours" kindly tell me what is the cause of my gold solutions only acting for a short time? I have made up solutions from the "E.M.," and from "Watt's" and other sources, and have managed to get the right colour at first; but after four or five times using I can get nothing but a very very pale deposit, and only that after the article has been in the solution for some time. I know a little about electricity, and am perfectly sure my battery is right, and know how to regulate the current accoring to articles, &c. I have tried all ways to get solutions to act right, but cannot succeed, and am rather discouraged thereby. I only want to gild small articles, such as gold and silver brooches, bangles, &c., and it is rather too expensive a process to make up solutions every few weeks for the small number of articles I want to do. The solutions are kept securely corked up in bottles when out of use, and are quite free from organic matter of any kind, and only use them about twice a week.—PUZZLED JEWELLER.

[61220.]—**Boxwood.**—Can any reader of the ENGLISH MECHANIC give me the following information? Approximate annual importation to Great Britain, in pounds, of boxwood? Where imported from, and average wholesale price? Principal uses, or any further information.—J. P. R.

[61221.]—**Cutters.**—Could any of your readers inform me how wire nails are cut to form the square points? A small drawing, showing how the cutters work, would oblige—VERNON.

[61222.]—**Electric Indicator.**—Would Mr. Conry kindly give the amount and gauge of the wire he would employ to wind the electro-magnets figured in his sketch? Also the length of the cores of the same? What should be the distance between the points N and S of the permanent magnets shown?—H. F. C., Liverpool.

[61223.]—**Balancing Millstones.**—I am working a pair of 4ft. 4in. French millstones, grinding wheat for flour. While standing they are a true balance, when running they are not on a balance, but drag on one side. The spindle is quite upright. The stone is driven by over drift. The foot of driving spindle takes equal bearing. The centre bar bites equal upon the driver. The cock-head is in good order. All irons are free and easy. Bed stone is quite true and level; yet the stone is not on balance when running. I have four other pairs in the mill all run well. Will any of our milling friends help me a little in this important matter?—CHATTERIS.

[61224.]—**White Metal.**—Can any reader tell me if white metal, such as is used for the cranks of many traction engines, would be suitable for stone spindles to run upon? Would it be better than brass; also cheaper (I am told it would be), and what is it made from? I should be much obliged for any practical advice upon the matter.—CHATTERIS.

[61225.]—**Ironing Machines.**—Will any kind reader tell me if there are any domestic ironing machines patented? We have read of one that was exhibited in London this year that was driven by steam.—MECHANIC.

[61226.]—**Barometer.**—Could any of our numerous readers tell an anxious amateur the cause of the glass weight of a mercurial barometer refusing to float back the weight, although the mercury comes up the tube. It comes up the side of the glass rod, and when it is floated up does not follow the mercury back easily, but spasmodically. The glass rod does not seem too thick for the tube. I wonder sometimes if the mercury is dirty, or the tube is greasy, and, if so, how must I proceed to make right?—A CONSTANT SUBSCRIBER.

[61227.]—**Model Boiler.**—To "T. C., BRISTOL," AND OTHERS.—I should be very pleased to be instructed how to make an engine boiler of an 8-gallon copper pot. The sides are nearly 1-16in. thick; the middle of the bottom $\frac{1}{8}$in. I should particularly like to know what pressure of steam it will stand with safety, if well made. The pot weighs 12lb. now the handle and other irons are taken off.—J. K.

[61228.]—**Lantern Transparencies.**—Can any of your readers tell me the best composition for stopping out transparencies for lantern? Have tried Bate's black varnish, but not sufficiently opaque.—DENSITY.

[61229.]—**To Mr. Striffler.**—I am making a battery as described by you on p. 240 of Vol. XLIV. Will you kindly say what you mean by preparing the porous cells with paraffin and tallow, and if it is often necessary to remove the sulphate of zinc from the porous pots?—HOLLAND.

[61230.] — **Watch Conversion.** — Can "Watchmaker," or any of our readers, tell me what size lever escapement I shall require for above purpose? The top plate measures $1\frac{1}{2}$in. and 3-16.—WATCH CHAIN.

[61231.] — **Dynamo (Ten 20c.p.)** — To MR. BOTTONE.—Wanted to know what pattern of dynamo is best for the above? Size of magnets and armature, quantity and size of wire for F.M.'s, and for armature. I have Mr. Bottone's book, and sincerely hope he will soon do for the "ring" armature what he did for the Siemens H armature.—BRIAN BORU.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 332, *Strand, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

***** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.**

CHRISTMAS DAY.

THE ENGLISH MECHANIC will go to press some hours earlier than usual next week, in order to complete publication before the Christmas holidays. All advertisements must, therefore, reach the office by 5 p.m. on TUESDAY, Dec. 21, instead of by 1 p.m. on Wednesday, as usual.

The following are the initials, &c., of letters to hand up to Wednesday evening, Dec. 15, and unacknowledged elsewhere:—

W. H. BAILEY AND CO.—C. Richardson.—T. E. Espin.—Rev. Edw. Harte.—H. Thorpe.—John Clarke.—W. Rammage.—M. Glover and Co.—Miller.—Woodworker.—P.—Arinas.—H—H. O., Glasgow.—One out of Work.—A. F. Shakespear.—J. J. S.—R. T.—Micky Dooley.—W. W.—F. M. E.—S. Bottone.

JAS. WRIGHT. (Referring to the article in Vol. XXXVI., it appears that a description of the galvanometer was given in the *Journal Universel d'Electricité*, while the illustrations in No. 911 represent improvements. In these circumstances, it does not appear necessary or advisable to reproduce the earlier description, which is, however, available in the journal mentioned.)—BLACK. (Methods of ebonising furniture and woodwork generally have been frequently given. See No. 1078, p. 246; No. 979, p. 371, and the indices generally.)—GEMINORUM. (For cleaning old books, see p. 120, last volume, where there is an article on the subject.)—G. CORRELL. (There is no truth in the statement that fruit stains in a table-cloth can be taken out by the sun's rays only at the time the fruit-trees are in blossom. The sun's rays act as a powerful bleaching agent at all times. Most fruit stains yield readily when the cotton or linen is well soaped, and a little powdered potash or common salt is sprinkled on the spot, which is kept moist and exposed to the sun.)—AN OBSERVER. (The "scientific reason" is the other way. The sun's rays do not put a fire out, as can be demonstrated by a simple experiment, which is the scientific way of treating such a question.)—MAGISTER. (You are suffering from progressive myopia, and just as your sight became shorter as you approached manhood so it will grow shorter still, unless you wear suitable spectacles. Friends who tell you that when you get stouter your former good sight will return, express a common belief; but you are short-sighted because your eyeballs have lost their normal form and are now longer from back to front than they should be. Mr. R. B. Carter, in his work on "Eyesight, Good and Bad," says: "When myopia is once established, and unless its influence is speedily counteracted, it provides for its own increase by the effect of convergence effort." Therefore, let an oculist provide you with suitable spectacles at once.)—A CONSTANT READER. (Yes, we believe petroleum is useful in the case; but see a paper on the subject in No. 1061, p. 456.)—J. H. ARTHUR. (We do not know of a book in which such directions are given. You will find directions in back volumes—e.g., p. 311, Vol. XXXIV. There are some directions for mounting crystals in Martin's "Manual," published by Churchill.)—AGRICOLA. (Is there such a book? You will find information about rams in Vol. XLII.; but we know of no work specially devoted to the subject.)—G. H. SUTCLIFFE. (There is a "Practical Carver and Gilder's Guide and Picture-frame Maker's Companion," price 2s. 6d., Savory, Cirencester. They are usually held in the vice. See index to Vol. XXXV.)—EXHIBITOR. (Yes, "something similar," with a considerable difference. There is no doubt about it, if the attachments are springs or elastic; but nothing is said about elastic strands on p. 195.)—OLDHAM CHAP. (In No. 1115.)—BLACKSMITH. (See indices of recent volumes—the last, for instance.)—E. DAVID. (Polish with rottenstone and oil, after removing all scratches with water of Ayr stone.)—T. REKSAT. (Mineral oil lamps can explode only when the reservoir is filled with a mixture of air and vapour of the oil. The majority of the lamp accidents are not explosions, but "falls." See p. 48, No. 1043, and a discussion in subsequent numbers. The real explosions are caused by moving the lamps rapidly or by blowing down chimneys to extinguish them.)—YOUNG MACANIC. (About half a dozen. Why use small carbons? See back numbers for many

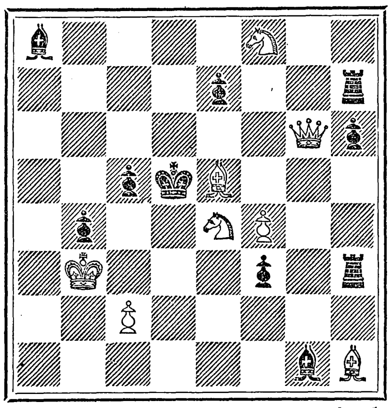
answers to such a question.)—SPENCER. (Do you not understand that the duration of any battery depends entirely on the amount of work it is called upon to do? The Leclanché lasts a long time when called upon to work at intervals only; but it is not really suited for electric lighting. See a number of replies on this question in No. 1082, p. 325.)—J. W., Manchester. (Perhaps it is a weak solution of acetic acid; but we do not know the composition mentioned.)—J. E. (See Hints Nos. 4 and 5 above. We gave the address. See No. 1118, p. 568. The other is a pocket machine.)—J. T. (The moulds are made of gelatine or glue, to which a little tannic acid or bichromate of potash is added. They become insoluble after exposure to light. The model is oiled, and the melted gelatine poured over it. When dry the gelatine mould is removed, and after exposure to light is ready to receive the plaster.)—TANGO. (The method of taking buckles out of saws, or saw hammering, was illustrated in No. 902, p. 407. There is a long article, also illustrated, on straightening saws in No. 635, p. 251.)—F. GIBSON. (Either of the preparations mentioned ought to answer; but fire-engine hose is made water-tight by impregnating the leather with glycerine to which three per cent. of carbolic acid has been added. Paraffin wax dissolved in benzoline ought to answer all purposes.)—CALDBECK. (Scarcely of sufficient interest to our readers. The expense will vary with the circumstances, and a barrister's course would be the lowest. The doctor and the accountant involve the passing of examinations, and much depends on whether the aspirant is an articled pupil or not.)—C. H. W. (Several preparations are given in back volumes; but one of the best is Leroy's, which has stood the test of years. See p. 445, No. 930; but of late years fossil meal, asbestos, and other materials have been utilised.)—C. A. W. C. (We do not know whether any steamship owners take apprentices in the engine-room. Apply direct to some of the companies.)—JOSEPH WHITE. (Quite true. The photographic charts of MM. Henry show more stars than have been seen with telescopes. Whether the "most powerful telescope" will show them is another matter. You will find all about the matter in the last volume, and in recent back numbers. 2. The absurdity of the other statement has been pointed out in our columns. Reference to almanacs or a little calculation will show that the 21st of June and the 21st of December cannot possibly fall on the same day of the week.)—HOUSEKEEPER. (Inadmissible as put, because the replies must of necessity be advertisements. See indices and advertisements. 2. For the stains try a solution of chloride of lime, and rinse the part through several waters after the colour is discharged.)—J. MCGLOUGHLIN. (Add a little white wax to the starch, and use a glossing or polishing iron—that is, an iron the nose of which turns up slightly so as to present on the ironing face an edge forming a sort of burnisher. The special iron is not necessary, but it is used at the best laundries.)—A SUBSCRIBER. (Answered many times. Clean the iron thoroughly, dip in a bath of hot oil or melted grease, and then immerse in molten tin. Wipe off superfluous tin with a wisp of greasy tow.)—W. W. RAMAGE, Colorado. (Thanks. Several devices of the kind have been on the market here for many years.)—WEIGHTS AND MEASURES. (We should understand the weights to refer to avoirdupois, unless otherwise mentioned.)—P. P. C. (If you cannot see any popular works on astronomy look in back volumes, or see the index to Vol. XXXV.)—JACK. (Soft iron is necessary—the softer the better.)—WESTWOOD. (It could be used; but if it is only for zinc, that is better done by dipping the articles in molten zinc.)—A READER. (You can get them from any warehouse which deals in such materials, and find a table in such a work as Molesworth's Pocket-Book.)—J. W. TOWNSEND. (Lithia is the oxide of lithium. Lithia water is made by adding carbonate of lithia to water in the proportion of 5 grains of the carbonate to 10 fl. oz., and then charging the water with carbonic acid.)—T. J. O'CONNOR. (The "History of the Invention of the Locomotive" is published by T. West, North-road, Darlington. See first page, Nos. 1119 and 1120.)—E. L. P. (We must refer you to back numbers. It is only those machines which have an electromotive force sufficiently high to overcome the resistance of the human body that are dangerous in the sense you mean)—W. J (You have no circulation at all. Carry the pipe from the top of the boiler to the top of the cistern, and it will work all right. See indices of back volumes.)—PERPLEXED. (Thorough ventilation is the only remedy; but see what has been said in back volumes. Steaming shop windows are often very difficult to cure.)—D.B. (Flood Rock, the last part of the work in clearing Hell Gate, was blown up on Oct. 10, 1885. You will find a detailed account of the works carried out at Hell Gate, New York, with a diagram of the galleries, &c. made in Flood Rock on p. 203, No. 1076, Nov. 6 1885)—C. W. W. (Pewtress and Co., Little Queen-street, Holborn, W.C., as stated on p. 193, and elsewhere.)—C. O. N. (Almost all the large musical instrument warehouses. Try Withers, St. Martin's-lane, W.C., or Dawkins, Charterhouse-street, E.C.)—J. A. (By means of polishing buffs, wooden wheels covered with leather.)—BOOK. (Nothing. They must be mixed together by a masticator, and subjected to heat and pressure. We believe the book published by the Society of Arts, John-street, Adelphi, W.C., is out of print. 2. They are out of print. 3. Electrical cement is made of rosin 5oz., beeswax 1oz., red ochre or Venetian red in powder 1oz. Dry the last thoroughly, melt the wax and rosin together, and stir in the powder by degrees.)—EXAM. (If you cannot refer to back volumes, you should procure a copy of the "University Calendar," in which you will find all particulars.)—NEEDY MECHANIC. (If you have all but the corners done, surely you can cut a paper pattern and see how that fits before cutting the leather. They are made on a former, which takes to pieces and releases the bellows when finished. 2. No one can tell the cause without examining. The water may dissolve the pipe, or may come over as water instead of steam.)

CHESS.

ALL Communications for this department must be addressed to J. PIERCE, Langley House, Dorking.

PROBLEM MXXII.—BY BLACK PAWN.

Black.



White. [8 + 10

White to play and mate in two moves.

SOLUTION TO 1,020.

White.	*Black.*
1. Kt-K 7 (ch).	1. K takes R.
2. B-R 5.	2. Kt-B 3.
3. P takes Kt, mate.	

We understand that this Problem is really by R. B. Wormald (No. 39) in "Chess Openings," 1875. It has also been published in "Chess Gems." It was sent us by a correspondent on whose good faith we thought we could rely.

NOTICES TO CORRESPONDENTS.

CORRECT solutions to 1,020, by J. Krasser, Link, White Pawn, and J. Mackenzie; to 1,019, by Hampstead Heath, J. A. M. (fine and deceptive), G. A. A. Walker (key move); to 1,021, by Black Pawn (very pretty) and A. Bolus.

BLACK PAWN.—We are obliged for the three-mover; it shall have attention.

LINK entered for A and B; J. Palmer and J. W. Hamill for B.

J. P. T.—Thanks for problem.

G. A. A. W.—We simply referred to Game Tourney by way of comparison of duration of time—two years to six months—and yet there is no difficulty in meeting with competitors, though the entrance fee is forty times as much. We are sorry for two or three reasons that we are unable to entertain your proposal.

J. A. M.—Thanks for the information.

J. MACKENZIE.—How do you proceed in 1,018, if 1. $\frac{\qquad}{\text{B-Q B 6}}$? If 2. $\frac{\text{Q takes P}}{\text{R-Q 3}}$, and we fail to see mate next move, if 2. $\frac{\text{Kt-Q 7 (ch)}}{\text{K-K 3}}$, and if 3. Q takes P (ch), B covers.

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a PINK Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

5s. 6d. for Six Months and 11s. for Twelve Months, Post Free to any part of the United Kingdom. For the United States, 13s., or 3 dol. 25c. gold; to France or Belgium, 13s., or 16f. 50c.; to India (via Brindisi), 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office Order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 4d. each to cover extra postage.

Messrs. JAMES W. QUEEN and Co., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes, they must be paid for at the rate of 4d. each copy, to cover extra postage.

Vols. IV., VII., XXVI., XXVIII., XXX., XXXII., XXXIII. XXXIV., XXXV., XXXVI., XXXVII., XXXVIII., XXXIX., XL., XLI., XLII., and XLIII., bound in cloth, 7s. each. Post free, 7s. 9d.

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in February and August, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d. each, through any bookseller or newsagent, or 2½d. each, post free from the office (except index numbers, which are 3d. each, or post free, 3½d.).

Indexes for Vols. I., VI., VII., VIII., and IX., 2d. each. Post free 2½d. each. Indexes to Vol. XL., and to subsequent vols., 3d. each, or post free, 3½d. Cases for binding, 1s. 6d. each.

CHARGES FOR ADVERTISING.

ADVERTISEMENTS in the SIXPENNY SALE COLUMN.

	s.	d.
Sixteen words	0	6
For every succeeding Eight words	0	6

*** It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions and in cases where the amount sent exceeds One Shilling, the Publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement, and charged for.

Advertisements *must* reach the office by 1 p.m. on Wednesday, to insure insertion in the following Friday's number.

OUR EXCHANGE COLUMN.

The charge for Exchange Notices is 3d. for the first 24 words, and 3d. for every succeeding 8 words.

Good Value Offered (cash or instruments) for all kinds of sound or repairable Scientific Appliances.—CAPLATZI, Science Depot, Chenies-street, near British Museum. Established 1862.

Wanted, **Photo Apparatus**, wet or dry, cameras, sundries, &c., in exchange for Microscopic or Magic Lantern Slides. —Apply, PIGGOTT, Chemist, Huddersfield.

Gas-Engine (Bisschop), 1 man power, cost £25; Water Engine, 1 horse, by Ramsbottom, working order; 2,000c.p. Arc Lamp. Offers.—W. HUTCHINSON, Liversedge.

Dynamos, four, two by British Electric Light Coy.; 3 Serrin Arc Lamps, switch boards, brushes, carbon, speed indicator, coil, &c. Offers.—W. HUTCHINSON, Liversedge.

One dozen pure nickel silver **Teaspoons**. Will exchange for anything to value of 3s. 6d.; sample, 4½d.—GILBERT, Oxford-road, Sheffield.

What offers for 52in. **Bicycle**, in good condition, with lamp, bell, spanner, &c., strong, and suitable for a beginner. Can be seen by appointment. Wanted good air-gun, and part cash. For value see Sale Col. advt.—C. E. K., Lady Cross, Gayton-road, Harrow.

Horizontal **Steam Engine**, 6in. stroke, 3in. bore, 24in. flywheel, new. Exchange for a small lathe, complete, to the value of £3.—Stamped addressed envelope to P. PITMAN, Mellor, Marple, near Stockport.

Chest of **Mechanic's Tools**; book, "Every Man His Own Mechanic," Spon's "Mechanic's Own Book," Engine-making, finished Parts of Engines, Musical Box, Exchange.—Above.

Splendid **Magic Lantern**, with 60 slides, all complete, in fine mahogany case. What offers?—J. GREIG, Rock-road Cottage, Killarney.

Vertical **Boiler**, 2ft. high, new water gauges, safety-valve, small steam gauge, ⅞ pump. Offers. Sketch, 2 stamps. —Letters, W. SMITH, Bilston-road, Wolverhampton.

Four **Electric Bells**, one invalid set, four room indicators, wires, batteries, new, unused; small Screw Steamer, perfect; Model Paddle Engine and Boiler, sundries. For exchange. Wanted, Electro Motor for sewing machine or pair Lanterns, &c.— Box 1, Mallow.

Two 3-light **Gas Dry Meters**, by Glover, gunmetal, 1in. steam cock, Devrince and Mullinson's patent, and 31 ls. copies "Pictorial Family Bible," published Sangster and Co. Dynamo, electric scarf pin, battery, or books containing recipes, small printing press in exchange.—BUSY BEE, Green-street, Upton Park, E.

Photographic Camera wanted, ¼ or ½-plate, double swing back; also Ross' Symmetrical, Dallmeyer's Rectilinear Lens; particulars. Exchange Browning's Lantern Microscope.—CHRISTIE, Cathcart, Glasgow.

Wanted, two 10 candle-power **Incandescent Lamps**, with batteries complete, for gent's silver English lever, capped, warranted.—31, South Quay, Yarmouth.

Wanted, **Electrical Apparatus** in exchange for model engine and boiler, 1½in. bore.—H. RODGERS, 127, Abbey-street, Bermondsey.

Vertical Engine, 1½-H.P., on cast-iron platform, which makes water tank complete, fitted with pump by James Davis, Millwall, London. Offers to value of £9; quite new, never had steam in.—W., 12, Church-street, Fulham, S.W.

4in. **Leg Vice**, in good condition, 10s. Pair Brass Standards, 4in. high, new, 3s. Wanted, smaller vice, also strong boiler for model engine.—CARN, 54, Dieppe-street, West Kensington, S.W.

Best make **Bellows Camera**, half-plate lens, with stops, in leather case, 3 double dark slides, folding stand, dry plates, baths, &c. worth £8. What offers in exchange? All letters answered. —M. ALLISON, Howwood, Paisley, N.B.

Wanted, **Electro Motor**, Cuttriss or Griscom preferred. Exchange six-cell Fuller's battery, half gallons, worth 30s.—C. G., 50, Graham-road, Dalston.

Exchange, **Lathe**, back-geared, 5in. centre, slide-rest, &c., and Humber tricycle, for screw-cutting lathe, 5½in. or 6in. centre.—H. G. W., Farley Lodge, Farley-road, Catford, Kent.

One **Opera or Field Glass**, cost 21s., for anything in cutlery or household requisites.—W. SMITH, 146, Otley-road, Bradford, Yorks.

Berri's Machine **Printing Press**, Type, &c. Want Safety Bicycle or Harmonium for same.—*Eagle* Office, Daventry.

Will exchange splendid Double **Combination** 8¼ by 6½ portrait lens, dia. 3¼, by Cox, of London, cost £12; for litho press, tricycle, or lathe.—Offers to F. FRAINE, 1, Lorn-villas, Priory-road, South Lambeth.

Organ, old, 2 manuals, pedals, 2 couplers, 12 stops, knobs, action, all complete except pipes and bellows. What offers? —Rev JAMES, Walberswick Vicarage, Southwold.

20 **Incandescent Lamps**, 20c.p.; 18lb. of double cotton-covered wire, 12 W.G., 50lb. 18 W.G. Offers.—HUDDLESTON, 40, Samuel-street, Woolwich.

Guitar, date 1827, condition good as new. Exchange anything useful. Offers.—J. H. MENHINICK, Egloshagle-road, Sladesbridge, Cornwall.

2in. centre **Lathe Heads**, steel spindles. Will exchange for good opera glass.—CARTWRIGHT, 15, Joseph-street, Hunslet, Leeds, Yorkshire.

Vertical Engine and **Boiler** combined; boiler 2ft. long by 14in., pressure 70lb.; first-class lot. Seen by appointment.— ALLMARK, Garden-lane, Chester.

Small **Lathe**, flywheel, crank, two driving pulleys, small dynamo, electromotor, battery, incandescent lamps, &c. Offers.—CHARCOAL WORKS, Hodson-street, Liverpool.

Wanted, a small **Saw Bench** and **Saws**, complete. Will give lady's gold watch and long gold chain, cost £13 10s., nearly new; will give small sum for a good bench, &c.—Apply at once, J. N. KNIGHT, 29, James-street, Barrow-in-Furness.

Fans, 4½ by 1⅞, compound motion, of brass, nearly new. Exchange for magneto machine in working order.—J. RAE, 33, Arden-street, New Brompton, Kent.

A bargain, small partly finished **Magneto-Electric Machine**, wrought iron armature. What offers, 36 silk?—B., 19, Milkwood-road, Brixton.

Oppen's **Stamp Album**, with 370 assorted rare stamps, in good condition. Exchange for anything.—H. BUDD, Stoke-road, Gosport.

324 Rare **Coins** and **Tokens**. Gent's Gold Watch and Chain. Exchange for slide-rest lathe or recent-make tricycle.—H. BUDD, Stoke-road, Gosport.

Automatic Knitting Machine offered in exchange, slide saddle, 3 crutch. What offers?—Wellesley House, Colchester.

9in. centre compound **Slide-Rest**, nearly new. Exchange to the value of £2 2s. Stamp for particulars.—SEDGLEY, Ryding-square, West Bromwich.

Lathe Heads, 5½ centre, face-plate, hand rest, ornamental slide-rest, wood and iron turning tools, worth 50s. Exchange. Offers.—F. POYNTER, Eton College.

Lathe, on iron standards, treadle, &c., 3ft. long. What offers? Exchange.—166, Siddals-road, Derby.

Quadrant, Singer's S.S., or Cripper type Tricycle wanted. Condition no consequence. Exchange capital Dynamo and Electrical Instruments; cost over £18.—A. J. S., 194a, Marc-street, N.E.

Wanted to exchange, "**English Mechanic**," 325 consecutive numbers, indices, clean, unbound; present date; for anything useful in Lathe Appliances.—FINCH, 47, Paul's-street, Cheltenham.

"**Elements of Natural Philosophy**," Golding Bird; 4th edition, 12s. 6d.; perfect; for "Microscope and its Revelations," by Carpenter, same value.—DENNE, Christchurch-road, Eastbourne.

Will exchange a Portable Circular **Fan Forge**, new, for an Air Pump or Lead Burner's Apparatus, in good condition.— TURNER, 1, Gainsboro'-cottages, South Hackney.

36in. **Facile Bicycle**, ball bearings, Hancock's tyres, in good condition; saddle, dropped handle bars, mud guard, bell. What offers?—TURNER, Gainsboro'-cottages, South Hackney.

Bicycle, 50in., Rudge's ball bearings back and front, half plated, nearly new. Also a 3in. Amateur Lathe, complete. Exchange for a 5in. Slide-rest Lathe.—H. TYSOE, 1, Clive-street, Grangetown, Cardiff.

Scientific Books. What offers? "Natural Philosophy" (Tyndall), published 2s. 6d. "Notes on Electricity" (Tyndall), published 1s. "Notes on Light" (Tyndall), published 1s. 6d. "Magnetism" (Harris), published 2s.

Books.—"Mind and Body" (Bain), published 4s.; "Art of Invigorating and Prolonging Life" (Dr. Kitchener), published 7s. 6d. "Dr. Paris on Diet," published 10s. 6d.

Books.—"Templeton's Engineer and Millwright's Companion," published 6s. "Steam-Engine" (Northcott), published 7s. 6d. "Elements of Mechanism" (Goodeve), published 3s. 6d. "Principles of Mechanics" (Goodeve), published 3s. 6d.

Books.—"Hydrostatics and Pneumatics" (Larder and Lowe), 5s. "Pneumatics and Acoustics" (Pepper), 2s. What offers? See last week's advertisement. Some left.—Mr. ANDREWS, 35, St. Martin's-street, London, W.C.

Lathe Bed and Parts of 5in. lathe for round smith's Bellows.—RIGBY SMITH, Fazackerley-street, Chorley, Lancs.

Leading Screw and Change Wheels for 5in. lathe. What offers?—RIGBY SMITH, Chorley, Lancs.

Ammoniaphone, 42s., half-charged, antiseptic, new. What offers?—6, St. Mark's-grove, Fulham-road.

Gramme Dynamo, 120 c.p., mounted on oak base, nearly finished. Also Hand Dynamo. Exchange good half-plate Lens or offers.—CAMP, William-street, Norwich.

Beautiful pearl-handled **Knife**, contains 6 blades, exchange for any of Miss M. C. Hay's novels.—GILBERT, Oxford-road, Sheffield.

S. R. Bottone's new book on the "**Dynamo**: How made and How Used." Exchange for 10 c.p. Lamp.—WALTER, 146, High-street, Peckham.

Coil, on polished mahogany stand, dovetailed, ebony ends to coil, with condenser, 100 sheets, 1in. spark; quite new; exchange for Microscope or anything in the mechanical line.—H. J. LONEY, Post Office, Gosport.

"**Knight's Practical Dictionary of Mechanics**," 30 numbers, new. Exchange for Twist Drills, Stocks and Dies, or Cutter Frame.—H., 36, Camden-road.

THE SIXPENNY SALE COLUMN.

Advertisements are inserted in this column at the rate of 6d. for the first 16 words, and 6d. for every succeeding 8 words.

Economic Cookery.—Patent Heat Conductors for roasting, 2s. 6d., baking, 2s. 3d.; boiling, 2s. per pair, carriage paid. See ENGLISH MECHANIC, Oct. 15, 1886, page 147.

The Patent Heat Conductors save a family pounds a year.—Agent, TALLACK, 28, Hatton-garden, London.

New Illustrated Price List of **Screws, Bolts, and Nuts** for Model Work, drawn to actual size, sent on receipt of stamp.—MORRIS COHEN, 132, Kirkgate, Leeds.

Fretwork.—Catalogue of every requisite, with 600 illustrations, free for 6 stamps.—HARGER BROS., Settle, Yorks.

"**Beginner's Guide to Photography**," one shilling. Wholesale of the publishers, LEJEUNE and PERKEN Hatton-garden, London.

"**Beginner's Guide to Photography**," one shilling. Free from abstruse technicalities. Retail of Opticians and Booksellers.

Electric Depot, 10, Deansgate, Manchester. Handiest shop in the trade. Largest stock. Greatest variety. Lowest prices.

Leclanche Batteries, 14s., 16s., 24s. per dozen. Sample, 1s. 9d., free.—SEDDON, 5, Queen's-road, Chadderton, Oldham.

Soda Water Machine, bargain. Engraving free post.—NATHANIEL SAINT GEORGE WILCOCKS, Bath.

Wimshurst Influence Machine.—Sole manufacturers of new and improved pattern. 12in. from 30s.—KING MENDHAM, and Co., Bristol.

Deposition of Smoke.—Complete Apparatus to perform this never failing experiment, with static electricity, 5s. 6d and 10s. 6d.—As above.

Standard Ohm, in boxwood cylinder, guaranteed correct to ten thousandth of ohm, 18s. 6d., with copper poles, 21s.— As above.

Galvanometer Cards for tangent and ordinary combined, vertical, astatic, reflecting, and unmounted compass cards.—As above.

Variable Resistance Incandescent Lamp Stand, invaluable for battery power, vide ENGLISH MECHANIC, Oct. 16, 1885, price 3s. 6d.—As above.

Write for **King, Mendham, and Co.'s** large new and reduced Price List, post free, 4 stamps.

Wheel-Cutting to 12 inches diameter in brass only. —CLEGG, 18, Belinda-street, Hunslet, Leeds.

Planing to 12in. by 12in. by 8in. Boring, Turning, Screw-cutting, Slide-rests, &c.—CLEGG, as above.

Aerated Water Machinery.—Repairs, Renewal, Additions, &c., skilfully executed.—N. St. G. WILCOCKS, 45, Avon-street, Bath.

Mica or Talc cut for all purposes by C. JOHNSON 7, New Oxford-street, W.C. Mica chimney covers, &c.

Grease Making without rosin oil.—Sample and particulars from J. M., 6, Hamlet-street, Bootle, Liverpool.

Mica or Talc.—RICHARD BAKER and Co., 9, Mincing-lane, London.

Lathes for every trade and every fancy. We make upwards of 250 varieties.—BRITANNIA CO.

Catalogue of Lathes and Parts, finished or rough, also of other Tools, six stamps.—BRITANNIA CO.

List of Second-hand Lathes and Fret Saws, one stamp.—BRITANNIA CO., Colchester.

London Showrooms.—Britannia Co., 99, Fenchurch-street. All correspondence Britannia Works, Colchester.

Lathes, Files, Steel, Saws. Cheap, good. List, 2 stamps. Cash or hire.—ROBINSON, Catherine-street, Sheffield.

Turning Woods for Amateurs.—Box, Cocus, Lignum Vitæ, Snake, from 3d. per lb.—HARGER BROS., Settle.

Skates (Acme), highly recommended, good value, steel plates, 4s. 3d. pair, free.—HARGER BROS., Settle.

Wood Planing.—Hand power 120, steam-power 1,200ft. per minute. Illustrated circulars free.—G. HAZELAND, Par, Cornwall.

"**The Wilcocks Eclipse**" turnover bottler for patent stopper bottles.—Maker, N. St. G. WILCOCKS, Bath.

"**The Wilcocks Power Cork Bottler**" for soda water, lemonade, &c.—N. St. G. WILCOCKS, Bath.

Lathe Castings, &c.—See T. Taylor's advertisement in ENGLISH MECHANIC every other week. Established 1847.

Carving Tools.—Set of 22, warranted, handled, well assorted, by post, 11s. 6d. See illustrated catalogue.—LUNT'S.

Saws, Disston's American, agent for same. Planes, new, London, malleable iron and gunmetal, every description.— LUNT'S.

Vices, bench, parallel steel jaws, to open 3½, 9s. 6d.; ditto 4, 15s.; ditto 4¾, 21s.—LUNT'S.

Taps (Engineers), warranted Whitworth, plug or taper, 3-16, ¼, 5-16, each 6d.; ⅜, 7-16, 8d.; ½, 10d.; ⅝, 1s.; ¾, 1s. 3d. Postage extra.—LUNT.

Tools, every description. See illustrated catalogue. 90 pages. Send 4 stamps.—A. S. LUNT, 297, Hackney-road, E.

Corundum for Aluminium or other purposes.— RICHARD BAKER and Co., Mica Brokers, 9, Mincing-lane, London.

Electrical Stock.—Clearing surplus under cost. Medical Coils, plated, with slide, 15s. Invalid Bell Sets, 8s. 6d.

Terminals, 20 per cent. off list. Wire, Electro-Motors, Batteries. Write for list.—759, Old Kent-road, S.E.

Brass **Model Engine Castings**, rough and finished, best quality. List, stamp.—WOOD, Dalley-street, Broughton, Manchester.

"**Sheet metal Workers' Instructor**" (Warne's) —Few copies cheap, covers slightly soiled.—94, St. Augustine's-road, N.W.

Two built **Wooden Booms**, about 60 feet lengths, by about 30in. diameter, with 16 and 18 strong iron hoops, also rings on each. Used for ballasting light ships during removal.—42 Box, Post Office, Newcastle-on-Tyne.

An **Overhead Traveller**, with winch attached, to lift 2 tons.—42 Box, Post Office, Newcastle-on-Tyne.

A heavy **Circular Saw Bench**, in good condition, with about 15 8½in. metal rollers, in strong metal standards.—42 Box, Post Office, Newcastle-on-Tyne.

Electric Bell Sets, comprising bell, battery, push, and 25 yards of wire, 7s. 6d. Catalogues of apparatus free on application to HUNTER and Co., 56, Wincheap, Canterbury.

Boilers, Vertical, Portable, and Cornish, one horse-power upwards.—GRANTHAM CRANK and IRON COMPANY (Limited), Grantham.

Lead Electric Accumulators made up and burned. Any class of of chemical work done. Soldering superseded. —HOWELL and BRIGGS, Practical Plumbers, 58, Rokeby-street, Stratford.

Marlborough **Tricycle**, quite new, to be drawn for, tickets 1s.—SMITH, 40, Calverley-road, Tunbridge Wells.

Self-feeding and Hand-feeding **Drilling Machines** for fine work. Write for list.—F. GREENAWAY, Maker, Slough, Bucks.

First-class **Lathe** (equal to new), with compound geometric, eccentric, and spherical chucks.—GEO. PLANT, Alsager, Cheshire.

Selection of interesting **Microscopic Slides** for Sale, from 6s. doz.—S. HARRISON, Dalmain-road, Forest Hill.

Powerful **Hydraulic Press**, to 500 tons, steel cylinder, 18in. ram, to be Sold, a sacrifice.—CAM.

Splendid **Launch Engine**, two 3in. single-acting cylinders, £25.—CAM and SON, Excelsior Works, Worcester.

Wood Planing.—Hand-power 120, steam-power 1,200ft. per minute. Illustrated circulars free.—G. HAZELAND, Par, Cornwall.

Metallic **Violin Strings**, acknowledged success, six Firsts, post free, 1s.—JOHN ELARCO, 24, Fern-grove, Liverpool, S.

Soda Water Machine, gas-work, turn-over bottler, recipes, &c., for working, £20; particulars free.—WILCOCKS, Bath.

Bentley's Electrical Stores.—The cheapest house for bells, batteries, wires, and fittings.—7, Newton-street, Manchester.

NOTES ON THE CHURCH ORGAN.
II.

By GEORGE ASHDOWN AUDSLEY, F.R.I.B.A.

IT is, perhaps, unnecessary to remark that in approaching the subject of the Church Organ, one enters on the consideration of a problem widely different in its general bearings to that presented by the chamber organ. Between the Church Organ and the chamber instrument there are few points in common beyond those which are connected with general excellence of manufacture and purity of tone. As the two instruments are designed for entirely different spheres of usefulness, so must they, if properly schemed and appointed, be widely different in their tonal structures and musical resources. While the maximum powers of expression (even at the risk of some loss of brilliancy), and the greatest possible delicacy and variety of tone are necessary for the chamber organ, less powers of expression and the greatest richness and dignity of tone are requisite in the true Church Organ. Excellence of workmanship, perfection of voicing, and general refinement of tone are required alike in both classes of instrument.

A Church Organ should be designed throughout on the simplest and most thorough principles: there should be no ambition on the part of its founders to make a display in the shape of a great number of speaking stops; but, on the contrary, a determination to have, in every possible way, a work of art—true and perfect in materials and workmanship, and developed on the soundest lines of organ building. The tonal structure of the instrument, be it small or large, should be characterised by gravity, dignity, and softness—gravity, secured by an adequate and properly-balanced Pedal department; dignity, by volume of foundation tone in all departments; and softness, by skilful voicing under a copious windage at a moderate pressure. Those who desire to realise what I mean by dignity combined with softness may listen to the Schulze *Diapason* in the Great department of the Leeds Parish Church organ. Such a *Diapason* is a Great organ in itself. Dignity combined with softness cannot be secured by small-scaled foundation work, numerous incomplete stops, and many ranks of acute pipes, blown by high pressure wind until they literally scream a coarse apology for their serious shortcomings. Gravity combined with softness cannot be arrived at by one master-of-all-work pedal stop—a "deep booming" 16ft. *Open Diapason*; and much less by an apology in the shape of a *Bourdon*, in which the fundamental tone and its second upper partial seem to be perpetually struggling for the mastery.

A properly appointed Church Organ, containing nothing but whole stops of full scale, and adequate Pedal department, and constructed, by a conscientious builder, with the best materials, must of necessity be a somewhat costly affair; but it will fully represent the money expended, and prove a lasting satisfaction to all concerned in its fabrication and use.

Just a few words addressed to those who may be interested, at any time of their lives, in the procural of a Church Organ, and I shall proceed with matters of detail. When an organ is required, and the funds, immediately available, are limited, there are two straightforward and sensible modes of procedure with reference to its construction.

Firstly, if the church is small, do not aim at having an instrument out of all reasonable proportion with it; but be satisfied with one which, containing a moderate number of thoroughly useful and well-balanced stops, will sustain the voices of the choir and congregation on all occasions in a perfectly satisfactory manner. Adopt this simple course, entrust the work to a builder known for his skill, taste, and probity, and remain persistently deaf to the allurements of the tradesmen, who, with fascinating lengthy list of stops and specious promises, offers tempting and *apparently* substantial advantages.

Secondly, if the church is large, and the funds are insufficient for the purchase of an organ of the necessary size and character, do not aim at having a complete instrument all at once. The best mode of procedure is as follows:—Select a builder with the before-mentioned high qualifications, and instruct him to submit a specification for a true Church Organ of just sufficient power and variety of tone for the church, and the extreme requirements of the highest service held, or likely to be held, therein. Then state the present limit of the funds, and consult with him as to the best way of expending them on the suggested instrument. Let the scheme, so far as the bellows, windchests, and all the mechanism are concerned, be carried out in its entirety, and preparation be made for all the stops contemplated. The balance of the funds, after paying for all this, carried out in the most workmanlike manner, should then be devoted to the procural of the foundation stops or those most necessary for the accompaniment of the service. The remaining stops may be added at subsequent intervals as money is obtained. Private generosity is ever at work in church matters, and an unfinished organ is a favourable field for its operation. When it is known that the organ has, so far, been constructed on the most perfect lines possible, and that provision has been made for the reception of further stops, one may calculate on the completion of the instrument at an early period. It will be a great and lasting satisfaction to all parties concerned to know that nothing has been done in a cheap and careless manner, and that all the work has been constructed of the proper materials. The beginning has been wisely and well essayed, and the ending, albeit somewhat delayed, cannot but be entirely satisfactory.

Of course, when funds are ample, all the difficulties hinted at above have no existence; but, in the name of art and common sense, let the money be expended in procuring an organ of the best materials and workmanship, with the requisite number of properly-balanced and well-voiced stops, suited for the highest class of accompanimental music, rather than a large instrument of inferior manufacture, which will eventually prove a huge disappointment to everyone connected with its construction and use, and which will entail a continual expenditure to keep it in working order. *The better an organ is built the cheaper it will prove to be in the end.* This is an important fact to be added to the great advantages, in a musical direction, secured by careful and skilful construction.

Claviers and Couplers.

Following the arrangement adopted in my previous articles on the chamber organ, I have now to consider the question of the number of manual claviers necessary for the Church Organ. The true Church Organ should never have less than two, whilst it need never have more than three manuals. When two are adopted, they should respectively command the Great and Swell departments; when three are introduced, they should command the Great, Swell, and Choir departments. The compass of all should be from C C to a^3, 58 notes. A higher compass is unnecessary in accompanimental music and the desirable class of voluntary playing. In the case of two claviers, the Great should occupy the lower and the Swell the higher position; when three are introduced, the lowest should be the Great, the middle the Swell, and the highest the Choir clavier. This is the arrangement I strongly advocate, although I am perfectly aware there are many who prefer the old-fashioned arrangement, which places the Choir clavier lowest. The matter is not one of very great importance, however, and need not be dwelt upon.

I know, in limiting the claviers to three, I shall be condemned by numerous ambitious church organists who desire organs of the first magnitude, or having the appliances strictly belonging to them, whereon they can display, not their self-restrained powers in the dignified and refined style of playing suited to the music of the Church, but the full extent of their powers as organists in *all classes* of music. I cannot help, and do not desire to escape, such condemnation: I simply adhere to my views that a Church Organ is not a concert-room instrument; and should not be impaired by any attempts to make it one, and, accordingly, rendered insufficient for its chief, and, indeed, only proper use. In an instrument of moderate size, schemed on the many-manualled concert-room type, an enormous loss of grandeur or volume of tone will be sacrificed to secure numerous solo or "fancy stops" of insufficient mixing and building-up powers. The organ, in such a form, becomes merely an "ear-tickler" instead of a noble element in the hymns and chants of praise. I preach no stupid crusade against solo or "fancy stops"; let the foundation-work of the organ be first adequately represented both in pedal and manual departments, and it matters little what is superadded to it, the Church Organ will at least be safe.

It must be borne in mind that the multiplication of keyboards does not affect the general tone of the organ; it merely gives the performer facilities for making rapid changes of tone—changes by no means indispensable or desirable in accompanimental music of ordinary character. In English organs of the first magnitude there are only four manual claviers, and very few of our Church Organs have more than three. In France, however, the largest church instruments have no fewer than five manuals; for instance, the grand organs of the cathedral of Notre Dame and the church of Saint Sulpice, at Paris. Such instruments invariably occupy the west end position, and are seldom, if ever, used for accompanimental music. Another smaller and strictly accompanimental organ is provided in the choir in each case. In the church of the Madelaine, at Paris, the grand organ is elevated over the entrance door, while the accompanimental organ is placed at the opposite end of the church, behind the high altar. The celebrated organ at Haarlem has only three manuals. In Germany, although several church organs which have been built or altered during the last quarter of a century have four manuals, the generality of the fine old instruments have only three.

Every Church Organ, whatever number of manuals it may have, must have a pedal clavier, compass CCC to F, 30 notes.

It is desirable that a Church Organ with two manual claviers should have all the following couplers, especially if the stops in the manual departments do not exceed twenty in number.

1. Swell to Great, unison coupler.
2. Swell to Great, sub-octave coupler.
3. Swell to Great, octave coupler.
4. Great to Pedal.
5. Swell to Pedal.

In larger instruments, which may have stops of 16ft. tone in both manual depart-

ments, the Swell to Great sub-octave coupler may be omitted. Some organists prefer the Octave coupler to affect the Great manual only; but I am satisfied, in organs of the true church type, the Swell to Great octave coupler will be found to be generally more useful. This coupler question, so far as the Church Organ is concerned, is not, however, one of paramount importance. A carefully appointed and well-balanced instrument will meet all legitimate demands made upon its musical resources, even if it has but one manual coupler—the Swell to Great unison coupler.

In Church Organs with three manual claviers, the following couplers are to be recommended:—

1. Swell to Great, unison coupler.
2. Swell to Great, octave coupler.
3. Choir to Great, unison coupler.
4. Choir to Great, sub-octave coupler.
5. Swell to Choir, unison coupler.
6. Great to Pedal.
7. Swell to Pedal.
8. Choir to Pedal.

It is not advisable to omit any of the above-named couplers. The best position for the coupler-knobs is, as in the chamber organ, immediately above the upper keyboard, arranged in three divisions—namely, four belonging to the Great, one to the choir, three to Pedal.

Draw-Stop Knobs and Combination Appliances.

The draw-stop knobs, belonging to the speaking stops should be conveniently and compactly arranged, in groups, close to the right and left cheeks of the manual claviers. In all cases, when no insuperable objections obtain, the draw-stop jambs should be placed at an angle, so that the knobs can be drawn towards the performer, and be more easily reached by his hands. This arrangement entails some additional mechanism; but the cost of the same is well represented in the greater convenience secured. M. Cavaillé-Coll carries this principle to its extreme development in the consoles of his large organs. The draw-stop jambs assume the form of a quarter of a circle, and are carried in tiers from the cheeks of the different claviers. This arrangement allows a large number of knobs to be placed within easy reach of the organist, without the necessity of placing any knob above the level of the upper clavier.

Whatever the arrangement of the draw-stop knobs may be, I strongly advise their being very distinctly grouped, so that those belonging to each department may be readily distinguished. The use of knobs of differently coloured wood or ivory, faced with white for the inscriptions, is much to be recommended. There are several minor matters connected with the draw-stop knobs which I should like to dwell upon; but space is too limited to permit more being said here.

It is highly desirable in a Church Organ to have a full complement of combination levers operating on the stops of different departments and couplers. Small foot levers, double action, should be supplied to bring on and put off the manual unison and pedal couplers.

In organs with pneumatic action, combination pistons should be provided under the respective manuals; these render the cumbrous system of foot combination levers unnecessary. I am afraid it will be some time yet before the beautiful invention known as the "Roosevelt patent adjustable combination action" comes into use in this country; but I feel sure that the day is not far distant when no organ of importance will be complete without it or some appliance doing the same work. As I shall have to speak particularly of this invention in my "Notes on the Concert-room Organ," I need not say more about it in this place.

Expression Levers and Tremulant.

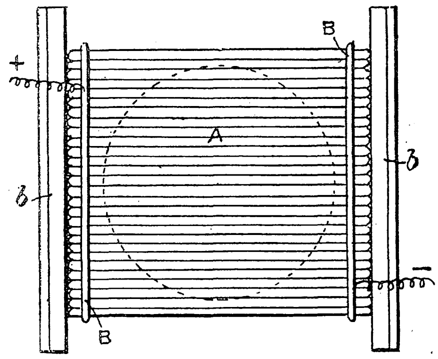
In a Church Organ of two manual departments there will in all cases be one swell-box, and in some instances two, as will be pointed out hereafter. In either case, the form of the Expression lever should be that already commented on in connection with the chamber organ—namely, the balanced lever. Its position, or their position when two are required, should be central, immediately above the pedal clavier. Two Expression levers will be required in an organ of three manual departments, and these should occupy the position recommended above.

As I have gone at some length into all matters connected with the Tremulant in the second article of "Notes on the Chamber Organ," it is unnecessary for me now to do more than direct the reader's attention to that article. All remarks there made are perfectly applicable to the Tremulant for the Church Organ. I may direct special attention to the particulars given respecting the methods of "bringing on" the Tremulant.

(*To be continued.*)

ANDERS' IMPROVED TRANSMITTER.

An improved transmitting telephone, which is apparently devised to overcome the difficulty in connection with the legal definition of a "diaphragm," has been patented by Mr. G. L. Anders, of Worship-street, Finsbury. The patentee says that the improved instruments which constitute his invention belong to that class of telephonic transmitters wherein is no diaphragm or tympanum to transmit the vibrations to the electrodes, but wherein the air-waves of the voice act directly upon the electrodes or contact pieces themselves. The electrodes are made extremely light, so that they are easily moved by the sound-waves, and they are also constructed so as to be loose and unconfined in those planes in which they are required to move in order to vary the contact when the sound-waves act on them. Rods or



thin tubes of coke, carbon, or other suitable material are particularly adapted for use as electrodes. These electrodes rest upon suitable supports, and against each other, in a free manner by their own weight, having no adjustment, but are prevented from falling by suitable framework or supports, or they may be supported by pivots thrust loosely into their ends through suitable supports. They may lie all in one plane, or they may lie in many planes, but always so that the sound-waves shall tend to act on them, as nearly as possible, simultaneously. They may be thickened at the ends if desired, and may be of any suitable form in cross section. The sound-waves may be directed upon or amongst them by means of a suitable mouth-piece or tube, and a sheet of oiled silk or other waterproof fabric may be interposed between the speaker's voice and the mouth-piece or tube, simply arranging it so that it serves to cut off the moisture of the breath from the rods or the like without acting as a diaphragm or tympanum. The figure represents the new telephone in plan. A are carbon rods or tubes arranged loosely in supporting loops or bars of metal or conducting material (B) fixed in the underside of the mouth-piece C, or in or to other suitable support. The battery wires are attached as shown; *b* are ribs to keep the rods in place. The transmitter may be mounted in any suitable way; but the patentee prefers to mount it desk fashion, and he also prefers to face the supports B with platinum foil for the contact of the carbon rods or tubes.

ELECTRICITY IN THE SERVICE OF MAN.*

Although "electricity" is often credited with the production of phenomena which it cannot possibly cause, there can be no doubt that it does form an important part of modern civilised life, and the reason is found in a sentence which the author of this work places in his preface or Vorrede—"In its power to assume always that form of energy which happens to be the most useful, lies the great importance of electricity." That statement is true, as has been abundantly shown in many recent exhibitions, but although there are textbooks almost innumerable (more or less useful), and an enormous number of papers in ephemeral publications, and the more lasting *Transactions* of societies learned or otherwise, there are few, if any, works which deal with electricity in the comprehensive manner indicated by the title of Dr. Urbanitzky's treatise. In its English dress it has been edited with copious additions by Dr. Wormell, who has not hesitated to alter the method of the author with great freedom, when he has conceived it to be out of accord with English modes of thought or reasoning, and has added much matter of interest which was not to be found in the German edition. Prof. Perry, who has indited an introduction to this volume, says pertinently that the history of electrical engineering differs from that of any other application of the principles of natural philosophy in this important respect: that long after practical men had developed elaborate mathematical investigations, the results of which were absolutely necessary to them, nearly all the teachers of the science of electricity in colleges and schools remained in a state of ignorance of everything except what may be called a list of "electrical tricks." Those who are old enough to remember the lectures of a quarter of a century ago will recognise the truth of that statement; but since 1870, when some of the more useful textbooks began to appear, the great value of "electricity in the service of man" has gradually made itself felt outside the telegraph office and the metallurgist's laboratory. The study of the few, aided by the intelligent observation of the many, brought about numerous discoveries, and every year electricity is mixing more and more with the daily life of civilised people. It must be confessed, however, that we owe more to the practical men who went, blundering it may be, from mistake to mistake until they discovered facts which ultimately became the staple data of the textbooks. With some few exceptions—notably the work issued by Mr. Sprague in 1875, which we may perhaps say first appeared in these columns—textbooks on electricity are misleading, and fail to convey to the reader any definite ideas of the subject. The author of the present volume, no doubt, wished to make his work complete, and accordingly Part I. deals with the principles of electricity; but a considerable portion of the matter in these 224 pages might have been left out to the improvement of the work. Part II. treats of the Technology of Electricity, and commences with a history of electric machines, which is freely illustrated—in fact, the illustrations are an important feature of the work, for there are nearly 850 which portray the progress of electricity as applied in the service of man. Thus, in the division relating to the generation and conduction of electricity, we commence with diagrams showing the principle of Pixii's machine, followed by illustrations of that machine, Clarke's, and Stöhrer's. Thenceforward, most of the historically-noted machines are illustrated and described, and in some cases the principle on which they worked is explained by a diagram. The famous Pacinotti machine, the forerunner of all the ring armatures, is described by a translation of the original paper written by Dr.

* Electricity in the Service of Man. From the German of Dr. ALFRED RITTER VON URBANITZKY. Edited by Dr. WORMELL. London, Paris, New York, and Melbourne: Cassell and Co., Limited.

Antonio Pacinotti. The diagrams in which methods of winding and other details are shown will be of special interest to the reader, as will such minor matters as Edison's tubes for the leads or conductors, his regulator, and meters. In the sections devoted to batteries there is an illustration and description of Pulvermacher's chain, which is said to be "used in medicine," and in connection with the Leclanché cell we are told that the zinc rod should be neither cast nor wrought, but drawn out. Details of similar character are mentioned in connection with other batteries, of which a considerable variety are illustrated, including the Grenet-Jarriant which is used for lighting the Comptoir d'Escomte in Paris. This is a zinc-carbon arrangement, the zincs dipping into mercury and surrounded to a certain height by a solution of sodium bichromate (1), sulphuric acid (3), and water (10 parts). The Grenet-Jarriant battery, however, is chiefly noticeable for the arrangements for lifting the zincs out of the solution, for supplying the latter and withdrawing it, and for rinsing the cells out after use. Some of the other constructions illustrated and described may be of use, and at any rate will have the effect of showing would-be inventors something of what has been already done. The descriptions of secondary batteries are not quite so complete; but a full explanation of the Planté is given. The history of the electric light is briefly written, and regulators and lamps are described at some length, including the details of manufacture of incandescent lamps, the mercury air-pumps, and the glass-blowing machine being illustrated; but more modern results of trials with incandescent lamps might have been given than those made at the exhibitions of Paris and Munich. Arc lamps and regulators are illustrated in a great variety of design, and the applications of the light and the current are shown in forms as numerous as could be desired—at all events sufficient to give an idea of the manifold uses of the electric light, for there are many illustrations of its application to railway stations, mines, lighthouses, navigation, and even the surgical appliances, including Leiter's gastroscope. Electrotyping is described with many important details, and the sections on electromotive power are exceptionally full and almost historically complete. The telephone and microphone naturally receive much attention, and all the best known instruments, with many others, are illustrated, together with the devices employed at central stations for communicating by telephone. The photophone, pherope, and phonograph, though they have at present done little in the service of man, are illustrated and described, and the electric telegraph, of course, has many pages devoted to it—in fact, nearly every useful invention in connection with electricity will be found in Dr. Urbanitzky's pages, the only notable exception being the at present undeveloped system of signalling from trains in motion, known as the "air line" telegraph—an invention which has only recently passed its preliminary trial, but which is already a sufficient indication of further wonders in the application of electricity to the service of man. Probably neither the author nor the editor would claim what may be termed critical accuracy for this work; but it is undoubtedly a useful and valuable volume, if only from the fact that practically all the useful applications of electricity are described in its pages. In that respect it has no rival.

THE AMATEUR WORKSHOP.—XXXI.

Brass Foundry.

It is cheaper to buy castings in small quantity than to make them, and those which are purchased are also mostly free from the defects of blow-holes and scabs, which amateurs are seldom able wholly to keep out of castings of home manufacture. Nevertheless, I think it well to devote an article or two to the subject of foundry work, because the series could hardly be deemed complete without it, and also because it is often desirable to be able to make sundry little castings at home for immediate use or for experiment, without the trouble and delay of going to a foundry for them. Often in rural districts there is no foundry within reasonable distance. Sometimes, also, when a foundry is handy, the men are so accustomed to rough or heavy work, chiefly in iron, that they cannot, or will not, take the pains required for many amateur jobs whose ultimate value may not be more than a shilling or two, but over which the amateur himself would be willing to spend hours of careful finishing and touching up. These jobs are not cared for in shops whose staple trade is of a more paying character, and so they are hurried through or else allowed to be shelved until a convenient season. If the amateur is an experimentalist also, he will, perhaps, find his occupation in the mixing of metals for the making of various alloys, in the reduction of metals from their salts or ores, &c., and in numerous studies besides, his melting furnace being his hobby, like another man's lathe or bench. Iron in small quantity also can be melted in a brass furnace, and, indeed, all the common metals and alloys. For these reasons, therefore, I shall now note in detail the construction of the furnace itself and the various appliances and tools used in connection therewith, adding a few hints relative to the practice of brass moulding itself, remarking, however, that success in that art, as in every other class of work, can only come after much practice.

The style and size of furnace is not arbitrary, and may be chosen according to the nature and quality of work to be done. A properly-constructed brass furnace is rather a cumbersome affair in a small shop; but it is the most suitable for the work, and can be made to such dimensions as are most convenient. But an iron stove, made open-topped with a movable cover, if furnished with a good draught and lined with firebrick, is efficient for light casting, so that choice may lie between the two.

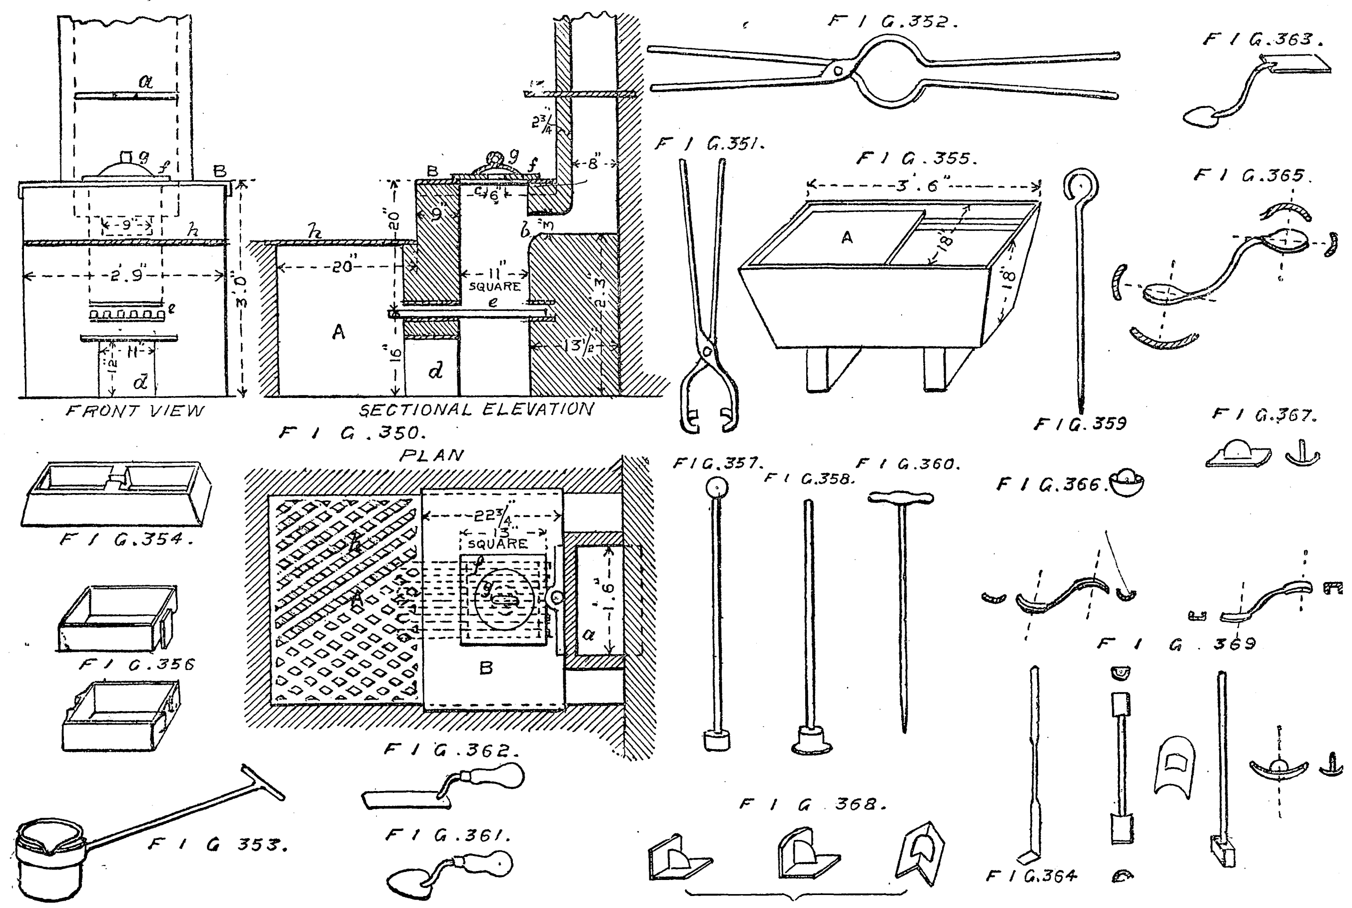
A proper brass melting furnace is shown in Fig. 350, and dimensioned for small crucibles. It is built wholly of firebrick set in fireclay. If a long chimney is available in the wall of the building against which the furnace is to be erected, a piece of pipe lined with firebrick can be led from the stove into it; but if not, the chimney must be built as shown, to a height of 20ft., or from that to 25ft. In the absence of the chimney, it would be necessary to use an artificial blast, and such was the practice among the early founders. The blast then should be heated, or fed in circuitously, since a current of cold air would be apt to crack the crucibles. A sliding damper, consisting of a plate of sheet iron, must be inserted in the chimney (shown at *a*) for the regulation of the draught. The smoke and fumes pass away through the opening *b*, into the chimney. Through the hole *c*, in the top of the furnace, the crucibles are lifted in and out. The ashes are raked from underneath the grate bars through the hole *d*, communicating with the ash-pit A, in front. The fire-bars rest upon bearers, and are arranged for convenience of removal when the grate has to be emptied of clinkers. A common method, simple and effective, is that shown in the figure where the bars *e* consist only of square rods of wrought iron, passing through an opening in the front brickwork across the bottom of the furnace to a similar opening at the back, and resting on sheets of iron built into the bricks. The bars stand out a few inches into the ash-pit, and when it is desired to put out the furnace they are drawn out with the tongs, and the fire falls down below.

The arrangements for the fixing of the furnace may be modified as happens to be most convenient. I have shown the type usually employed in brass foundries. Two or three such furnaces precisely alike, except that their capacities usually differ, are ranged side by side, and communicate with a common chimney. From the figure it is seen that the top of the furnace stands a few inches only above the level of the floor, and the reason of this is that the workman shall stand right over the crucible when lifting it in and out. This is desirable in any furnace, and is essential when heavy crucibles have to be manipulated. But a small furnace can, like a stove, be erected on a stone, or properly protected floor, and the making of an ash-pit be avoided. The top of the mouth *c* is covered over with a plate *f*, perforated with a circular sight-hole, and this again is closed with a second iron plate called a tile, *g*, and so named because an earthenware tile was originally used. The removal of this light tile is more convenient than having to move the cover itself whenever a sight needs to be taken for the purpose of noting the progress of the melting operations. It is desirable also that the top of the furnace should be protected from injury by means of a covering plate of cast iron, B, which may be made in open sand and perforated with a square hole to clear the furnace mouth, and also furnished with a shallow flange around the bottom edges of the two ends to embrace the upper edges of the bricks, when the furnace is built as shown in the figure. The ash-pit in front is covered over with a perforated grating *h*, or gratings, so that the floor is made good, at the same time that air for draught is allowed free admission. These plates are cast in convenient lengths (in this case one only) and dropped into rebated recesses prepared for their reception in the floor, and only lifted for the cleaning out of the ashes.

If an iron furnace is preferred, some kind of plain stove can be utilised by being lined with firebrick, the draught being derived from an ordinary chimney. The stove may consist of flat plates bolted together in a rectangular form, or it may be circular. Small crucibles can be withdrawn through a door in the front, but as this is an inconvenient arrangement, the better plan is to make a special cover perforated with a hole of sufficient diameter to take the largest-sized crucible and tongs which are likely to be used. Over this hole a cover of sheet or of cast iron can be slid. The particular type of stove is not of so much importance as the obtaining of a sufficient draught, together with the means of its regulation by an efficient damper, and convenience for working the crucibles, and watching the fire and the melting process, if possible, from above. When these conditions are satisfied, details can be modified. Regard must be had to the fixing of the furnace clear of all woodwork. Bricks, stone, sand, iron plates should alone be permitted around the immediate vicinity of the furnace, and these conditions are easily fulfilled in foundries. An amateur might in some instances utilise an outhouse for the purpose. But in towns small furnaces must often be put into boarded rooms. Then the furnace must be kept clear of floor and walls by proper non-conductors, such as bricks resting on sheet-iron plates, so that the risk of conflagration shall be prevented.

The best crucibles, or "pots," as they are shortly called, are those made of plumbago—i.e., they contain only so much clay as will serve to bind the plumbago together, or about one of clay to two of plumbago. They are smoother than the clay crucibles, and therefore retain less of the metal adhering to them. They cost roughly 1d. per lb. capacity, or a trifle over that. Thus, one of 20lb. capacity would cost about 1s. 10d., of 24lb. 2s. 3d., of 28lb. 2s. 7d., and so on in about the same proportion. They are marked for pounds or kilogrammes, the number being stamped on the crucible, according as they are ordered. A new pot requires annealing, effected by being turned mouth downwards over the fire for awhile. When uniformly heated it is turned mouth upwards, its bottom resting on a bed of coke; hard coke (i.e., "foundry" or "furnace" coke, not gas coke)* broken into small lumps is then put all round it, and up level with the mouth; the metal is charged, either now or before the pot is put in; the lid put on, then a few large lumps of coke are put above the lid; and, lastly, the tile is put over the mouth of the furnace. Nothing is now disturbed until the metal is melted, the average duration of this period soon being known by experience, and, if necessary, its progress being noted by removal of the tile and cover. When the metal is melted, the pot is lifted from the fire by means of the tongs (Fig. 351), a flux added if there is much impurity, and either poured direct by means of these tongs into the mould, or transferred therefrom to the double shank (Fig. 352), if the charge is a heavy one, or to

* The essential difference between "gas coke" and "hard coke" is that the former is only a by-product of the gas retorts, from which the illuminating hydrocarbons have been removed as far as possible, while the latter is the main product, in which the bulk of the hydrocarbons are retained, having been subjected to such a degree of destructive distillation in close ovens that their carbon is deposited in the coke, rendering it hard and dense, and therefore able to resist the weight of the contents of the furnace and the action of the blast, whilst its heat-giving value is much increased. Gas coke is dark and dull in colour, furnace coke is comparatively light and silvery in appearance, consisting almost entirely of pure carbon, with but a small proportion of ash. Gas coke is light, hard coke heavy. Its cost is more than twice that of gas coke, or about 25s. per ton.



the single shank (Fig. 353), if of less than 30 or 35lb. weight.

The proper mixing of alloys is an art of which we engineers know little in comparison with the professional brass founders of Birmingham and other centres. Gun-metal, hard brass, and some fusible alloys are the chief mixtures we have occasion to use; hence I must be content to state a few main principles connected with the mixing of these alloys only.

For general work, much the readiest way is to buy metal of required quality already cast into ingots, and remelt. Where this is not done it is the usual practice among brassfounders to mix their metal, and ingot it before using it for casting purposes. An ingot mould is shown in Fig. 354. The metal poured gently in at one end fills up the first division, and passes on through the notch into the second. The mould is warmed previous to pouring, and a little oil sometimes run over the bottom, since a very slight degree of moisture will cause the metal to fly. The second melting is believed to have the effect of more thoroughly amalgamating the alloy. But where special mixtures are wanted for special work, founders make their own alloys in preference to buying, as being more reliable, and also usually ingot them. When mixing alloys, the less fusible is melted first. When melting copper and tin, for example, the copper is first melted, and afterwards the tin added in lumps; the whole is then either covered down, or stirred only for a few minutes until the fusion is complete, when a bit of yellow soap or other suitable flux is added, and the moulds or the ingot poured. There is no difficulty in melting the alloys of gunmetal, neither is there in the case of brass containing copper with moderate proportions of tin and lead. But the mixing of zinc sometimes causes considerable difficulty in obtaining the proper amalgamation without excessive loss by volatilisation. Everyone knows that if zinc is put into an uncovered pot it will go off in bluish white fumes of oxide (ZnO), and since this occurs at a low temperature, it is difficult to prevent the volatilisation before the proper union of the metals has taken place. Under any circumstances, there is an unavoidable loss of zinc, much larger in proportion than that of the other constituents. There are two common methods practised for diminishing this loss. The one which is usually followed in engineers' oundries is to melt the copper first, then add he tin or lead, and last of all the zinc in small lumps, taking care that they are free from moisture, thrusting them below the surface, and stirring the while to promote amalgamation. When all are mixed, the surface is covered with a flux, a piece of borax, charcoal dust, or broken glass, the cover put on for a few seconds, and then removed, the alloy skimmed, stirred, and poured. The second method, and one which is more employed by the ornamental brassfounders, is to make two separate mixtures of metal before finally adding them together in the proportions to form the required alloy. The most volatilisable metal is added in a certain quantity to the more infusible, advantage being taken of the fact that the melting points of alloys are lower than those of their constituents. Thus, a portion of tin or antimony would be added to copper in the proportion of two or three of the former to one of the latter, and these when fused, added in small quantities to the softer metals or alloys. The first portion of the alloy is called "temper," and the amalgamation is more perfect than if all were mixed at once.

When iron and brass are turned, planed, or shaped at the same machines, the iron borings, filings, and chips become mixed with those of brass, and unless removed before remelting, spoil the castings by making them pinny—that is, they form aggregations of hard globules which stress the cutting tools greatly. Hence previous to remelting these, a magnet must be employed for the removal of the particles of iron and steel.

When pouring the molten metal, regard must be had to the temperature at which it is run. The chilling influence of small moulds causes the metal in these to set very quickly; therefore in such cases it should be poured as hot and fluid as possible. The amount of fume which metal gives off is a test of its high temperature: as it becomes dead the fumes diminish. For the heavier works the metal is required dead, because in the first place hot metal in mass causes the sand to become burned, and so imparts a rough skin to the castings; and second, because in alloys which are imperfectly mixed, or which contain metals of very different specific gravities, there is time for a partial separation due to delay in solidification, so that the different portions of the casting show different degrees of hardness. Lastly, the dross or sullage must be bayed back, or skimmed from the surface at the moment of pouring, to prevent its entry into the mould.

These few hints embrace the essential principles of melting and casting. Our remaining notes will have reference to the appliances, tools, &c., employed by the brass moulder, together with their mode of use. A brassfounder does not, as a rule, kneel on the ground at his work, as is usual with ironfounders, because his moulds are usually small, and therefore suitable for manipulation upon a bench. Either an iron core bench is used, in that case simply a plate of cast iron ⅝in. or ½in. thick, having a shallow flange running round the back and two ends, leaving the front edge clear, the plate resting on trestles, or on brickwork. Or a moulding tub or trough (Fig. 355) answers the double purpose of a bench and a receptacle for sand. The trough is a wooden vessel somewhat like a large washing tub, and furnished for a portion of its length with a movable sliding top, A, upon which the smaller boxes are rammed up. It is conveniently laid against the wall and supported on wood blocking. The boxes or flasks being light, are usually without handles, often also without pins, Fig. 356 being a common type. They are held together during the pouring of the metal either with superimposed weights or with a pair of screw clamps. For special work special boxes are, of course, used—longer, narrower, or deeper, as the case may be—than the example figured. For temporary and amateur use, wooden boxes are usefully employed.

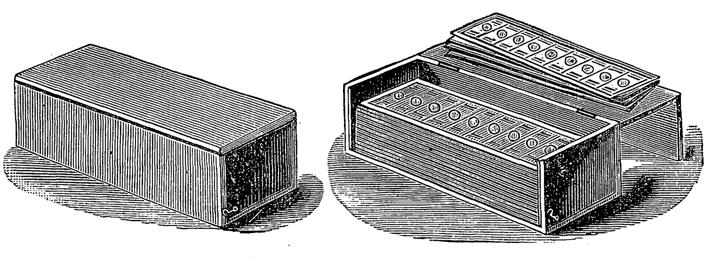
Subsequent figures show the principal types of tools used. The rammers are of three forms: the pegging rammers (Fig. 357) and the flat rammer (Fig. 358), the first being used for punching the sand immediately adjacent to the patterns and in narrow and contracted spaces, the oval end being used first, and the hemispherical end afterwards; the third or flat rammer being for levelling over the top sand, and therefore used only when the latter is about on a level with the edges of the box. A pricker or piercer (Fig. 359) is used for lifting patterns from the sand, or the fingers alone are used for that purpose; a vent wire (Fig. 360) is also employed, but the real function of the latter instrument is the "venting" or honeycombing of the sand with small holes for the escape of the gas generated in casting. The heart (Fig. 361) and square trowels (Fig. 362) are used for sleeking over broad surfaces, scraping and cutting down the sand to form the joints around the patterns, mending up moulds, &c., while the heel of the wooden handle is

improvised as a mallet for driving in stops or chaplets into the sand, and sprigs for sprigging broken moulds; in fact, the trowel is a kind of universal tool, like a shipwright's adze. The heart and square trowels are again combined in Fig. 363, differing only in size from the previous examples. A cleaner and lifter (Fig. 364), spoon tools (Fig. 365), a button sleeker (Fig. 366), pipe sleeker (Fig. 367), square corner sleekers (Fig. 368), are illustrated. The remaining group comprised in Fig. 369 illustrate various forms of bead tools and cleaners, whose uses are obvious from their sectional shapes, being the mending up and finishing of the surfaces of moulds whose outlines correspond more or less therewith; and all are made in various sizes either in brass or iron; lifters, trowels in the latter, while the bead and spoon tools are cast in each, many of the beads and sleekers being made by the moulders themselves to various shapes as occasion for their use arises. A good kit will contain several tools of the shapes given above, but differing in size.

I must defer my remarks on the practice of brass moulding to the next article.

MEDLAND'S PORTABLE CABINET FOR MICROSCOPE SLIDES.

IN the annexed engravings we illustrate a neatly-made portable cabinet for microscope objects, which has been introduced by Mr. J. B. Medland, 12, Borough, S.E. The cabinet is rather smaller than 11in. by 5in., by 3½in., and contains 16 trays, capable of holding nine slides in each. Each glass slip is held at its ends by the projecting side flap of the tray, which is held down by the succeeding tray, and so on, the lid holding the whole firmly down. When open, the lid and front fall back, as shown in the engraving, forming a stand or table to place the trays upon, which are thus less liable to get displaced or upset, as when



placed among other apparatus, or upon the desk or work-table. The designer considers that the advantages of size, compactness, and the improvements over the ordinary case, strongly recommend it to demonstrators of practical physiology, histology, medical students, and all microscopists who may require to carry a number of objects in a small space, with the least possible risk of damage.

NEWALL'S OCCULTER.*

By R. S. Newall, F.R.S., F.R.A.S.

I LATELY designed, and had made by a clever local optician, an addition to the eyepiece of my telescope, which I find of the greatest advantage in examining the satellites of planets and multiple stars. My idea was to produce an instrument exactly the reverse of Dawes's solar eyepiece; that is, to interpose a screen which shall shut off the bright object, and thus allow of the faint companions being more easily seen, and, at the same time, the apparatus must be simple and capable of easy manipulation and adjustment. I had my eyepieces each fitted with a stop, that is, a piece of tube the same diameter as the adapter, into which the eyepiece fits, and the stop is cut of such length that when the eyepiece is pushed in it shall be in the focus suited to my sight, so that I have no trouble in adjusting.

The occulter is a ring of brass, about ¼in. thick and ⅜in. broad. It slips stiffly on to the eyepiece, as shown in the accompanying drawing. The ring is bored with three holes, as in the section, and into each is fitted an ivory sphere, ⅜in. diameter. They are held in place by brass springs, which have a ¼in. hole in each, to admit of the movement in any direction of a small platinum wire, which passes through the sphere. On one end of the

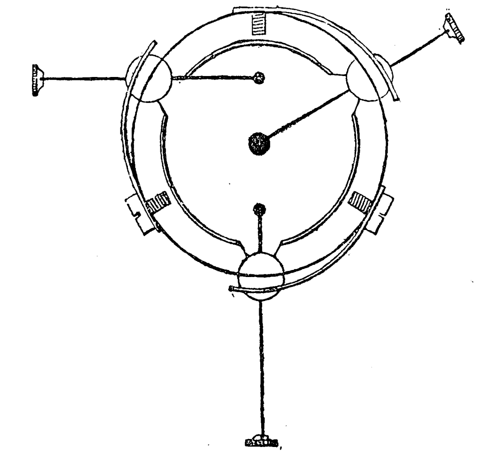


Fig. 1.

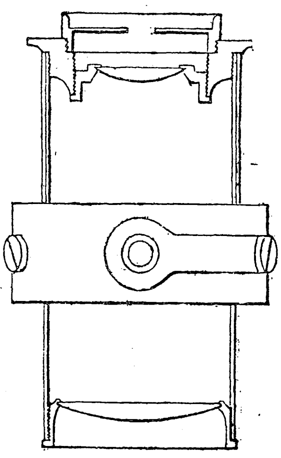

Fig. 2.

wire is a disc, and on the other a small button or handle. By these means the discs may be placed in any required position to eclipse the object, or they may be pushed to one side, so as to be entirely out of view; and when drawn back up to the ivory sphere the ring can be slipped off the tube, and the eyepiece is as it was, having only three holes in it corresponding to those in the ring. The centres of these holes are, of course, in the plane of the focus of the eye-lens, but the spheres allow of the discs being placed out of focus, which is sometimes of advantage. One disc would be quite enough for most work, but a spare one or two may be convenient occasionally, so I made mine with three discs slightly varying in size.

ACTINIC CONTRAST IN PHOTO-MICROGRAPHY.

DR. G. A. PIERSOL considers that successful photo-micrography depends especially upon three conditions: (*a*) having all parts of the object exactly in the same plane; (*b*) having well marked differentiation between the elements of the tissues; and (*c*) having the object so stained and illuminated as to insure sufficient actinic contrast between it and the surrounding field or background.

The successful acquisition of the condition of actinic contrast is not always readily had. While the blue stainings (hæmatoxylin, methyl blue) are, of course, more actinically powerful than the reds and browns, yet so much depends upon the individual specimen, in regard to opacity and thickness, that each case must be determined for itself. While a thick section stained in carmine will yield but a dark mass without detail, a similar section stained in hæmatoxylin may furnish a satisfactory picture. But the days of thick sections are past; the question now is, How shall we stain and illuminate the thinnest possible section so as to yield good photographs?

While a very delicate section well stained with hæmatoxylin is all that can be desired for examination, we shall soon find that actually it is far too transparent to produce a vigorous photograph, there being insufficient actinic contrast between the general blue colour of the field illuminated by the blue monochromatic light from the ammoniacal sulphate of copper cell and the bluish-purple of the section. When the preparation of the section is under control, it will be found advantageous to prepare a few sections, as already suggested, by which the thinnest section in the brown colours always markedly impress the plate.

In many cases, however, it is inexpedient to specially prepare objects for photography. For such cases a very valuable adjunct will be found in the use of different coloured lights produced by tinted glasses carefully adjusted to the intensity and colour of the staining. The use of glass, or of solutions of colours, has long been employed in the arts in reproducing paintings. Koch in his "Traumatic and Infective Diseases" related his experience with this method, but condemns it as impracticable. On account of the length of exposure and vibration "the picture does not have sharpness of outline sufficient to enable it to be of use as a substitute for a drawing, or, indeed, even as evidence, of what one sees." Notwithstanding the unfavourable experience of this skilled investigator, some subsequent results by this methsd have been most encouraging. Defrenne obtained excellent photographs of the *Bacillus tuberculosis* by means of fuchsin staining and green glass; and quite recently the author's own experience with the same bacterium and stain have been very gratifying. Since then a number of modifications have been tried. As a result of the experiments the practical deductions have been reduced that when the staining and thickness of the specimens are insufficient to give the necessary actinic contrast with the colour of the field, we can best succeed by employing a coloured glass whose tint will be such as to give the contrast as well as to afford light to sufficiently impress the plate where not occupied by the object. Such a colour will not be the complementary one in many instances. With blue staining the use of complementary yellow would yield but a faint image, since the weak actinic power of the transmitted rays are insufficient to deeply affect the unoccupied portions of the field. The substitution, however, of a suitable shade of green affords sufficient contrast of the object as well as permits the passage of rays sufficiently actinically powerful to adequately impress the surrounding parts of the plate.

With all these colours the exposure is greatly lengthened; with a medium green it being five to seven times longer than with blue light; as, however, the normal exposure is seldom over one second, the increase has practically little disadvantage. Not only for very minute objects, as bacteria stained with methyl blue, under high powers, but equally for very thin hæmatoxylin or carmine sections under low amplification, has this green glass proved most useful. By its use it is always possible to obtain pictures where all the merits of vigorous negatives with the beautifully sharp details alone, procurable from the thinnest sections, are combined, and where the usual method yirlds but a weak image.

These suggestions apply specially to sunlight. To those engaged in such work who have never employed these means, the shades of green offer themselves as valuable modifications of illumination well worthy of a trial. The exact time required, a matter of importance, must be determined for existing conditions by each manipulator. Mr. J. W. Queen suggests a trial of the stained gelatine plates now coming into use for the purpose of securing contrast. The sensitiveness of the plates is much greater than usual, so that the time of exposure will be diminished instead of lengthened, and by using plates variously stained, suitable contrasts might be obtained with differently stained specimens.

Mr. R. Hitchcock also refers to the so-called ortho-chromatic, or iso-chromatic sensitive plates now sold, which may be found useful in photo-micrography; but it is well to consider that they differ from the plates mainly in their greater sensitiveness to the less refrangible rays, while they are scarcely less sensitive to the blue, which still preponderates. For this reason, in order to obtain strictly uniform results for all colours, coloured screens must be used, particularly when working with sunlight. The great advantsge of such plates rests in the fact that they are sensitive to the red and less refrangible rays, which do not at all, or only slightly, affect the ordinary plates.—*Jour. Roy. Mic. Soc.*

IT is stated by M. H. Dunville that if two glasses of water be placed, one upon the north pole of a powerful magnet, and the other upon the south pole, in four or five minutes the former acquires a slightly alkaline reaction, while that on the south pole becomes slightly acid!

DEPREZ'S GALVANOMETER.*

TO rivet scientific facts in the mind, study and practice must proceed together. This is especially true in electricity, where a multitude of conditions are imposed for every phase of the subject. No one can go very deeply in the study of electricity without reaching the subject of electrical measurements; certainly very little can be done in this direction without a galvanometer of some kind. Among all the galvanometers yet invented, there is, perhaps, none possessing all the good qualities of the one shown in the annexed engraving. It is very simple; the materials are inexpensive, no great mechanical skill is required in its construction; and its sensitiveness and accuracy are sufficient for the requirements of most electricians. Besides all this, it is perfectly "dead beat," so that no time need be wasted in waiting for the instrument to come to rest. This galvanometer is the invention of M. Deprez, of Paris, France. It consists essentially of a rectangular coil of fine wire, suspended on strained torsional wires in a strong magnetic field. To the base is secured, by means of angle plates, a compound U-magnet, 7in. high, formed of three steel magnets, one-quarter inch thick, secured together and to the angle plates by bolts. The distance between the inner faces of the poles of the magnet is $1\frac{7}{16}$in. Two and three-quarter inches behind the centre of the magnet a brass column rises from the base, and is provided near its centre with an adjustable brass arm, supporting at its outer end, and exactly in the centre of the space between the poles of the magnet, a hollow soft iron cylinder, $2\frac{1}{4}$in. long, $1\frac{1}{32}$in. external diameter, $\frac{13}{16}$in. in internal diameter. The top of this cylinder is even with the upper ends of the magnet. To the top of the brass column is secured, at right angles, an arm that extends over the hollow iron cylinder, and is provided with a vertical sleeve, in which is clamped a rod having on its lower end a small silver hook, arranged axially in line with the iron cylinder.

To a block attached to the base, opposite the centre of the magnet, is secured a tapering spring $\frac{1}{16}$in. thick and $3\frac{3}{4}$in. long, carrying at its free end a small silver hook, which is arranged in line with the axis of the iron cylinder. A rectangular coil of No. 40 silk-covered copper wire, large enough to swing freely over the iron cylinder, is suspended a hard-drawn No. 32 (0·008in. in diameter) silver wire from the hook above, and is connected by a similar wire with the hook on the spring below. The upper wire is $2\frac{1}{4}$in. long between its connections, the lower one $2\frac{3}{4}$in.

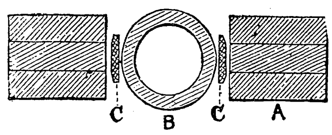
The sides of the rectangular coil are flat, being about $\frac{1}{8}$in. thick and $\frac{5}{16}$in. wide. The resistance of the coil is 150 ohms. The silver hooks are connected with the opposite ends of the coil, in the manner shown in Figs. 2 and 4. Each hook is provided with a flat head, which is secured between two thick plates of mica, the shank of the hook projecting through a hole in the outer mica plate. Each pair of mica plates is secured in place on the coil by a winding of silk, which is coated with shellac varnish to prevent the plates from slipping. The hooks are arranged exactly in the middle of the ends of the coil, so that when the coil is supported in the position of use by the silver wires it will oscillate freely between the poles of the magnet and the iron cylinder. The terminals of the coil are soldered to the silver hooks. The upper hook is made a little more than a half-inch long, to receive a small concave mirror (as shown in Fig. 4), which is secured in place by cement or wax. The mirror has a focus of 30 or 36in. The relation of the magnet A, the coil C, and the iron cylinder B, are clearly shown in Fig. 3, which is a horizontal section taken through those parts.

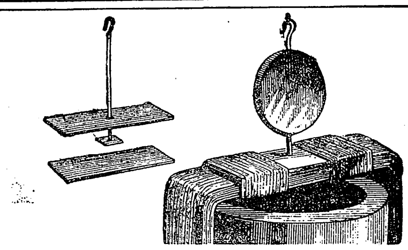
A glass shade protects the delicate parts of the instrument. The two binding posts which are outside of the glass shade are connected under the base with the brass column and the spring, so that the current passes from one binding post to the column, thence down the upper silver wire, then through the coil, the lower silver wire, and the spring to the other binding post. The silver wires are placed under considerable tension, and the coil is adjusted to a central position by turning the hooked rod at the top of the instrument.

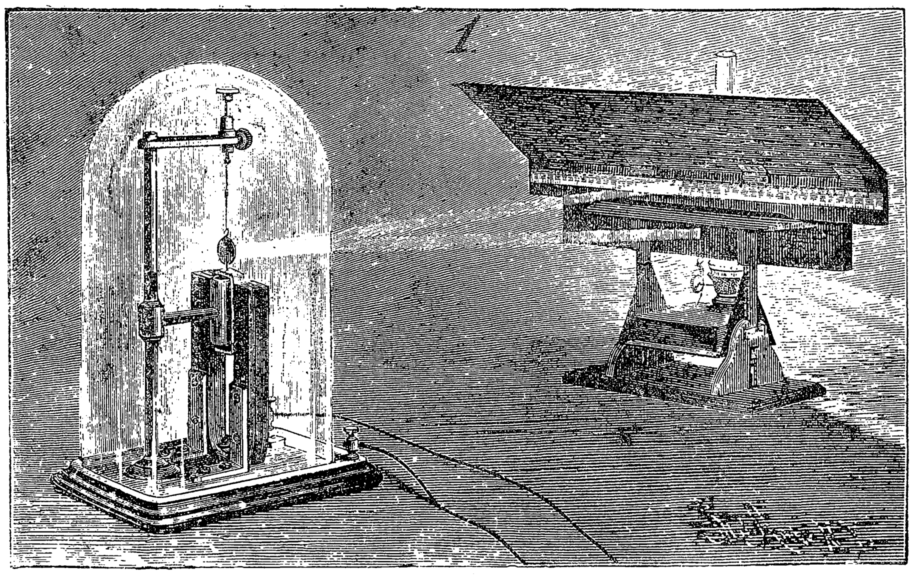
When an electrical current is sent through the coil, it tends to assume a position at right angles with a line joining the two poles of the magnet, the amount of displacement of the coil from its normal position depending on the strength of the current. As the deflection for a very light current is small, a beam of light reflected from the concave mirror is employed as an index. The scale is arranged as shown in Fig. 1, the light being projected from a lamp, supported at the proper height behind the scale, through a slit below the scale and on to the concave mirror. The mirror reflects the beam on to the scale. The mark at the centre of the scale is 0, and arbitrary numbers, running upwards regularly, are arranged on the marks on opposite sides of 0. The common paper scale used by draughtsmen answers for this purpose.

* By GEO. M. HOPKINS, in the *Scientific American.*

3







When the coil is at rest, the light spot remains at the centre of the scale; but when a current passes through the coil, the beam moves steadily forward and stops without oscillation, the distance through which it moves depending, of course, on the strength of the current. The coil is returned to its normal position by the spring of the silver wires. By employing shunts in the usual way, heavy currents may be measured by the aid of this instrument. The sensitiveness of the instrument is so great as to indicate a current when the ends of two No. 18 copper wires connected with it are placed on opposite sides of the tongue.

The coil is carefully wound over a form covered with paper, each layer of wire being varnished with shellac varnish as the work of winding progresses. When the coil is complete, the coil, together with the form, is heated in a warm oven until its varnish becomes hard throughout the coil. The concave mirror may be purchased from the optician, or a very fair mirror may be made by cutting a small disc from a double convex spectacle lens of 60 or 70in. focus, and silvering it. A simple and quick way of silvering a small surface consists in scraping from the back of a piece of ordinary looking glass all of the silvering, except a patch of the size of the mirror to be silvered. A small drop of mercury placed on the patch soon loosens it, so that it may be slid from the glass and transferred to the disc. The disc must be perfectly clean. After the patch is in position on the disc a piece of tinfoil is placed on the back of the disc, pressed down firmly, and allowed to remain long enough to absorb all the surplus mercury. It is then removed, and the transferred silver will be found adhering strongly to the disc. The various dimensions above given are taken from an almost exact copy of a Deprez galvanometer made by Carpentier, of Paris. The copy operates admirably. It is probable, however, that a considerable deviation from these dimensions might be made without seriously affecting the value of the instrument.

CASTING ALUMINIUM BRONZE AND OTHER STRONG METALS.*

THE difficulties which beset the casting of aluminium bronze are, in some respects, similar to those which were encountered in perfecting methods for casting steel. There is much small work which can be successfully cast by methods used in the ordinary mouldings of cast-iron; but in peculiarly proportioned, and in large bronze castings, other means and extra display of skill and judgment will be generally required. In strong metals there appears to be a "red shortness" or degree of temperature, after it becomes solidified, at which it may be torn apart, if it meets a very little resistance to its contraction, and the separation may be such as cannot be detected by the eye, but will be made known only when pressure is put upon the casting. To overcome this evil, and to make allowances for sufficient freedom in contraction, much judgment will often be required, and different modes must be adopted to suit varying conditions. One factor often met with is that of the incompressibility of cores or parts forming the interior portion of castings, while another is the resistance which flanges, &c., upon an exterior surface, oppose to freedom of contraction of the mass. An illustrative case, which the writer had to deal with, was the casting of some blast-furnace tuyeres, the dimensions of which were about 12in. diameter at the small end, and 14in. diameter at the large, and 17in. long. These tuyeres were made hollow for the passage of water to keep them cool when the furnace was in blast. The core to form this hollow space was one which foundrymen would term a "mean core" to make and to use, and the stronger it could be made by means of the mixture of the sand, the easier would it be to make and to handle. But it was proved at the hydraulic testing of the first casting that these conditions were the worst for causing leakage. It was found that in order to procure a casting which would not leak, the core must be "rotten" and of a yielding character. This was obtained by using rosin in coarse sand and filling the core as full of cinders and large vent-holes as possible, and by not using any core-rods or irons. The rosin would cause the core, when heated, to become soft, and would make it very nearly as compressible as a "green sand" core, when the pressure of the contraction of the metal would come upon it. It might be well to state that the size of this core was such as would leave 1in. thickness at each end, and one $\frac{1}{2}$in. at the inner and outer sides of the casting, and was all surrounded with metal, excepting four 1in. round openings through which the core delivered its vent or gas. By means of dried resin or green-sand cores we were able to meet almost any difficulties which might arise in ordinary work from the evils of contraction, so far as cores were concerned. For large cylinders or castings which might require large round cores, which could be "swept," a hay-rope wound around a core barrel would often prove an excellent yielding backing, and allow freedom for contraction sufficient to insure no rents or invisible strain in the body of the casting. To provide means for freedom in the contraction of exterior portions of castings which may be supposed to offer resistance sufficient to cause an injury, different methods will have to be employed in almost every new form of such patterns. It may be that conditions will permit the mould to be of a sufficient yielding character, and again it may be necessary to dig away portions of the mould, or loosen bolts, &c., as soon as the liquid metal is thought to have solidified. In any metal there may be invisible rents or

* By THOMAS D. WEST, extracted from a paper read before the New York Meeting of Mechanical Engineers.

strains left in a casting through tension when cooling sufficient to make it fragile or to crack of its own accord, and it is an element which, from its very deceptive nature, should command the closest attention of all interested in the construction of castings.

Like contraction, the element of shrinkage is one often found seriously to impede the attaining of perfect castings from strong metals. In steel castings much labour has to be expended in providing risers sufficient to "feed solid" or prevent "draw-holes" from being formed, and in casting aluminium bronze a similar necessity is found. The only way to insure against the evils of shrinkage in this metal with work requiring "risers" or "feeding heads" was to have them larger than the body or part of the casting which they were intended to "feed." The "feeder" or "riser" being the largest body, it will, of course, remain fluid longer than the casting, and as in cast iron, that part which solidifies first will draw from the nearest uppermost fluid body, and thus leave holes in the part which remains longest fluid. The above principle will be seen to be effective in obtaining the end sought. It is to be remembered that it is not practical to "churn" this bronze, as is done with cast iron. A long cast-iron roll, 1ft. in diameter, can by means of a "feeder" 5in. in diameter and ½in. wrought-iron rod, be made perfectly sound for its full length. To cast such a solid in bronze the feeding head should be at least as large as the diameter of the roll, and in length about one-quarter longer than the length of roll desired. The extra length would contain the shrinkage hole, and when cut off a solid casting would be left. This is a plan often practised in the making of guns, &c., in cast iron, and is done partly to insure against the inability of many moulders to "feed" solid, and to save that labour. There is nothing in the way to prevent obtaining large guns of aluminium bronze as perfect as are made of cast iron. It is simply a question of having enough "riser" or "feeding head," and such guns would surpass in strength any other metal now used in their manufacture.

A method which the writer found to work well in assisting to avoid shrinkage in ordinary castings in aluminium bronze, was to "gate" a mould so that it could be filled or poured as quickly as possible, and to have the metal as dull as it would flow, to warrant a full-run clean casting. By this plan very disproportionate castings were made without "feeders" on the heavier parts, and upon which "draw" or shrinkage holes would surely have appeared, had the metal been poured "hot."

The plan or principle adopted in pouring this bronze is similar to that employed for casting steel, which, as is well known, consists in pouring through a spout controlled by a valve, which lets the metal flow from the bottom of a ladle instead of the top or lip, as practised in pouring cast iron. The exact plan which the writer used for castings weighing over 50lb., was to make the pouring basin sufficiently large to contain all the metal necessary to fill the mould, and give any surplus which might be required for a "flow-off," or to fill up "feeding-heads," &c., and so to prevent any metal from flowing into the mould until it was all in the pouring basin. The entrance of the gate would be stopped by means of an iron plug, and the moment all was ready it would be pulled, and the metal would almost instantly fill the mould, so large would its gates be made. By such a plan it will, of course, be readily seen that there was no danger of any "scum" or oxide entering the mould, an element which would seriously mar the appearance of a casting. Besides the difficulties from difference in the colour which resembles gold, such oxide would be very liable to cause a disunion of the particles of the body, or make an unacceptable surface when the casting was finished up. The metal itself is one that works well in our ordinary moulding sands, and "peels" extra well. As a general thing, disproportionate castings weighing over 100lb. are best made in "dry" instead of "green" sand moulds, as such will permit of cleaner work and a duller pouring of the metal, for in this method there is not that dampness which is given off from green sand mould, and which is so liable to cause "cold shuts." When the position of casting work will permit, many forms which are proportionate in thickness can be well made in green sand by coating the surface of the moulds and gates with silver, lead, or plumbago.

From "blow holes," which are another characteristic element likely to exist in strong metals, it can be said that aluminium bronze is free. Should any exist, it is the fault of the moulder or his mould, as the metal itself runs in iron moulds as sound and close as gold. Sand moulds to procure good work must be well vented, and if of "dry sand," thoroughly open sand mixture should be used and well dried. The sand for "green sand" work is best fine, similar to what will work well for brass castings. For "dry sand" work, the mixture should be as open in nature as possible, and for blacking the mould, use the same mixtures as are found to work well with cast iron.

The different problems for making strong metal castings all present peculiarities which call for special treatment in the manner of moulding, &c.; but the difficulties to be overcome mainly hinge more or less upon one or other of the three elements, oxidation, shrinkage, or contraction. These are being controlled better every day, and progress is made by which almost any kind of casting can be procured as readily as of cast iron. With aluminium bronze, "Mitis," and steel castings to be had, the engineer should not want for strong metals to meet almost any conditions.

SCIENTIFIC SOCIETIES.

ROYAL METEOROLOGICAL SOCIETY.

THE usual monthly meeting of this society was held on Wednesday evening, the 15th inst., at the Institution of Civil Engineers, Mr. W. Ellis, F.R.A.S., president, in the chair. Mr. G. R. Fancombe, B.A., Mr. C. E. B. Hewitt, B.A., and Capt. S. Trott were balloted for and duly elected Fellows of the Society.

The following papers were read:—

1. "On the Proceedings of the International Congress of Hydrology and Climatology at Biarritz," by Mr. G. J. Symons, F.R.S. This congress was held in October, and was divided into three sections—viz., scientific hydrology, medical hydrology, and climatology, scientific and medical. The total number of papers read was 109. An exhibition was also held in connection with the congress. The excursions were of primary importance to the medical men, and extended over a period of three weeks. The places visited were—Bayonne, Cambo, Dax, Arcachon, Pau, Eaux-Bonnes, Eaux Chaude, Cauterets, Lourdes, Bagnères de Bigorre, Luchon, Ussat, Ax, Montpellier, Cette, Boulou, Amelie des Bains, La Preste, Banyulo-sur-Mer, and Thues.

2. "Report on the Phenological Observations for 1886," by the Rev. T. A. Preston, M.A., F.R.Met.Soc. The weather was, on the whole, very ungenial, and everything much retarded. It was also very fatal to insect life, so that the complaints on this head have been far less than usual. Bush fruits were very abundant, strawberries and peas were spoilt by drought, in many places, stone fruits, except plums, were not abundant; plums were extraordinarily plentiful, so much so that they realised nothing in the markets, the cost of picking and carrying often being more than they realised. Apples were very poor, from the destruction of the bloom by heavy rain. Hay was good and plentiful, and well harvested. Corn and other grain were not up to an average. Root crops were, as a rule, remarkably good.

3. "A Criticism of Certain Points of Prof. Langley's Researches on Solar Heat," by Prof. S. A. Hill, B.Sc., F.R.Met.Soc. These experiments were carried out at Mount Whitney, in Southern California during 1881.

4. "Account of the hurricane of March 3rd and 4th, 1886, over the Fiji Islands," by Mr. R. L. Holmes, F.R.Met. Soc. This storm was the most destructive that has ever been known to occur in the Fiji group. The lowest barometer reading was 27·54in. at Vuna, in Taviuni. The storm was accompanied by a great wave, from 18ft. to 30ft. in height, which swept over the land, and caused an immense amount of damage. It was reported that 50 vessels were wrecked, and 64 lives lost during this hurricane.

5. "Results of Meteorological Observations made at the Military Cemetery, Scutari, Constantinople, 1866-85," by Mr. W. H. Lyne. The annual mean temperature is 58·4°; the highest temperature registered was 103·6° on June 22nd; and the lowest 13·0° on January 25th, both in 1869. The annual rainfall is 29·29in.; the greatest fall in one day was 4·06in. on Sept. 25th, 1866.

LIVERPOOL ASTRONOMICAL SOCIETY.

THE usual monthly meeting was held on Monday, the 13th December. The chair was taken by Mr. H. Hudson. Thirty-three members were elected and 25 candidates proposed, and Messrs. W. Thynne Lynn, B.A., F.R.A.S., and Herbert Sadler, F.R.A.S., were elected Associates of the Society. Mr. Herbert Sadler, in commenting upon a former paper on the masses and distances of binary stars, complimented Mr. Gore on the care and accuracy of his computations; but took exception to the data on which they were founded. Amateurs were too apt to accept such results as absolutely proved, whereas they were, in reality, matters of much uncertainty. The celebrated star 61 Cygni was a case in point, for, although numerous measures of the orbit had been obtained, they were not at the present time sure that it was a binary at all. The calculations of the Astronomer Royal for Ireland gave a parallax of 0·467″ for 61² Cygni; whilst Prof. Asaph Hall, by precisely the same method, obtained a final result of 0·270″. The former would give a light passage of less than 7 years; but if they accepted the figures of the American astronomer, it would take more than 12 years. He merely gave this as an example of the uncertainty which attended such investigations.

Mr. W. S. Franks, F.R.A.S., commended the study of coloured stars as in every way suited to beginners with small telescopes. To the amateur in astronomy, what could be more pleasing than to contemplate the colours of those gems of the midnight sky? The hidden meaning of the colours was in itself a theme for wonder; since, why should the richest tints of blue, green, and violet be confined to the companions of double stars? That they were not an effect of contrast could easily be proved by occulting the brighter star. The bluest of isolated stars was Vega, which many would not consider blue at all, and the greenest was β Libræ; but it was only when they came to such stars as β Cygni, γ Andromedæ, and others that the most gorgeous colours were obtained.

In a paper on "The Quadrantid Meteors," Mr. T. W. Backhouse said the ensuing shower would occur under fairly favourable circumstances on the 2nd of January, though, as the maximum would take place in daylight, observers in this longitude would not be fortunately situated. Next to the August Perseids the New Year's display of Quadrantids with their billiant, streaked appearance, was the most striking. Their time of maximum was, however, shorter than most periodical displays, and this rendered an exact calculation of their period important. Mr. W. F. Denning, F.R.A.S., attributed a special value to the notes of Mr. Backhouse. His table of results for last January proved the shower to have been decidedly conspicuous, though it could not be seen to any advantage at Bristol. On January the 2nd, he had watched the sky whenever a break in the clouds permitted, and had counted 17 shooting stars, of which only four were Quadrantids. Of course this was under unfavourable conditions; and Mr. Backhouse's results afforded clear evidence that it was a fairly bright display. He had determined the radiant at 228° + 52; but the paths had been too few to obtain a reliable average. The mean point of divergence from a considerable number of radiants by other observers gave 230·5° + 51·3°.

A paper by Mr. J. E. Gore, F.R.A.S., was read on some suspected variables of the Algol type. This class of variable stars was a very rare one, only seven having been detected. They were in order of Right Ascension:—

Star.	D. Period.	Variation.
U Cephei	2·49132	7·2 to 9·1—9·4
β Persei (Algol)	2·86727	2·2 „ 3·7
λ Tauri	3·952	3·4 „ 4·2
S Cancri	9, 11h. 37·75m.	8·2 „ 9·8—11·7
δ Libræ...........	2, 7h. 51m. 20s.	4·9 „ 6·1
U Coronæ.........	3, 10h. 51m. 14s.	7·6 „ 8·8
U Ophiuchi	0, 20h. 7m. 41s.	6·0 „ 6·7

Owing to the fact that in these remarkable variables all the light variations took place in the course of a few hours, whilst for the remainder of the period it remained constant, it would be seen that the discovery of this class was a matter of great difficulty, and this would, he thought, account for the paucity of such stars amongst the many thousands known to astronomers.

Mr. T. G. Elger, F.R.A.S., in a third paper on "The Moon Surveyed in Common Telescopes," dealt with Gassendi and the eastern side of the Mare Humorum, and described in detail the various points of interest which might be observed with very moderate telescopic means. The remarkable peculiarities of Gassendi itself; its low and attenuated state on the south-east, and the degradation of a great portion of its northern wall were well worthy of scrutiny. The complicated structure of the magnificent central mountains—which had been compared by the late Prof. Phillips to an associated group of dolomitic or trachytic rocks—together with points of interest in the neighbourhood, were illustrated by a number of autographed sketches, which the members were advised to compare with the actual appearance in their own telescopes. A paper on the present and future of celestial photography by Monsieur Lihou was also read, and Mr. W. F. Denning contributed the third series of his valuable papers on "Telescopes and Telescopic Work."

ROYAL MICROSCOPICAL SOCIETY.

THE third meeting of the session was held on the 8th inst. at King's College, Dr. Dallinger, F.R.S., the president, in the chair.

Mr. Crisp read a letter received from Mr. Durkee, the designer of the electric lamp which was described and figured in the December number of

the *Journal* (p. 1053), and there stated to have been "received anonymously from America." The letter explained that a full description had been sent by the same mail as the lamp, but it had miscarried, and the letter now to hand unfortunately did not arrive in time for the explanation to be inserted in the *Journal* with the description.

Mr. J. Mayall, jun., said that Mr. Crisp at their last meeting had pointed out that if microscopes were to be made for every special purpose for which they could be used, there would be a large field open, and he had to introduce to their notice that evening another of this class. It had been designed to measure with great accuracy the divisions ruled upon a diffraction plate, which was about the severest test that could be applied to any method of dividing fine lines. The microscope upon the table had been constructed with great care by Mr. Hilger after the designs of Sir Archibald Campbell, and was capable of executing measurements over a space of nearly 6in. The diffraction plates with which they had hitherto been familiar only occupied a space of about 1in.; but he believed Sir Archibald had devised a ruling machine which would be able to rule to 6in. The instrument was extremely firmly made, having a massive stand of iron carrying a heavy bar on which the microscope traversed. Motion was imparted to it by means of a screw cut with 100 threads to the inch, and a series of verniers enabled the observer to read down to the $\frac{1}{100000}$in. For strictly end measurements an application of electricity was employed, so that by means of a weak battery and a galvanometer it could be arranged that a contact should be made when passing every line, such contact being shown instantly by a deflection of the galvanometer needle. In this way end measurements could be made with great accuracy. The first time he saw this apparatus he felt that, as there was no fine adjustment, it was hardly available for high powers, and it seemed to him that if comparatively low powers only were used, the accuracy of the results might be likely to suffer, because a person could hardly tell if he was looking at the middle of a line or not. He pointed out this want to Sir Arch. Campbell, who had since devised a fine adjustment for the purpose, of a somewhat original form, consisting of two tubes one inside the other, fitted with a collar having a thread cut upon it, and moved by a tangent screw. One objection to a tangent screw was that there was always loss of "time" in using it; but in the case before them the work, as carried out by Mr. Hilger, was so true that no objection of this kind was experienced, and the motion obtained was so exceedingly slow that several turns had to be made before any motion could be appreciated under a $\frac{1}{8}$in. objective. He had particularly emphasised the necessity for a very slow motion, because he thought that most of those usually made were too fast, and this new one was the slowest he had ever seen. Another ingenious arrangement, devised by Sir Archibald, was a method of illuminating the object from above by a mirror made of speculum metal, held by a horizontal arm, and fitted with condensers with screw motions to direct the illumination. He felt bound to say that the trials he had made with these gave him the impression that they were rather too coarse for such fine work as it might be required to perform. Certainly, with a power as high as $\frac{1}{12}$in., it would not be possible to manipulate an apparatus of this kind which necessitated having to touch the microscope. All such arrangements should be separate from the instrument, otherwise it would be impossible to prevent very inconvenient tremors. He did not think this method of illumination so good as that devised by the late Mr. Tolles, in which a prism was inserted behind the front lens of the objective, though for low powers it might do very well.

Mr. Mayall also exhibited and described a new form of heliostat, also made by Mr. Hilger, for use in solar photo-micrography, consisting of a plane mirror equatorially mounted and rotated by a clockwork movement; but also having a second mirror mounted upon a universal joint attached to the polar axis so as to admit of motion in any direction. The pencil of sunlight reflected from the first mirror could, by means of the second, be directed in any desired direction, affording to the worker the very great advantage of being able to place his microscope and camera in any position he pleased. When properly adjusted, with the polar axis parallel to that of the earth, the clockwork would enable the reflected beam to preserve the same direction for about six hours.

Mr. F. R. Cheshire exhibited and described an improved form of inoculating-needle for use in connection with bacterium culture tubes. It was well known that the usual plan was to have a platinum wire fused into the end of a piece of glass rod, which served as a handle; needles of this kind had the merit of being easily made, and being also inexpensive. The one he exhibited cost rather more, but possessed sundry advantages which he thought might compensate for the extra outlay. It was mounted in a wooden handle having a square ferrule which prevented it from rolling when placed upon a surface which was not level; in this was inserted a piece of very small silver tube, at the end of which was the platinum wire. On the tube a circular disc of silver was fixed, which, when placed over the flame of a lamp, rapidly became hot, and communicated the heat to the needle—silver being a very good conductor of heat. The silver tube, being very much less thick than the glass rod, could more easily be introduced without coming into contact with the sides of the glass tube; but a much greater advantage than this also arose from its comparatively small size. The diameter of the ordinary culture-tubes was generally about $\frac{1}{2}$in., whilst that of the glass rods was about $\frac{1}{4}$in. On introducing the needle therefore the glass rod displaced a large quantity of air from the tube, and on its withdrawal the in-draught would cause a quantity of outside air to pass in, and in this way impurities might be admitted, whereas, owing to the small size of the silver tube the displacement of air by it was extremely small. He also thought that there might be less danger to the operator in the use of the new pattern, because the needle perhaps charged with anthrax could not come in contact with the table at all if laid down upon it. It would also be found more convenient to use it in cases where it was desired to separate the different forms in a colony. In order to keep these needles intact, they could readily be inserted into small pieces of glass tube, and when thus placed in a case they could be carried about with great facility.

Mr. E. M. Crookshank thought this kind of needle might be found very useful in some cases, but he fancied that most bacteriologists would prefer to have the ordinary kind with the platinum wire simply fixed in the end of a glass rod by holding over a Bunsen burner. As regarded the suggestion that there might be danger from anthrax getting upon the operating table by the use of the ordinary glass rod, he pointed out that in practice it should be made a constant habit always to sterilise a needle after use by passing it at once through the flame without putting it down.

Prof. Bell called attention to some specimens exhibited of *Tænia nana*, the smallest of the human tape-worms, originally found by Bilharz in Egypt in 1850. Though extremely rare, it had the great advantage to the physiologist at least (though perhaps not to the patient) of being found in considerable numbers. In the present instance the worms had been found in quantities in the duodenum of a girl aged seven years, at Bellegarde. The latest specimen met with was only 15mm. long. Prof. Bell further referred to the observations of Leuckhart on the subject.

Mr. J. D. Hardy called attention to a statement by Dr. O. Zacharias in the October number of the *Journal* (p. 799) with reference to the desiccation of rotifers, and in which it was stated that they could never be revived after desiccation. He thought a protest should be entered against this, as it was within his knowledge that "revivification" had taken place over and over again. He had frequently tried the experiment, and had found that when the dried mud was moistened the rotifers constantly revived.

Mr. Crisp, having read the paragraph referred to by Mr. Hardy, and also a paragraph bearing upon the subject from the December number of the *Journal*, p. 989, said that, as intimated in every number, the society did not hold themselves responsible for the views of the authors of the papers noted, the object being to present a summary of them "as actually published." With regard to the merits of the question, if a few minutes after the moistening they found the adult forms moving about, it must be obvious that they could not have come from eggs, as stated by Dr. Zacharias.

Prof. Stewart pointed out that a good deal must turn on what was meant by "desiccation." It was exceedingly difficult, under ordinary circumstances, to produce a condition of complete desiccation, and it was, therefore, very probable that in all cases of revivification there was sufficient moisture retained to preserve life.

Mr. A. D. Michael agreed in Prof. Stewart's view. That rotifers did apparently revive after desiccation was perfectly clear, and if a full-grown rotifer was revived in the manner stated, it was strange how anyone could be found to suppose that it had come direct from the egg. He did not see any great difficulty in freely accepting the idea that the rotifers which revived had not really been absolutely desiccated. It was quite likely that they became covered with a coating of hardened mucus which prevented them from altogether drying up.

Prof. Bell said that this explanation had usually been accepted as the real one when this subject perennially came to the front. The most curious part of Dr. Zacharias' paper, however, was that he did not in any way attempt to criticise the observations of his predecessors on the facts, but simply declared them to be fables, not inquiring at all into the conditions under which the revivals took place, so as to ascertain whether or not they were desiccated in the same sense in which his objects were when dried up in a granite basin. Prof. Bell also read from Dr. Hudson's and Mr. Gosse's "Rotifera" the paragraphs relating to the desiccation of rotifers (pp. 95, 96), in the course of which the observations of Mr. Davis, recorded in a paper read before the society in 1873, were quoted.

Mr. R. T. Lewis said he remembered that on the occasion when Mr. Davis read his paper upon the subject, he brought to the meeting by way of illustration some grapes which he had coated with gelatin, and had afterwards exposed for many hours to the dry heat of a slow oven. On being cut open in the room the fruit was found to be in a perfectly natural condition, showing that a gelatinous coating was competent to preserve the contained moisture from evaporation.

The President said he thought the question was practically settled so far as the judgment of microscopists was concerned.

Col. O'Hara's note on the dissimilarity of appearance of crystals of blood as examined by him and the illustrations in textbooks was read by Prof. Bell.

Mr. P. H. Gosse's paper "On Twenty-Four New Species of Rotifera" was read by Mr. Crisp, and two plates drawn by Mr. Gosse in illustration were handed round for inspection.

The President said that those who had seen the drawings could hardly fail to be struck with the touch of them, especially when they considered the age of Mr. Gosse. In returning their thanks to the author he could only say that they were proud —he used the word advisedly—to have the paper.

Borated Fish.—The question to decide in connection with the employment of boracic acid as a preservative of fish is not the economic or the commercial one. The point is whether the use of boracic acid is calculated to deteriorate the fish as an article of food, or to cause derangement, not to say disease, in the human economy. Nothing short of the experimental method will afford a decisive and accurate conclusion. But we tread on safe ground when we assert that fish perfectly fresh and kept no longer after its removal from the watery element than is absolutely unavoidable, must be considered to be a better article for consumption and less liable to effect harmful changes in the organism than any kind of borated substitute. However, if fish must be preserved, are there any known facts that should recommend the employment of boracic acid? It is a good antiseptic, and will undoubtedly prevent putrefaction if used in sufficient quantity. Does it cause disease when introduced into the healthy human body in minute doses and for long periods? It certainly is of value internally administered in some morbid conditions of the stomach and intestines. For the last question we have no certain data on which to give a satisfactory answer. But we should think that, if used accasionally and in very small quantities, the acid would probably not prove injurious to the health of the animal organism. It may be urged that washing, boiling, or cooking would free the fish from any boracic acid that might have penetrated into its substance; but probably some of the salt would remain in the fish. The salicylage of beer is a more wholesale saturation, both of beer and consumer of beer, but so far as can be judged *a priori*, the use of boracic acid to preserve fish, though not desirable, would, with proper precautions, not prove harmful.—*Lancet*.

"St. Govor's Well," Hyde Park.—Near the bottom of Broad-walk, Kensington Gardens, and about a hundred yards below the Round Pond, is situated a sunken well bearing the inscription "St. Govor's Well, 1856." A few years ago the water, which issued in a considerable stream from a leaden spout, was credited with medicinal virtues and was distributed to children and curious people in many coloured glasses by an old woman who attended daily. We have heard of the beneficial action of the waters on crippled joints. Since the woman disappeared (from over-indulgence in the waters?) a metal cup has been attached to the spout, and the well has been the constant resort of thirsty children and nursery maids. During the past summer, while the Round Pond has been drained St. Govor's Well has run dry, and it is said that some pipes were discovered under the two or three feet of stinking mud at the bottom of the pond which had the appearance of communicating directly with the well, so that it seems probable that the water has been filtered through the mud, and not through the intervening bed of gravel. Can its reputed medicinal virtues be due to the organic impurities of stagnant water? It is to be hoped that the source of the water will be fully investigated, and, if it is found to be the mere drainage of the pond, that the well will be closed, or else that a supply of pure water will be laid on from a known source. The well would be very much missed by the children, as there is no other drinking fountain in the gardens.—*British Medical Journal.*

SCIENTIFIC NEWS.

THE death is announced of Dr. Robert Dyer Lyons, a well-known Irish physician, chief pathological commissioner to the army in the Crimea, and author of several works on medical subjects.

The death of Father Scortechini is announced from Calcutta, his exertions in the botanical exploration of Perak having brought on an attack of dysentery. He had made large and valuable collections, which will be utilised at Kew in perfecting portions of the flora of British India.

Members of the Geologists' Association will recollect that, at the time of his death, Prof. Morris had made considerable progress with a new edition of his "Catalogue of British Fossils," and they will be glad to hear that a relative has made arrangements for the revision and completion of the MS. and guaranteed the expenses of putting it through the press, as the best monument to the memory of the enthusiastic and accomplished geologist. Dr. H. Woodward will act as editor in chief, assisted by a number of specialists, and the syndics of the Cambridge University Press have undertaken the publication of the work, which will probably appear in the course of 1887.

At one of the science lectures recently delivered at the Royal Victoria Hall, Prof. Boyd Dawkins spoke on the subject of the introduction of the arts into Britain. He began by calling attention to the fact that things were not always as they are now, but our surroundings were entirely due to the labours of those who had gone before us; and he carried the audience back through the many intervening ages between us and our primeval ancestors, that he might show them who those ancestors were and for what we were indebted to them. In a number of magic-lantern slides were then successively displayed the implements in use among the men of the neolithic age, the mines they dug, their dwellings, the articles found in their dwellings, the various kinds of grain grown, the domesticated animals, and the tombs and skeletons. Prof. Dawkins explained the history attaching to all these objects, and the results accruing from them, and then proceeded to illustrate by similar views the life of man in the bronze age, showing how it finally led to the iron age, and concluded by asking his hearers to realise that their present life was the direct outcome of those stages of development which had been represented to them, and so to feel that it was the duty of each one to do something which would add to the good of mankind, and raise man even higher than he was at present. The penny science lectures will not be continued until after the Christmas holidays, the next being on January 25, when Mr. Arthur Stradling will lecture upon "Snakes and Snake-Charming," and bring with him 40 living illustrations.

At the distribution of prizes, &c., at the Liverpool Institute last week, Dr. B. W. Richardson gave an address on "Natural Selection for Science or for Art," in the course of which he said that the time had now come when all students should determine by their own investigations into their characters in which direction their studies should go, so as to lead them onwards in the course of life that was best adapted to them. It seems to Dr. Richardson that the block which has been put in the way of human progress by the ignorant transposition of living science into living art, and the reverse, can never be known until the folly of the transposition is seen in the astounding results that will follow upon the reformation of the false and blind system which now exists of letting expediency instead of fitness decide the fate of the student in his early days, and of allowing the sharpness of competitive examinations to drive the student, hopelessly, into a career for which there has been no test whatsoever either of aptitude or affection. Newton, he said, was the greatest man of science who ever lived, and Turner was the greatest painter of his kind; but Newton probably knew as much of art as Turner did of science. Neither of them had time to learn much beyond his own pursuits; and yet he cannot but believe that even those concentrate minds were improved if sometimes they left their own labour to find rest by change into other and kindred spheres. Certainly, in many great works, by the combination of science with art, the noblest results have been obtained.

The Council of the Society of Arts have offered to award two gold medals and four silver medals for prime movers suitable for electric light installations. The conditions, which can be obtained from the secretary, specify that the motors shall be divided into two classes, to each of which one gold and two silver medals will be awarded. These classes are, briefly, "Motors in which the working agent is also produced"; and "Motors to which the working agent must be supplied." The engines and boilers must be fitted up in accordance with the regulations of the Royal Agricultural Society, and an entrance fee of 50s. per H.P. must be paid on entry. Entries must be sent in not later than Feb. 28th next, and the competition will take place in London next May or June.

The statement that an "electrical metronome" has been established at the Paris Opera-House, enabling the leader to conduct choruses at any distance from his chair, appears to be based on the fact that M. Carpentier has exhibited to the Paris Academy of Sciences an appliance which answers the purpose. The instrument is a simple black plate, with grooves in the form of the letter V, in which a small rod is placed and connected with an electric current. The rod is half white and half black. When the conductor presses a button the rod turns regularly round and round, presenting alternately the black and white face, so as to give the optical illusion of a white pendulum, which moves across the black plate in rhythmical measure.

According to the *Times*, a new storage battery has been devised with which "it would appear to be possible and easy to carry out isolated electric lighting efficiently and economically." Each cell is contained in a wood casing measuring 11in. long by 6in. wide and 7in. deep. The whole weighs 20lb. and has a capacity of 115 ampère hours. Each cell contains six anodes and seven cathodes immersed in a solution of sulphuric acid. The negative plates are specially prepared, and are set into a very hard and durable substance possessing great porosity and conductivity. They will not only bear transport, but can be stored dry for use at any time. The conductor is so protected as to prevent its oxidation, thus avoiding loss of capacity by the buckling of the electrodes, and the active material cannot become detached or disintegrated. The cathode is spongy lead, and the whole constitutes a feeble primary battery. The plates are therefore removed from the cells, charged by a dynamo, and replaced for use. It is proposed to charge the plates at the company's works, to deliver them to the consumer, who will use them until they are exhausted and then send them to be recharged. The description rather strangely concludes, "The current produced can be used either for lighting, supplying motive power, working a telephone or electric bells."

A complete set of Prof. Ewing's apparatus for recording earthquakes is now being tested at University College, Dundee, previous to its being sent to the Observatory on Ben Nevis, where it is to be placed.

Electromotors and accumulators are to be tried by the Philadelphia Traction Company, which controls most of the street tramways in that city.

The Municipal Council of Paris has granted to the Committee of the Jubilee of Railways the free use of 900 acres of the most attractive portion of the Bois de Vincennes, including the lakes, and it is stated that the works will be commenced immediately.

Saccharine is stated to possess high antifermentative and antiseptic properties, and is recommended for administration to diabetics, as it passes through the organism unchanged, and can thus be used to render food palatable without itself exercising any deleterious effect. It is an excellent antiseptic in cases of indigestion caused by abnormal fermentation.

The council of an Italian Anti-rabies Society held at Milan, state that their investigations have enabled them to diagnose the presence of the virus of rabies in those bitten by dogs, and that they can apply, and have applied, Pasteur's method with results superior to those attained by the distinguished savant himself.

Cocaine has a rival in an alkaloid obtained in Australia from the juice of Euphorbia Drummondii, which Dr. John Reid, its discoverer, calls Drumine. The new local anæsthetic acts almost entirely by paralysing, and does not excite.

At a meeting of the Royal Scottish Society of Arts last week Dr. Sang read a description of a new mirror level, the invention of Mr. R. B. Pollitt, Manchester. The level consists of a pendulum and frame carrying an arrangement of plane mirrors showing accurately the relative position of the pendulum and the frame. The frame is similar in appearance to the ordinary striding spirit level, and carries an adjustable mirror, while the other mirror is rigidly attached to the pendulum, which is suspended on a knife edge and agate plate. The position of the mirrors is such that when the level stands on a perfectly horizontal plane they are parallel in every direction. In reading, the image of a vertical scale is reflected from the mirrors and read by a telescope. When the level stands on a horizontal plane the scale is reflected perfectly, otherwise the image appears distorted. It was claimed for the level that it gives advantages in reading small angles, and is not liable to deviations, as was the ordinary spirit level. In the discussion which followed, it was objected that the level appeared to be too delicately constructed to be serviceable for ordinary uses.

At the meeting of the San Francisco Microscopical Society on Nov. 10, Mr. Wickson stated that he had recently found insects on some laurel trees in the Experimental Gardens at the State University. At first sight they appeared to belong to the *Amphidæ*; but a closer inspection showed them to be neuropterous insects of the genus *Psocus*, which embraces some sixty species. They are very active in the larval and pupal stages, as well as in the perfect form. They live in groups, usually on the under side of the leaves. A microscopical examination shows them to have free mouthparts. The compound eyes are exquisitely beautiful, and many other points in their anatomy are of great interest.—At the meeting on Nov. 24th Mr. Wickson stated that the *Psocus* would not attack the scale insect. Specimens of an Australian Polyzoan, *Bicellaria ciliata*, were shown by Mr. Howard, who also exhibited an alga (*Trichodesmium* Sp.) found floating in immense quantities in the Pacific. It consists of rod-like filaments transversely striated, and of a light olive-green colour. The average length and diameter are respectively ·015 and ·0003 of an inch. One peculiarity of growth is that the filaments arrange themselves in bundles of about 25 to 50. This minute plant forms a considerable part of the food of the right whale, and it is, in fact, known to many mariners as "whale-feed." The process of spore formation does not seem to have been observed as yet.

THE use of intermittent light to indicate the speed of engines or other moving bodies has been proposed by M. Gustave Hermitte. His plan is to illumine a Giessler tube by the sparks of an induction bobbin, giving a constant and known rate of vibration per second, say, from thirty to forty, each vibration giving a corresponding flash of the Geissler tube. By optically arresting the moving objects at different points of their course, he proposes to obtain their speed. For example, if a disc of cardboard be made to revolve by clockwork at a uniform and known speed, say, one turn per second, and if it be lighted by the Giessler tube giving thirty flashes per second, we shall see the disc thirty times during one second, or, in other words, while it makes one revolution; and if there be a visible spot on its surface, thirty spots will be seen. If the disc turn ten times per second, the succession of images will disappear; owing to the persistence of impressions on the retina, the disc will appear to be immovable, and we shall see three spots on its circumference occupying fixed positions. If the number of turns of the disc is equal to the number of flashes of the tube the disc will be seen to be immovable. A printed page revolved in this way could be read as if it were fixed.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, *332, Strand, W.C.*

All Cheques and Post-office Orders to be made payable to J. PASSMORE EDWARDS.

*** *In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks, a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

DOUBLE STARS—U CYGNI—α ARIETIS—COMET f, 1886.

[26612.]—SINCE sending the results of my observations on U Cygni I have received some valuable information respecting this star from Mr. Sadler. By this it would appear that the star has been but seldom observed on the meridian, and therefore no definite statement can be made as to whether it has any proper motion or no.

The principal star of the pair is Arg. DM + 47°, 3077; but it was not observed with the Bonn Circle. From five observations in R.A., and four in Declination, made with the 6·4in. meridian circle at Dunsink, its place for 1875 would be 20h. 15m. 43·750s. + 47° 30′ 2·03″. The companion star, DM + 47° 3078, was called white by Dr. R. Copeland on July 25th, 1875, but blue on August 3rd in that year; it is certainly blue at the present time. The only micrometrical measures with which to compare my own are Sir Robert Ball's in 1880, who found Dist. 63·5″, P.A. 51·7°; a very close agreement in angle.

Barnard's Comet was observed here at 5h. 45m. on the 14th inst. shortly after sunset, with the 10½in. reflector, power 30. The nucleus appeared very bright, and was rated equal to a 3rd mag. star, but was ill defined, and higher powers showed no distinct stellar point; the surrounding nebulosity is nearly circular, and very bright. The two tails were well seen, the shorter being *preceding*, as described by Mr. Hopkins, while the principal tail (if such it can be called) was traced for about 10°, several small stars being visible through it. A rough setting of the position circle of the micrometer gave 43° as the angle contained by the two tails. The colour of the comet appeared greenish. The same evening I observed α Arietis, and rated the star (marked G on Mr. Gaudibert's drawing) at 11·3 Σ; it was readily visible in strong moonlight. I have examined this star with apertures up to 15in., and have never seen the slightest trace of any close companion.

Kenneth J. Tarrant.

Letchford House, Pinner, Dec. 16.

THE LUNAR RAY SYSTEMS.

[26613.]—The "Ray systems" are among the most important and interesting of lunar phenomena, and are far too little studied. They exhibit many peculiarities, and are among the strictly individual features presented to us by the moon. So far as we know they have no terrestrial analogues; and one of the most important branches of a study of them ought to be an inquiry to ascertain if none such can be found. Terrestrial analogues to lunar phenomena are too little sought for, though in point of fact they are among the most suggestive and instructive portions of the research: too many selenographers appear to forget that seleno*graphy* ought to be regarded mainly as a first step to seleno*logy*. These ray systems are among the most extensive of the lunar details, and are very widely distributed. Webb says they "issue, though in widely differing proportions, chiefly from seven different centres." He mentions the systems of Tycho, Proclus, Copernicus, Kepler, Byrgius, Euler, Anaxagoras, and Messier. Besides these, there are systems associated with Tobias Mayer, Thales, Aristarchus, Marius, Aristillus, Alfraganus, and Olbers. It is to be wished that a complete list of all the ray systems could be compiled. I have thought more than once, when libration was favourable, that portions of several great systems curve round from the invisible hemisphere, and can be traced at the edges of the visible disc. It is to be noted, that every opportunity which one gets of seeing the less ordinarily visible portions of the moon's surface—those brought into view by wide libration—indicates that their details and structure are precisely similar in character to those of the portions we usually see. It is not a suggestion altogether unreasonable, therefore, that were we to note these rays on the edges carefully, and observe their angles of divergence, we might be enabled to guess at the probable position of some of the great centres of past activity on the invisible hemisphere.

A little study soon shows that the ray systems differ in character, and Birt grouped them in three classes, and I think it is desirable that this classification should be generally adopted provisionally. No doubt, of course, it is always hazardous, and often inadvisable, to attempt at an early stage to systematise and classify; but the harm is only done when it is not clearly understood, and borne in mind, that such classification can only be regarded as provisional. However, a system founded upon types, rather than upon abstract definitions, has in it much more of a permanent character, and is often of extreme value in suggesting fresh ideas and observations. Birt's classification of the lunar ray systems was into Tychonic, Copernican, and the Messier rays. The last, however, are unique, so far as is definitely known; though I think a careful investigation would bring more instances to light. The "Tychonic" rays are those resembling the rays issuing from Tycho. These are narrow and definite, and quite distinct. The "Copernican," on the other hand, are those resembling the vast cloud of filmy light surrounding Copernicus. Their character is totally different, being that of a cloud-like, delicate, and inextricable, network. The two are generally separate, and the Tychonic is the commoner; but I do not know if Birt observed that they seem *sometimes* to be combined; at least, one of the rays from Proclus seems quite "Copernican" in character.

As to the observations required, they are good maps and accurate descriptions of the separate known systems, and a careful search for such smaller ones as may have escaped detection, and also a scrutiny of the rays referred to as coming round from the invisible hemisphere. It is to be noted, that some of the systems are by no means so conspicuous as they might otherwise be, inasmuch as they cross ground almost as bright as the rays themselves. This is the case, in part, with the Proclus system. A rather low power is best at first. It is, of course, best to observe them under a high illumination; but it is inaccurate to say, as is often said, that the rays disappear under a low one. It would be well to take note of the period of the lunar day when any given system becomes visible, and of the period when it disappears, and to extend the inquiry to individual rays of the system. The base from which each system starts ought also to be carefully studied. In the Tycho system, most, if not all, of the rays start from a bright ring inclosing a dark ring immediately encircling the crater. In that of Proclus, there is no complete concentric dark ring, but only an incomplete one on the western side. The rays here have several points of origin, from each of which issue several rays. In the Anaxagoras system there seems to be a combination of each of these ways. The rays seem in some cases mostly to lie on *one* side of the formation from which they start. Perhaps it would be more correct to say that they seem to avoid certain directions. Thus, in Proclus, the rays run S.W., W., N.W., and N., but none run E. So far as I have observed, the systems of Tycho, Proclus, Anaxagoras, Byrgius, Tobias Mayer, and Thales are "Tychonic"; those of Copernicus and Kepler, "Copernican." The connection between the rays and the lesser light-markings—the spots and the streaks—also deserves inquiry. I believe it will be discovered that the same association as has been found to exist between these latter, will be found to exist to a certain extent between the rays and some spots. Finally, I may point out that the relative brightnesses of the rays of any given system, and of their parts, ought to be watched, as they afford an excellent means of ascertaining data for the determination of the questions relating to the existence of a lunar atmosphere and an obscuring medium.

S. Maitland Baird Gemmill.

Glasgow.

A GOOD BATTERY.

[26614.]—I AM sorry that "Harry Frivoli" is disappointed at my withholding the working details of above, as asked for by "Peregrinus" and others; but he must bear in mind that such a result as I have obtained from my battery was not obtained without much work and expense, and it is only natural I should wish to be repaid for my labours. Although my battery was patented early this year, the crude idea only was claimed, which has during the past year been so much improved and altered that before I publish details other patents may be necessary to secure my rights. I must, therefore, ask all of "ours" who are interested in electrical matters to wait a little longer.

A syndicate is now being formed to undertake the commercial working, and very shortly I hope to exhibit an installation in London which will prove that this is not "another battery puff," full details of which shall be placed at our Editor's disposal as soon as possible; the scepticism created by unwarranted puffs—to use a mild term—having, I can assure you, been felt very forcibly in my efforts to obtain the necessary financial assistance. However, seeing is believing, and as that is the principle upon which I am working, I hope all sceptics will, in the end, be brought to believe in my statements, marvellous as they may appear.

Even "Nun. Dor." (61129) may believe that a battery may run for 70 hours with once charging, when I show him, as I can, a battery which shall, under his own observation, maintain a lamp for 120 hours with once charging, and which term shall be spread over 24 days of five hours per day if he likes.

Cato.

ORGAN SOUNDBOARDS.

[26615.]—YOUR correspondent, "N. H." is quite wrong in supposing that the Roosevelt soundboard requires two pressures of wind. Each motor is closed by a light spring, not by higher wind-pressure, which Roosevelt discarded twelve years ago. The altered position of the auxiliary motor or "buffer" is not peculiar to Mr. Drechsler, and answers equally well with the Roosevelt soundboard, which I prefer for several other reasons than the absence of second wind-pressure.

Denbigh. **Thomas Casson.**

STREET LIGHTING.

[26616.]—IN the last number but one of this paper a letter upon "Street Lighting" came under my notice.

I agree with the writer of the letter upon his arrangement of glass lenses. The majority of street lamps that light up our large towns at the present day are not at all perfect. Some of the older forms of lamps throw as much light upon the clouds as they do upon the ground, simply because they have no reflectors. Others of more modern date have been fitted with reflectors; but in many cases they are of little good, as they are either inclined at too steep an angle, or too flat a one. The lamps are not wide enough, and with a steep inclination of reflectors, the light, instead of being thrown down upon the ground, is just thrown on to the reflector directly opposite it, and in this case they are of little good. Again, in another form of lamp the reflectors are nearly horizontal, so that the light is thrown down at the foot of the lamp instead of being distributed over a large area of ground.

Lamps, or rather reflectors, should be either circular or octagonal, so that the light will be thrown out in every direction.

The opposite reflectors should be a good distance apart, so that, when placed at a steep angle, all the light thrown off one reflector will pass out of the lamp clear of the opposite one, and also will allow the heated gases from the flame to pass up to the top of the lamp without smoking or overheating them.

The reflectors should either be metallic or mirror reflectors—preferably mirror reflectors, as they are not liable to being injured by cleaning as metallic ones are.

A series of subdivided lenses, as the writer of the recent letter advised, are very suitable for "street lighting," and I am of opinion that, before long, a new incandescent or regenerative lamp will be invented, which will, with properly-arranged reflectors, give a light as satisfactory as the "electric" for ordinary street lighting purposes.

J. G. S.

CUTTER BAR.

[26617.]—IN reply to letter 26584 I use Mushet's steel in tool holders or cutter bars. Size of steel $\frac{7}{16}$ by $\frac{3}{16}$, which was rolled specially for my holders. It is used with edge upwards. I find it excellent for roughing and finishing wrought iron and mild steel, and for roughing cast steel, if latter is well annealed. It will not keep a fine edge for finishing, or a fine point for cutting screws in c.s., and is much inferior to a good c.s. tool for cutting any extra-hard stuff, especially if heated in grinding: I break a bit from rod and grind on an emery wheel. I should be glad to send "Evod" a bit of above size or ¼in. square to try for himself if he will advertise his address.

Glasgow. **H. O.**

VESICLES.

[26618.]—IS it asking too much of "F.R.A.S." to give the meaning he attaches to the word "vesicle" in his reply to query 61145? On consulting four dictionaries, Johnson's "Standard Edition" being one, I take the meaning to be "a small bladder inflated, or else filled with a fluid."

My reason for writing is that there is a very common idea, which I am certain "F.R.A.S." does not entertain, that the particles of condensed water which form fog, cloud, or steam (as it appears

when blown off from a boiler) are hollow bubbles or "vesicles," which, from their lightness, keep afloat in the atmosphere. This is, however, a fallacy. All vapour, from the lightest summer-evening fog that lies on the surface of meadow land to the heaviest thundercloud, consists of spheres of solid water, subject as any other body of water to the common laws of gravity, but delayed from reaching the earth's surface by their friction in the atmosphere, this effect being much augmented by the great increase of superficies from subdivision as compared with their weight.

The above does not, of course, include any theory of electrical repulsion or attraction.

Several physicists, including the younger Helmholtz, have apparently proved that visible fog or cloud cannot be formed in air perfectly free from dust, the particle of dust being necessary as a nucleus for the sphere of water.

December 18. **R. J. Lecky.**

THE STRONGEST MOTIVE.

[26619.]—I FEAR we are not likely to settle the long-standing problem of free will in the pages of the ENGLISH MECHANIC. But it appears to me that in this controversy the word "motive" is nearly always used in a wrong sense. It is spoken of as if it were a cause, whereas it is an end. In adopting a certain line of conduct towards an individual my motive is either to injure or to benefit him—that is the end to which my action is directed. So that a motive is really an end in which self-satisfaction is sought, and therefore made the goal of endeavour.

If the question be, can we act in any other way than what would be most agreeable to us at the time—in other words, in opposition to our strongest present desire? I think it must be within the experience of every one that we can and do often so act. And it is just here that the formation of character begins.

In a motive there are two elements—1st, a desire to be gratified; 2nd, a belief about it whether it be right or wrong. In adopting a desire and making it a motive or an end to be sought, a man identifies himself with it and recognises it as his own creation. He is the author in the same way of all the acts which have made him what he is. I am glad to see that Mr. Conybeare (letter 26582) upholds the same view.

18th Dec. **J. A.**

A QUESTION IN COAL ECONOMY.

[26620.]—AT a recent meeting of the Metropolitan Board of Works Mr. E. R Cook is reported to have stated that in one street in West Ham there were five or six factories which contributed £15,000 to £20,000 a year to the coal dues. Assuming these figures to refer to the consumption of coal in steam-engines, it struck me that they represented an enormous amount of power; but it may be that they are used in some other way. Nevertheless, a little consideration of what the figures imply may be instructive. According to my calculation, taking round figures, £20,000 would represent the tax on 400,000 tons of coal, and as there are six factories, that is 66,000 tons a year each. Taking 300 days as a working year, that is 220 tons a day, or 20 tons an hour, allowing 11 hours as a working day. A ton of coal ought to give through a good engine 700 horse-power for an hour, and therefore 20 tons an hour would represent 14,000 horse-power as the working power of each of these six factories for eleven hours in each day. Can any of your readers throw some light on this matter? Do West Ham Engines use 10 or 20lb. of coal per horse-power, or is the coal used in some manner less economical than a steam-engine, or what is the explanation? I know that in the Midlands where coal is cheap the waste is enormous; but surely nowadays 3lb. per I.H.P. is a fair estimate for a good steam-engine.

Nun. Dor.

RANGE OF BAROMETER.

[26621.]—THIS is a matter on which information from different latitudes is greatly needed. We know vaguely that the extreme range increases with latitude from less than 0·1in. at the Equator to fully 3·0 in Scotland (at sea-level); but does it exceed this at higher latitudes? Everywhere the mean is between 29·7 and 30, and much nearer the highest limit than the lowest. The occasions of sinking below 28, and still rarer ones of rising above 31, within living memory, might surely be given in a short table, and would all be confined, I think, to the coldest months. Our June or July range hardly ever exceeds the annual one of California, as given by "M. C. B." (letter 26583)

E. L. G.

[26622.]—M. C. B——, of San Francisco, gives 29·65 as the lowest, and 30·25 as the highest he has seen in California.

Contrast this with the records in the *Daily Telegraph*, many of which I have cut out and pasted in a book for years.

I give the following, all of which have been corrected for sea level and reduced to 32° F.:—

Year.	Month and Day.	Height of Bar.
1869	Dec. 5	30·7
"	" 11	29·5
1870	Jan. 16	30·5
"	" 19	30·65
"	" 31	29·8
"	Sept. and Oct., for nearly a month	30·5
"	Nov. 19	28·45
"	Dec. 1	30·77
1871	Nov. 30	29·0
"	Dec. 1	28·87
"	" 8	28·87
1874	" 8	28·45
"	" 11	28·6

In the *Times* of March 15, 1876, there is a letter showing fluctuations on one day 28·46 and 28·82.

Year.	Month and Day.	Height of Bar.
1876	March 12	28·8
1877	Nov. 11	28·6
"	Dec. 14	30·35
"	" 22	30·4
"	" 25	29·5
1878	Jan. 8	29·4
"	" 11	30·15

Note.—1877, October 15, there was the cyclone which had been telegraphed from America. Cleopatra's Needle nearly lost. Bar. 29·47.

Year.	Month and Day.	Height of Bar.
1879	Dec. 12	30·75
"	" 13	30·79
"	" 22	30·80
1881	" 20	28 9
"	" 23	30·5

A rise in $3\frac{1}{2}$ days of 1·6in.

The highest known in London was, I believe, Jan. 18, 1882, when some say it touched 31·0, but most agree that it was only 30·95. My own aneroid stood, on 17th, 30·86.

The last low state of the barometer of which I have a record is so recently as on evening (midnight), Dec. 8, 1886, 28·2. I do not say that this is the lowest point known; but taking my records, which, I say, are from the *Daily Telegraph*, the highest and lowest have been:

Highest	30·95
Lowest	28·2
	2·75, or $2\frac{3}{4}$in.

R. S. T.

HORIZONTAL WIND-POWER.

[26623.]—WE who are outsiders, and seekers after knowledge in science and mechanism which many of your contributors amply possess, are bound to approach with great diffidence any experimentalist who gives us the benefit of his experience, and is good enough to teach us how we may accomplish the same measure of success that he himself claims to have achieved. Thus, when Mr. P. Vallance states that he has driven seven ploughs through a stiff and heavy soil (which always required three horses to each plough) by two horizontal wind-mills of six 12ft. arms, each arm carrying a sail 12ft. high by 6ft. wide, we are bound to believe him.

We may listen with mistrustful ears to what a man is going to do; but what he really has done, and can doubtless produce plenty of witnesses to prove, he may defy the world to discredit. And, besides, what he has by his skill and ingenuity once achieved, may be done again. Such a cheap and useful engine should become very popular; but where is it to be seen? And this brings me back to my original inquiries, of which that was not the last; yet it is one to which no reference is made either by Mr. Collingridge, or by Mr. Vallance himself, in their letters to you (26597 and 26598, p. 346) of your No. for Dec. 17, purporting to be in answer to mine of the 3rd December, at p. 303.

Will Mr. Vallance permit me to call his attention to some apparent inaccuracies in the figures he has put before us, to satisfy us of the possibility of what he has set forth as the result of his experiments? In the first place, he describes the wind engine he most approves of as carrying 24 arms of 14ft. long in two tiers of 12 arms parallel to each other, between which are set 60 sails of wood, each sail being 7ft. long by 9in. wide. This would give $5\frac{1}{4}$ square feet as the extreme area of each, and there being five to each pair of arms, we have a total of $26\frac{1}{4}$ft. of working sail, or the 12 = 315ft. at the outside for all. But Mr. Vallance takes credit for 600ft., which arithmetic cannot reconcile with his basis of calculation. Again, from this 315ft. a liberal deduction must be made for a strong resistance that has to be met, on the side constantly pressing against the wind, or what may be called the return side of the engine, in action. The thick edge of the sail, or that on which it turns, is stated to be $2\frac{1}{4}$in., and five of them on each arm would offer a solid resistance per arm to the wind of 7 superfical feet, and the breeze would be so much the stronger on that side by the velocity with which they were driven against it. There are many other *impedimenta* which I need not particularise—and even on the side that was going before the wind, the sails would be liable to becalm each other, in various positions, so that the 600ft. claimed is reduced to the actual surface possible to use, of 315ft., at least one third of which will be in a perpetual struggle against the wind (in greater force). We may therefore conceive that the actual power would not be that of the clear surface of two complete arms, which would be a spread of about 50ft. In fact, lower down in his letter, Mr. Vallance seems to acknowledge this, when he says:

"The best total width of sail I found, after experiment, was about $\frac{1}{3}$rd more than the diameter of the circle described by the sails, so that the sixty sails, 9in. wide, will be 45ft., and the diameter of the circle 30ft."

In his estimate of cost, and his explanation of the materials required, one is rather staggered, in our appreciation of the good qualities of Mr. Vallance's windmill, by its cumbrousness and ponderosity. The weight of the wood alone, which he specifies, with its fixings, would not be less than two tons, not counting the shaft, and, I imagine his calculation of expenses leaves out the charge of the necessary appliances for putting it together, and the platform for afterwards attending to it. And, possibly, Mr. Vallance has taken no account of his own valuable time in superintending the construction.

The problem of a popular horizontal windmill has long puzzled the engineering community. Nor have we yet, I fear, sufficient evidence that either Mr. Vallance or his disciple—Mr. Arthur Collingridge—have resolved it. The latter seems to have reluctantly gone back to steam, and the former has not told us where his invention can be seen in operation.

London, Dec. 20th. **Raymond Browne.**

ELECTRO-THERAPEUTICS.

[26624.]—THE following extraordinary effusion appeared recently in a provincial paper, and is well calculated to raise a hearty laugh amongst those who have not made electricity a "special study," but have taken the trouble to understand the rudiments of the science. This is what the newspaper says:—

"The public of Portsmouth and vicinity are indebted to Captain Arthur Byng for placing electricity for an alleviation and cure of all kinds of nervous diseases easily, cheaply, and safely within their reach. We understand that Captain Byng has made this science a special study for some years past, and he has, after numerous experiments, fitted rooms with appliances that will enable electricity to be taken with perfect ease by any number of people at the same time. The rooms are situated at 23, Landport-terrace, and being quite close to the King's-road Tramway Junction they are easily accessible from all parts of the borough. They are comfortably furnished, and are situated on the ground floor so as to be on a level with the street and obviate the climbing of stairs. From a personal inspection we are enabled to speak of the complete success attending the various methods by which electricity is administered. There is no occasion to take off even outside wraps, and the current may be taken either sitting or standing. A number of regulators are placed in the room, which are worked with the utmost ease and accuracy by the patients themselves, so that they actually regulate the force of the current themselves and take it any strength they like. They are also enabled to instantaneously diminish the strength of the current as they wish. Captain Byng claims no new method of generating electricity, as his patent applies only to a new method of subdividing the current so as to disseminate it equally throughout a room and administer it in various strengths to individuals sitting in that room. The positive and negative poles of a large coil are placed in connection with an insulated floor and an insulated ceiling, the floor consisting of sheet metal, and the ceiling consisting of wires broken by steel points, so that anybody placed on the floor of the room by that simple act is actually between the poles, and thus becomes charged with the electric fluid. Although heavily charged our representative ascertained that he could sit, read, write, or do any of the ordinary requirements of business without the slightest inconvenience, thus renewing vitality at the expense of no bodily labour. The medical men of Portsmouth, we may assume, will not be slow to appreciate the benefits thus placed within reach of a very large proportion of their patients, at whose disposal the rooms are now placed at most reasonable charges. We understand that the electrical rooms will be worked by a company, of which Mr. J. Y. Martyr is the secretary, to whom the public should apply for all information. The rooms are to be opened from

ten till four, and patients will be charged from one shilling to five shillings, according to the treatment they receive and the length of time they remain in the electrical room." One would like to know if there is a science school in Portsmouth.

E. M. F.

VACCINATION A PREVENTIVE OF SMALL-POX.

[26625.]—A LETTER from Dr. Allinson in your issue of the 29th October last contained, amongst other matter, the following statement:—

"Vaccination does not prevent small-pox, as any-one may see who will go statistically into the subject."

Circumstances led me some years ago to make a careful inquiry into the matter, with a result exactly the opposite to that stated by Dr. Allinson.

Before replying to his letter I was desirous of obtaining the latest available returns, and finally applied to the Registrar-General for information.

This I have lately received, and, as I anticipated, it proves that vaccination is a preventive of small-pox, and would be still more so if vaccination were repeated at the age of 16 to 18; its protective power being less marked after 20.

The last year's return for London was as follows:—

Deaths from small-pox	899	
Unvaccinated	330	
of which—		
Vaccinated	218	569.
Not stated	351	

Proportion of persons vaccinated to those unvaccinated, 19 to 1. These last figures are approximate, but the Registrar-General informs me that they are substantially correct.

Now, the total number of deaths is in round numbers 900, and taking the proportion of vaccinated to unvaccinated persons as 19 to 1, on the supposition that vaccination is no protection, the deaths should be in that proportion nearly—viz., vaccinated 855, unvaccinated 45.

On comparing these numbers with those actually registered, we find the deaths of persons not vaccinated were $7\frac{1}{3}$ times more numerous than they would have been on that supposition; whilst on the other hand the deaths amongst the vaccinated (including those entered not stated) were 286 less.

Thus, making every allowance, there is undoubted proof of the protective power of vaccination.

This becomes more marked if we take the proportion of deaths under 20 years of age: the total number was 428. Taking as before the proportion of 19 to 1, the deaths should have been—

Vaccinated	407	they were	200
Unvaccinated	21		228

(including 159 doubtful with the vaccinated, which were registered at 41, thus making 200). This gives the deaths amongst the unvaccinated $10\frac{1}{2}$ times more, and amongst the vaccinated less than half what it would have been had vaccination been no protection.

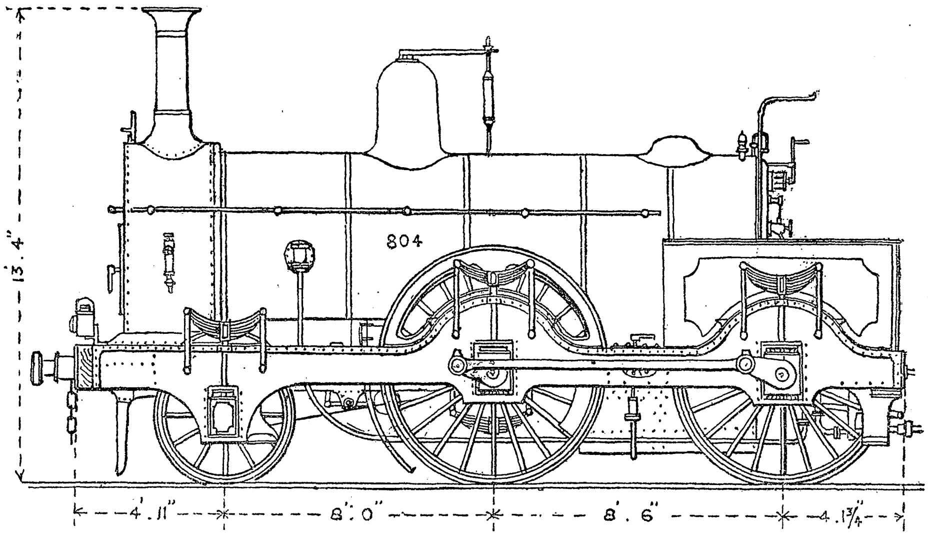
In other words, amongst the $\frac{1}{20}$ of the population not vaccinated, there were more deaths than amongst the $\frac{19}{20}$ who were. I have in all cases added to the vaccinated those deaths in which no report was made as to whether vaccinated or not; but there is no doubt that a considerable number of them should have been on the other side, which would have made the disparity more striking.

I believe Dr. Allinson must have been led into error by not taking into consideration the relative number of persons vaccinated to those unvaccinated, without which it is impossible to arrive at any correct conclusion as to the protective power of vaccination. I have seen small-pox in countries where vaccination is not practised, and the effects of it in an epidemic form are so terrible that I consider it a duty to protest most strongly against any statements which may tend to lead to vaccination being neglected.

Lavant.

MIDLAND ENGINES—800 CLASS.

[26626.]—YOUR correspondent "Midland," page 348 in this day's issue, is perfectly correct when he states that the 800 class of Midland engines, although constantly referred to, has never been illustrated in your columns, and I believe no engine of the class has ever been illustrated in any paper. The only drawing I have is one I made of No. 804 in July, 1870, when the engine was quite new and commenced to work trains from London to Leicester, the dimensions of her being taken daily during the times she was standing at the locomotive sidings at Leicester. The 800 class (800 to 829 inclusive) was designed by the late Mr. Kirtley and constructed by Neilson and Co., 1870. The engines had cylinders 17in. by 24in., and four coupled wheels 6ft. 8in. diameter, and, therefore, capable of exerting a tractive force of 86·7lb. for each pound of effective pressure per square inch in



the cylinders; distance between centres of cylinders, 2ft. 6in.; total wheel base, 16ft. 6in.

	Tons.	Cwt.	Qr.
Engine	35	18	2
Tender	24	15	2
Total	60	14	0

All the other dimensions of these engines have been given in back volumes, and it is unnecessary to repeat them. It may be pointed out that the engines are all similar in appearance, with the exception that some have a step on either side of the leading axle box. Various forms of reversing screws were fixed upon the foot-plate, and since their construction they have been rebuilt.

The 800 class, it is well known, has done excellent and very heavy work on the Midland Railway, and that is the *sole* reason why I have spoken highly of it; and I can assure "Midland" (page 348) that the fact that I knew the designer, or that 20 years ago I entered the engineering profession as a pupil, *does not in any way* influence my opinions.

Clement E. Stretton.

40, Saxe Coburg-street, Leicester, Dec. 17th.

PASSENGER TRAINS AND PARTING COUPLINGS.

[26627.]—I DO not see why an electrical contrivance should be used to warn a driver that he has lost part of his train, when a simple cord will answer as well. In the accident referred to by Mr. Rogers, p. 348, a goods train parted, and a passenger train ran into the hind portion. There does not seem to be any insuperable difficulty in running a cord from the rear brake to the engine, and in so attaching it to the latter that any strain upon it will cause the whistle to sound—an unmistakable method of calling the driver's attention. The cord would take a few minutes to arrange when the train was made up, and a minute or so to alter when waggons were dropped at stations; but it would be a safeguard, and would at least prevent a driver going on in the belief that he had all his load with him. The cord must be strong enough to exert the required pull on a lever attached to the whistle before breaking, and the expense would be merely nominal. I should like to know what objection, if any, can be urged against the adoption of so simple a device.

The accident to which Mr. Rogers refers has not been clearly reported—that is, not reported with knowledge; but I was lucky enough to catch the train that preceded the goods, and according to my reckoning it was a train fitted with only the old-fashioned hand brakes that ran into the goods. The line is on a down gradient from Farringdon; but in spite of that, I think a train fitted with even the vacuum brake could have been pulled up in time. Be that as it may, it seems to me that goods' drivers ought to be supplied with some automatic indicator, so that if the tail of their train breaks away they should know it directly. No doubt this event will be kept as quiet as possible, and we shall hear no more of it than we did of the King's-cross accident, when trains from two lines tried to run into the station at the same time.

Nun. Dor.

THE MAY ISLAND ELECTRIC LIGHT.

[26628.]—THE May Island Lighthouse, off the Firth of Forth, now throws a powerful electric beam across the waters, and some of your readers may be interested in a few particulars. The light was formally installed the other day, and we can now see the four flashes which are given in quick succession with a dark interval of 30 seconds. The May Island Lighthouse in itself is a good example of the progress made in connection with mariner's guide posts at night. Two hundred and fifty years ago an open coal fire was shown from the top of the old tower, now used as a pilot's shelter. This light, though kept up at considerable cost, was uncertain in its appearance, varying with the ever-changing character of the weather. The coal fire gave place in 1816 to reflectors and Argand lamps, fed with sperm oil, inclosed in a glazed lantern. Fifty years ago the reflectors, in their turn, were superseded by a dioptric apparatus with a central flame from a four-wick lamp. At a later date colza oil was substituted as the illuminant for the more expensive sperm, while in 1874 paraffin took the place of colza, the intensity of the flame being thereby increased by fully 10 per cent., and this, too, at about one-fifth of the cost. The power of the beam of light from the paraffin flame when operated on by the apparatus and exhibited to the mariner was equal to 9,500 candles, while that of the electric light now shown is equal to about three million candles, or fully more than three hundred times that of the intensity of the paraffin light, and can, if desired, be increased to six million candles during fog. The new dwellings and engine-house are placed in a gulley which intersects the island crosswise, at some distance from the tower. At the northern end of this gully there is a small lake which has been converted into a reservoir, the water being used for condensation purposes. In the engine-house there are two steam-engines for driving the electric machines, each of 16H.P. There are also in the engine-room two electrical machines supplied by Baron De Meritens, Paris. Only one engine and one electric machine are as a rule used at a time, the spare engine and machine being provided to guard against accident, and unless when very foggy weather occurs, it will not be necessary to use the full power of both engines and electric machines. The electric machines are "alternate current" magneto-electric machines of the largest size hitherto made, having 60 permanent horse-shoe magnets arranged round a centre in twelve sets of five each. The pulsations of electrical energy are taken off by collectors at each end of the central shaft, and conveyed to the lighthouse tower, situate at a distance of 880ft., by copper rods, 1in. diameter. These rods or conductors are placed in a groove in a low wall of cement rubble concrete, which has been built between the engine-house and the tower, and alongside of which a pathway has been formed. The engine-house and tower are also placed in communication by telephone. The conductors are led up the tower to the lamps inside the dioptric apparatus. The electric lamps are of the most improved kind, one being always in its place inside the dioptric apparatus, while another is ready, with the carbons adjusted to the correct height, to be shunted into the focus of the apparatus when required. The carbons are fully $1\frac{1}{2}$in. diameter, and have a small core of pure graphite running through the centre. These improved carbons are found to burn with great steadiness and regularity.

Dunbar. J. M'I.

UNCAUSED VOLITION — EXPRESS RUNS—DISPERSERS OF SOUNDS—LUMINIFEROUS ETHER.

[26629.]—IF a man be actuated by a motive of strength = 10 to do a certain act, and by a motive of strength = 8 to refrain from doing it, then, to my mind, it is as certain as anything can be that he will perform the act, and I cannot see how the reverse theory can for a moment be upheld. I take it as being axiomatic that if a man does an act, the motive or motives urging him to do it are of greater intensity than the motive or motives

urging him to desist. Mr. Conybeare (letter 26852, page 325) will scarcely contend that a man would or could run away from his guns while his courage and sense of duty were greater than his fear of being hit by the enemy. I quite agree with my friend that a man may remain at his post while very much afraid indeed; but in this case his fear, great though it might be, would necessarily be less than his sense of duty, dislike of being deemed cowardly, and fear of being shot for running away. A story is told of two officers going into action, one of whom was very pale and nervous. His companion remarked, "Jack, I believe you are frightened"; to which, replied Jack, "Yes, I am very frightened; and if you were half as frightened as I am you would run away." I think that what Mr. Conybeare terms the "agent's view of the environment" is really involved in the terms constitution and training. No doubt men differ enormously in the view they would take of precisely the same external environment. A set of conditions which would cause one man to take hydrocyanic acid would merely nerve another to energetic efforts to extricate himself. The problem as to what a man will do under a given environment is usually a difficult one for others to solve; but cases are by no means rare in which his action can be predicted with as much certainty as though he were a piece of mechanism, every detail of which was perfectly understood. Let us consider first a case in which approximate certainty can be attained, and then see the change which converts the approximation into exactness. A man makes a winning score at a rifle meeting in a competition for prizes in kind, and is called to choose his prize; he will generally take the article of highest value, but not invariably. He may not be a smoker, and may therefore choose an article of less intrinsic value than the cigar-case to which his score entitles him. He may choose a cup of less value than a timepiece, because he has already won a timepiece; or, on the contrary, he may take a timepiece of less value than a cup, because a timepiece is most useful. Thus we see that in a general way the action of the competitors can be predicted, but not with certainty. If, however, competition be for money prizes, then the action of each competitor may be predicted, not merely approximately, but with absolute certainty; he will take the highest prize to which he is entitled. Of course few cases in practice are as simple as even the first of these, but I give them to show that, under certain circumstances, the action of any number of men may be predicted not approximately, but certainly. All our laws, all our dealings with each other, whether in business or friendship, are based upon the theorem that a person will act in obedience to his strongest motive, and, in fact, did people really exhibit "uncaused volition"—the free will about which many persons talk so fluently—it would be well-nigh impossible for society to exist. The only places where anything like free will—i.e., utterly capricious action without assignable or discoverable motive—is to be found are lunatic asylums, and even there the capriciousness is more apparent than real, and mainly arises from our inability to follow the workings of the diseased nerve centres. An insane man not only has insane opinions, but he reasons from these insane ideas in an insane way, and hence it is often impossible to deduce from the acts of a lunatic the particular delusion to which he is subject. I assure my friend that I do not think the problem of "free will" at all simple: it is not possible except in few cases to solve the equation

$$A = \psi\ (C.T.E.);$$

but to imagine that the solution is capricious and uncertain savours of absurdity; and the idea of "uncaused volition" is forbidden alike by the views of the scientist and by the dogmas of the theologian.

In letter 26288, page 86, I asked for details of run of 10 a.m. express London to Grantham; I now wish to remind our railway correspondents that the question has not been answered.

It is well known that sound can be refracted like light. Does anything analogous to dispersion occur in the refraction of sound? No textbook mentions it; but neither does any book I have read state that it does not occur.

I hope to say a few words next week in reply to "Sigma" on the subject of the Luminiferous Ether (query 61033, p. 310).

W. John Grey, F.C.S., Analytical Chemist. Newcastle-on-Tyne.

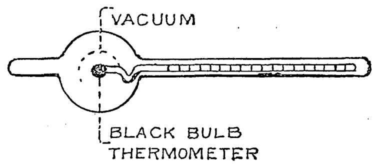
THE Carrier-Pigeon Service in Paris is now most carefully organised, and the latest census shows that there are 2,500 trained birds, which can take despatches in and out of the capital in the roughest weather. Some are taught to go to the neighbouring forts and towns, others to distant parts of the provinces.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[60514.]—**Silvertown Firing Battery (U.Q.)** —This battery was made up in two forms, square and round. In the square, the zinc was of the U shape, as in Grove's batteries, thus offering a large surface. The large carbon plate (nearly the same size as the opposing surfaces of the zinc) was fitted in a sort of canvas bag, wherein was also inclosed the carbon and manganese. The internal resistance was obviously very small, while the current, when the circuit was closed, was a "sudden and powerful rush," and immediately sank to almost nil. Is was eminently suitable for firing purposes, and that was all.—S. BRETTON.

[60815.] — **The Sun's Radiation.** — Now "B. R." has enucleated his query, and thrown more light upon the "modicum of *confined* air," as he has it, one may now see what he wants to know. I am very well acquainted with the fact that an absolute vacuum is a practical impossibility; but, speaking of the infinitesimal amount of air remaining in an exhausted tube "as the modicum of confined air" at once sets one off the track. Do you see much confinement about air attenuated to 100 times its original volume? How about the airlike freedom the aëronaut enjoys in the diminished atmosphere at an altitude of only a few thousand feet above the sea-level? Is this confinement? My critic has in his original query the following statement:—"I suppose when the sun shines for any lengthened time, the modicum of air confined in the glass containing the vacuo thermometer becomes more heated than when it shines but a short time, and so gives a higher record, &c." Well may one look at this with surprise. It is evident to the youngest of children that the more you heat a body the hotter it becomes. Confound this modicum of air that has so entangled itself in your brain! The more physically perfect the vacuum in which the blackened bulb thermometer is contained, the more perfect the instrument; in short, it is this "modicum of air" that prevents philosophical instrument makers from producing a really reliable instrument. The following cut may assist the



querist in solving the enigma that *will* present itself. When a blackened bulb thermometer is contained in an exhausted tube, as above, it is isolated from currents of air that would materially affect its registration, and, consequently, this specific arrangement gives a higher record by as much as 20° or 30° than one immersed in air under precisely the same conditions. It is the mercury in the thermometer that is expanded by the direct impact of the solar rays, and not through the agency of the minute portion of air left, which is supposed to pervade the whole of the circumambient space with equal tenuity. In answer to your query on page 287, I may state that the very name obviously indicates its purpose — *id. est*, to measure the amount of radiant heat impinging upon the earth at any noted time. Our distance from the sun, of course, varies as we journey around him, and, therefore, instruments of this description are necessary for the determination of his heating effect upon our crust. A sky may appear optically clear and unobstructed by clouds, but, when we apply the instrument to determine the amount of solar heat, we find that it records very little above the air thermometer in the shade. From this we learn the invisible, yet real, obstruction of radiant heat is due to minute particles of water held in suspension in the air. The earth absorbs heat during the day, and radiates it into space during the night. Perfectly dry air is as transparent to heat rays as a vacuum. The vapour or moisture in the air prevents the sun's rays from their terrestrial heating effect during the day, and also the radiation of absorbed heat during the night. Therefore this vaporous inclosure acts as a blanket upon the cosmical surface, maintaining it at a higher temperature than it would be if did not exist. From the above maxims gardeners profit, by covering up their tender plants that would inevitably be "nipped up" by the chilling effect of radiation during the night, although the air thermometer may be some degrees above the freezing point. "B. R." may read my previous answer without the slightest reservation.—A. TREYER EVANS, Newport, Monmouthshire.

[60866.]—**Equatorial Pedestal.**—Why does not this querist look up back volumes, and choose the mounting which he thinks will suit him best? Try Mr. Vallance's stand, illustrated in No. 1049, p. 189; and see Nos. 973, 976, 979, for some useful papers on equatorial stands generally.—THUBAN.

[60868.]—**Numbering Stamps.**—Better procure fresh ink. It seems strange, though, that while "not apparently sufficiently fluid," it should at the same time not dry quickly. These inks are usually kept in the moist condition by means of a little glycerine, and they ought not to be fluid in the usual sense, though they ought to sink into the pad.—SAML. RAY.

[60869 and 61185.]—**Twin Screw and Paddle Engine.**—Twin screws are advantageous, or supposed to be so, because they enable the vessel to be manœuvred with more celerity, and also because to obtain the driving power now required, a single propeller has to be of enormous size, with other parts in proportion. Similarly, twin screws are employed where the draught of the vessel is not sufficient to allow of the use of a single propeller large enough to transmit the full power. Then it must be remembered that in case of accident to one set of engines, the vessel is in a safer condition, and is enabled to prosecute her voyage, and, finally, the use of twin sets enables the builder to run a longitudinal bulkhead from stem to stern, by which means he obtains a great increase of strength, and presumably adds to the safety of the ship. To a certain extent these remarks apply to paddlewheel boats, as it is a great advantage to a tug, for instance, to be able to disconnect her wheels at pleasure and work them independently. This query appears again on p. 355, so the gentleman is evidently in a hurry.—NUN. DOR.

[60871.]—**Coir Yarn.**—Is this stuff bleached in practice? However, the querist can easily make a few experiments with the fumes of burning sulphur, and with suitable apparatus may be able to save the sulphurous-acid gas by absorbing it in water, which can be used for soaking the coir before submitting it to the fumes.—SAML. RAY.

[60873.]—**Business Done in the Dark.**—It has been decided that meetings of boards of guardians may be held in private, Lord Chief Justice Cockburn holding that it was the proper course to pursue when matters affecting the conduct of a particular person were being discussed. Every local board or urban authority has power to make regulations with respect to the management, &c., of their meetings, and can therefore exclude reporters. As a rule, I think reporters are admitted; but when they are excluded systematically, the electors have the remedy in their own hands by appointing as members of the local boards those persons who pledge themselves to admit reporters. —SAML. RAY.

[60874.]—**Dynamo.**—This querist may be recommended to look in back numbers—recent ones —and see in what way he can utilise his "oddments." At present his query is very much as if he said, "I have some pieces of brass tubing, how can I make them into a telescope?"—OHMI.

[60881.]—**Pitch-pine Stopping.**—I do not think there is any good and efficient stopping for pitchpine, if by "stopping" your correspondent means some transparent preparation which will prevent the exudation of the resin or turpentine. Pitch-pine is usually varnished on the wood; but if to be painted, the knots may be killed by means of patent knotting. Still, the query is very indefinite.—NUN. DOR.

[60887.]—**Enamel.**—The best thing "Pro Bono Publico" can do is to polish his tinplate reflectors. An enamel is produced by a frit, which is melted on the plate by considerable heat, more, I think, than the tin would stand; but if he must have enamel, he will find plenty of recipes in back volumes. Tin melts at something less than 450° Fahr.—NUN. DOR.

[60889.]—**A Good Battery.**—I observe that on p. 356, an impatient correspondent asks whether this query has been answered. Referring to "Cato's" letter on p. 219, it will be seen that it ends with the sentence, "I shall be happy to give any further particulars to those interested." Those particulars do not seem to have been given. Probably the battery is not yet patented, and it would be unwise to give more details.—E. M. F.

[60905.]—**Induction Coil.**—I should think that if this querist looked through the last volume, for instance, he might find some useful information about coils; or, if he refers to p. 138 (Oct. 8 last), the principal data for a coil which is practically identical with the one he wishes to construct.—THUBAN.

[60912.]—**Dividing Brasses.**—Do makers ever find the "correct angle" for dividing brasses? If so, what is it? Brasses are made in pairs or halves, that is all.—M.I.M.E.

[60914.]—**Writing Ink.**—If querist makes his ink of decoction of galls and sulphate of iron, it will not turn brown or rusty. There are plenty of recipes in back volumes. Roasting galls is practised, because it is found that it develops a little pyrogallic acid, which is very soluble in water, and strikes an intense bluish-black with the iron salt at once.—NUN. DOR.

[60915.]—**Tannin.**—In Slater's "Manual of Colours and Dye Wares," published by Lockwood, "O. J. K." will find a method of ascertaining the percentage of tannin under the head "Divi-Divi."—F. C. S.

[60916.]—**Daniell's Battery.**—It depends on the resistance of the lamps; but you would probably require at least a dozen such batteries.—E. M. F.

[60936.]—**Oxygen.** — What does "Holland" mean by "when the light is removed"? And, again, when he says "the gas is turned lower, and immediately stops when the light is taken away?" Does light mean heat.—R. S. T.

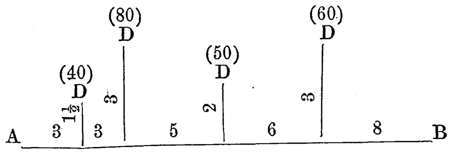
[60975.]—**Paraffin Oil or Coal-Gas.**—Replying to "Jimbo," the first part of the query is, no doubt, answered by the particulars received from the "Patent Paraffin Gas Lighting Company." Personally, I am not acquainted with the system of manufacture patented by this company; but the idea has been tried in different forms over and over again. The manufacture of oil-gas is very simple, and the apparatus could be put together by any handy fitter; there is also very little skill required to keep the apparatus going. It is necessary, however, to free the gas from carbonic acid by passing it through a lime purifier. Crude paraffin, which is obtained from bituminous shale at a low heat, can be made into a good gas; but it is not so permanent as coal-gas, and this is very noticeable where it has to be stored or passed through long lengths of pipe. Taking 6d. per gallon as a fair value for the raw material, it has been found that the gas costs 5s. 8d. per 1,000ft.; for 25-candle gas, fuel, attendance, interest on capital, &c., would be about 10d., making 6s. 6d. per 1,000ft. Mid-vein shale, holding about 11 per cent. of hydrocarbon, yields 9,000ft. per ton of 20 to 30 candle-gas. Oil-gas in its different forms has been made, I believe, for some years in America, on account of petroleum being so cheap and coal-gas the reverse, and the naphtha (a lighter distillate than paraffin) is preferred for gas making. Reckoning the cost of the raw material there at 3d. per gallon, it was found that one gallon of the ordinary commercial naphtha would produce 80ft. of 70-candle gas. The cost of manufacture was about 4s. 10d. per 1,000ft., which allows for fuel and renewal of retorts; but not for labour and interest on capital. In using this oil-gas, however, considerable trouble was experienced after a time with the meters; it was also found that carbon accumulated very quickly in the retorts, thus causing a waste of material. Less trouble, no doubt, would arise with consumers in introducing oil-gas where coal-gas had not been previously used; no residuals result from the manufacture. Special circumstances, such as a long distance from a railway station, may warrant the making of oil-gas, on account of price, &c.; but the pros and cons must be weighed very carefully, and judged entirely by local considerations before undertaking either one system or the other.—F. M. E.

[60982.]—**Chronic Inflammation of Nostrils.**—I have just read through the answers to "Misery" on his query. I may thus sum them up: "Ponto" sends a homœopathic remedy, which mode of treatment is only mild allopathy. "B.Sc., Plymouth," recommends a nasal douche as a palliative, and iodoform snuff. "R. E. F." advises a sulphate of zinc douche, and to improve health by drugs. (Curious advice this—improve health by means of poisons, which the system cannot use as food.) "A. E. O." says that zinc ointment will cure. Then he wants to know if piercing the ears will prevent respiratory diseases, as he believes it does the eyes good. This boring of the ears to improve the eyesight is a piece of humbug that wants to be ousted from the brains of all intelligent persons; it must have originally been invented by some jeweller to increase his trade as an ear-piercer. "Doctor Medicinæ" shoots at him a whole chest full of lotions, each guaranteed to cure (until it fails). To this external warfare he adds internal treatment with arsenic, and other equally poisonous drugs. If "Misery" does not get worse under this treatment, especially if he takes that damnable drug (excuse the strength of expression, but I mean it), he will surprise me. "Cured and Thankful" swears by a cold bath and injection of eucalyptus oil. A. Dunlop Stewart, M.B., says this complaint is due to inhaling cold air while the body was warm. (Pray, doctor, is the body ever colder than 98° Fahr. in health?) He says other lotions are bad; but recommends one of his own, and says nothing will cure if cold baths are used. Any sensible reader of the "E. M.," after reading these answers over, must pinch himself hard to know if he is dreaming or not, for the advice varies in every case—no two alike. The reason of this variety is because none of the writers (please include those qualified by law and nothing else) have a proper idea of disease and its origin. All disease comes from disobedience of hygienic laws; whilst the form and locality depend on the patient's habits and personal constitution. "Misery" is living wrongly and breathing bad air; very possibly gas-laden air. The wrong living causes retention of waste in the system, whilst the irritating bad air is the exciting cause of the local inflammation. Now, "Misery," observe these rules: To be well, you must learn to live hygienically; you must take no intoxicants, as ale, wine, or spirits, as they waste vital power and produce disease. In the same way, you must not use tobacco in any form. Have three meals a day, five hours apart, eat your food slowly, chew it well, and stop at the first feeling of satisfaction. Eat brown bread always instead of white. Do not drink above one large cup of fluid at a meal; cocoa is less harmful than tea or coffee. When tea or coffee are taken they should be weak. All fluids and foods must be drunk only lukewarm, and not hot. At breakfast have a cup of cocoa, brown bread and butter, an egg, or stewed fruit; or porridge and milk eaten with brown bread. At dinner, about 4oz. lean beef, mutton, poultry, or fish, two vegetables always, afterwards a milk pudding, a fruit pie, or fresh fruit. At tea take a cup of cocoa or weak tea, brown bread and butter, some stewed fruit, or some green stuff, as boiled Spanish onion, boiled celery, or salad; a little jam or plain cake may be eaten. Exercise regularly two hours a day, or walk from six to eight miles. Breathe pure air always, and have bed-room window open two inches all year round. Have a tepid sponge down daily and a fortnightly hot bath, or a weekly warm bath alone. Live as I direct, and you will enjoy better health than you have done for years. No medicine or drugs required. If you want to know how Nature cures disease, and how the doctors interfere with her, read my leading articles in the medical column of the *Weekly Times* and *Echo* for Dec. 11th and 18th. They can be got for two stamps each from the office of the "E. M.," 332, Strand, W.C. They will repay perusal.—T. R. ALLINSON, L.R.C.P., Author of "A System of Hygienic Medicine," &c.

[60983.]—**Chloride Battery.**—The modified form of bichromate known under the above name not being suited to the querist's wants, I beg to give him particulars of a form of Leclanché that will probably serve his purpose. An engraving of it is to be found in Vol. VII. of the *Electrician*, page 235, or if he would like to procure the number from the office, its date is August 27th, 1881. The name of the cell is Howell's Patent Manganese, made by L. Clark, Muirhead, and Co. It consists of an outer jar A, perforated stoneware jar B, and porous cell C. Put porous cell inside B. In the space between A and B the usual carbon, with a mixture of crushed carbon and dioxide of manganese, with manganese sulphate (the white manganese of commerce) added. The zinc rod is put in C, with some mercury at the bottom to keep it amalgamated. Inside B (that is, the space between the outside of porous cell) sulphuric acid is placed, 1 to 4 of water. In the porous cell containing the zinc a solution of sulphate of ammonia, 25 grammes to 1 litre of water. Its E.M.F. is 2·14 volts, with an internal resistance of 5 to 6 ohms. I should be glad of the opinion of Messrs. Sprague and Bottone concerning this cell, especially as to its constancy. I am told a great many of them are used.—ASSOC. SOC. OF TEL. ENGS.

[61033.]—**Preparation for Mixing Bronze Powders.**—When I have wanted to mix some Bessemer gold or bronze paint and have been out of the special varnish, I have used copal which has been treated to a dose of quicklime in small pieces and thinned severely with turpentine. Shake well and allow to settle. I have been told that this is the special varnish sold for the purpose; but be that as it may, it answers perfectly.—NUN. DOR.

[61048.]—**Electric Conductors.**—I am much obliged to Mr. Edward Conry for his long reply to this query, and shall be much pleased to hear from him on the subject (in Address Column). At the same time I think it may be useful to many readers of the "E.M." if we continue to discuss this question, which has reference to a real project for applying water-power to the working of a railway by means of electricity. Mr. Conry has reversed my question, or at least the question I intended to put, and asks the weight of train I wish to run, its resistance, &c.; whereas this is just what I wish to arrive at through him and such others who may kindly assist me. I have certain power at my disposal for turning dynamos which are in certain relative positions and distances from the line upon which I wish to run trains, and I think I gave sufficient information, except that I did not say at what points in the line the various branch cables would deliver their currents. If the Editor will kindly insert the synoptical sketch below, I think the position will be made clear. The figures are somewhat different to those given at first, as I have since received more favourable information, and find 230H.P. instead of 170. The sketch is in plan. The plain figures indicate the distances in



miles, and those in brackets the H.P. of the respective four turbines at D; A, B the main conductor 25 miles long. As the maximum and almost ruling gradient of the 25 miles of line would be 1 in 20, I consider stored electricity, as suggested by Mr. Conry, impracticable because of the power required to take the weight up such an incline, and have in my mind a conductor or a pair of conductors in the middle of the road, unless the two rails themselves could be made to serve as conductors; but I shall be pleased with any better idea. Now, what I wish to know is the best means of applying this power, leaving the question of "ampères and volts" to those kind enough to reply, preferring that the tension should not be so high as to endanger the lives of workmen on the line. What loss of power will there be between the dynamos D—which would all be suited to work together—and the motors of the train or car (for we shall not be able to take up a heavy train)? Or (1) What available H.P. can I reckon upon all along the line? (2) What should be the size and shape of the various conductors? (3) What tension is recommended at the dynamos, and what would be available at the main conductor for the motors? I can then work out the weight and speed of the trains which could be run upon it. Any suggestions about using the motors reversed as dynamos (as they naturally would be if left attached) during the descent to be used as brakes, and to help in generating electricity, and so helping an "up" train. In all cases should the idea be carried out, good plant would be adopted; but as there appears to be a good supply of water power, a good margin may be taken for resistance where that would considerably reduce the cost.—ACIER.

[61060.]—**Gut v. Leather Belts.**—Don't use gut at all, use either soft line or twisted leather. The 1in. flat belt will not be as effective as a round one, if the pulley is less than 8in. diameter, except at quick speeds. You had better make your own hooks and eyes, as those sold in shops have either hardly any thread at all or else a very sharp one. The thread should be deep with the tops well rounded off to prevent cutting the band. Hooks and eyes made thus will resist a strain of about 60lb., provided, of course, they have not been burnt in hardening. If a strand in the band breaks, get a new band at once. Some mechanists I know are so devoted to an old band as to add new pieces every time it breaks. I have seen bands in use on the heaviest 200mm. foot lathes with no less than four sets of hooks and eyes.—A. F. SHAKESPEAR, Lüttichaustr., 14, III., Dresden.

[61069.]—**Telegraph Wires.**—The metal flaps about which Mr. Thurlow inquires are intended to preserve the grouse. It is found that all birds are apt to kill themselves or lose their wings by flying against the wires, and where there are many grouse the loss is sufficient to cause complaint. They do not seem to see the wires, but it appears that they can see the flaps; at all events, the method of hanging them on the wires answers very well. Some people imagine the birds are killed by electricity; but this is entirely a mistake—it is practically impossible.—R. S. CULLEY.

[61070.]—**Lathe.**—I understand the principle of the reversing motion well enough. What I want to know is how the rocking-plate is in fixed gear and out of gear, also what it rocks on? I may add that the lathes I have seen here have the rocking-plate swinging on the tail of mandrel or on the cross-piece; while on a lathe upwards of 30 years old there is a bungling contrivance of a slide, a slotted plate, and a weight.—A. F. SHAKESPEAR, Dresden, Lüttichaustr. 14 iii.

[61071.]—**Planing-Machine Tools.** — I had already, before writing query, tried turning the tool-box about in every direction, but all to no purpose. My slewing-plate turns 45° from the perpendicular. The plate is not pivoted at the end, but near the centre; will this affect it?—A. F. SHAKESPEAR, Dresden, Lüttichaustr. 14 iii.

[61090.]—**A Rule of Grammar.**—"Weald" is wrong in his German grammar. "Es est mich" would be both awkward construction and bad grammar. The reply to "Wer ist da?" would be "Ich bin es," or, quite short, "ich." "Mich" could not be used in any case. There appears to be a certain amount of elision in the phrase "It is I." "Who is there?" "I am there," "It is I

who am there." You could not say, "Me is there."—P.

[61081.]—**Number of L. and N.W. and G.W. Engines.**—The following, from Dorsey on "English and American Railroads" (1883), may be of interest:—

Name of Railway.	Total No. of Locomotives.	Average earnings of each Loco. in 1 year.	Miles in Work.
L. and N.W.	2,451	£4,228	1,793
Midland	1,629	4,520	1,381
G.W.R.	1,577	4,957	2,268
N. Y., Lake Erie, and Western	785	5,615	—
Boston and Albany	244	6,643	—

—SPECTATOR.

[61084.]—**Fireclay.**—"H. B." gives the following as analysis of two fireclays:—

	No. 1.		No. 2.	
Silica	98·0	per cent.	50·0	per cent.
Alumina	0·72	"	32·6	"
Iron	·18	"	3·5	"
Potash	·14	"	2·3	"

I always thought clay was a silicate of alumina, and No. 1 is as much silicate of alumina as a plum-pudding without the plums. Again, I do not see plasticity or power of cohesion in No. 1. Is No. 1 really correct? And for what is it used, and where? If it will hold together, will it not easily fuse? If I am wrong, please set me right, and, if you please, set me down as well.—R. S. T.

[61091.]—**Phosphorescent Insect.**—I do not think that "W. E. D.'s" insect is a glow-worm, which latter is an insect of the Coleoptera family, Malacodermata, though "Gamma Sigma" says it is not an insect; but "W. E. D." has found a phosphorescent arthropod, a centipede (commonly called). I have found them rather rare; but when found in a place they are found in considerable numbers—i.e., are very localised in their habitat. I believe that they differ from other phosphorescent creatures in that the light shows along their whole length, and specially at their joints, and not only from the cells composing the lower ventral layer of the abdominal segments, as in the glow-"worm." These luminous centipedes also leave a trail of phosphorescent fluid for a short distance behind them, the oxidation of the phosphorus (?) is, however, soon accomplished. I remember collecting about 500 of these centipedes in the gardens of Morden College, at Blackheath, during the late autumn in 1870.—GERARD SMITH, Upper Clapton.

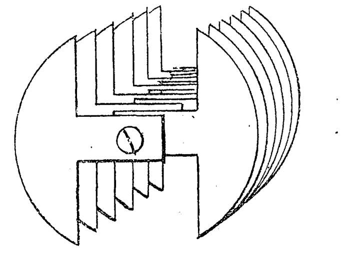
[61092.]—**Hot-Air Motor.**—TO MR. SEAL.—I should very much like to have drawings to scale of ¼ man-power, or of 1 or 2 man-power, which would be better still, if you will kindly send them. —G. M. S.

[61099.]—**A Rule in Grammar.**—It seems to me that both sides are, to a certain extent, right. Nouns not being inflected in English, the case depends upon their position, the first being the nominative and the second the accusative. "The man struck the woman" is one thing; "the woman struck the man" is just the reverse. In Latin this is not so; you may arrange the words in any order you like, the sense will remain the same. So, even in English, with pronouns—"he struck her," "her he struck," "he her struck" all mean the same; if you want to reverse it you must say, "she struck him." In Dean Alford's example the sentence is not fully completed. "If you see, &c., that [man] will be me," is correct; or you may put it, "I shall be that man." In the original query, I or me would depend on the full answer. "Who is there? Who did it?" "It is I who am there. It was I who did it," shortened colloquially into "It is I." A reply bringing "me" in would be so ponderous that it would not be ordinarily used, and so custom takes the simplest form for granted, and says "It is I."—P.

[61101.]—**Stars visible from Well.**—I am quite unable to conjecture how 8½° of latitude may appear when "viewed from the stars" [*sic*]. "E. D." does not seem to be *very* clear about it himself, and I would recommend him to read the other answers in the same number (1134).—R. E. F.

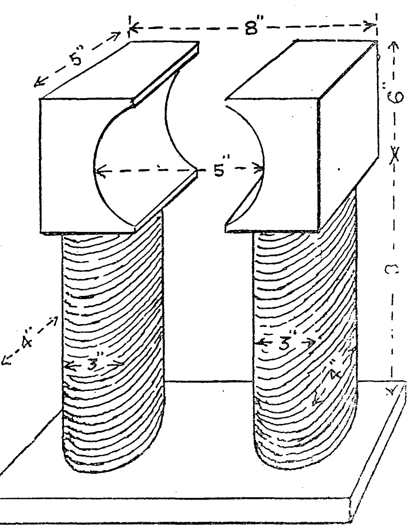
[61101.]—**Stars Visible from Bottom of Well.**—I think "E. D." must have misunderstood the letter of "R. E. F." on this subject. As a matter of fact, according to Sir John Herschel's statement in his "Outlines," that only those stars are visible which *pass* the zenith, γ Draconis would be about the only star likely to be seen in the latitude of London; and as regards the remainder of "E. D.'s" contention, 8½° variation in latitude would (on the same principle) include several bright stars in Ursa Major, Cassiopeia, &c., with a Northern Declination corresponding to a given intermediate latitude. But, on the other hand, Arago, in his "Popular Astronomy," says (if I remember rightly) that any star whose distance from the zenith is less than 50° should be visible in the supposed position. This extreme seems to me to amount almost to an absurdity; but with two such eminent authorities as Herschel and Arago at variance, I do not see how the matter is to be solved. Perhaps "F.R.A.S.," or some other talented correspondent, would favour us with their estimates of the radius in degrees of such a circle as Arago supposes to be visible.—B. A., Handsworth.

[61114.]—**Dynamo.**—TO MR. BOTTONE.—The slight difference in size will not make much difference in power, provided the iron be nice and soft. In the laminated armatures I send out, made from punchings of sheet iron, the shape of half a section of an ordinary H armature, the laminæ are laid as in the annexed sketch—viz., one to the right and



one to the left of the spindle—until the spindle is full up. By this means the laminæ are closely clamped together at their centres, but have air spaces at their extremities.—S. BOTTONE.

[61119.]—**100-Candle Dynamo.**—TO S. BOTTONE.—Herewith you will find sketch, with



dimensions, for Edison-Pacinotti dynamo, which is the best form; have the yoke below as a base plate, and pole pieces upwards. If wound as a series machine, put about 4lb. of No. 18 on the armature, and 8lb. of No. 16 on the fields. You will easily get 100c.p.—S. BOTTONE.

[61122.]—**Magic-Lantern Slides for Boy's Lantern.**—Gelatine films, 3¼in. square, are sold (see Sixpenny Sale Column) for tracing magic-lantern slides. Lay the gelatine film over the engraving to be copied, with a piece of thin tracing paper, or transparent oiled tissue paper between, and trace with Indian ink, using a fine-pointed pen. When finished, mount between glass slips or squares, as the tracing makes the surface rather uneven and wrinkled. In back numbers of "Ours" there are full directions by "Sable" for both outlining and painting slides, which have been reprinted and published by Mr. W. C. Hughes, who advertises in this paper. "Sable" recommends, for plain outlining, lampblack in oil mixed with mastic varnish and turpentine, using a very fine sable-hair brush. If "M." has not got this book, the outlay of 1s. over it will repay him in the information gained.—ARINAS.

[61127.]—**Force Pump.**—Such a pump as is used in connection with an air-gun seems what you want. It is an iron tube about $\frac{11}{16}$ diameter, 14in. long, having a smooth bore and a well-fitted iron piston about 2in. long, with a piston-rod, which by means of a cross-piece is held by the feet while the receiver is worked up and down by hand. Air is admitted by a hole in the tube when receiver is up, and at opposite end of stroke it is forced through a hole about $\frac{3}{32}$ at upper end of pump. For simplicity, make your tube of mandrel-drawn brass tube, and the plug of lead, tin, or type-metal cast in tube and on to piston-rod; smoke inside of tube before casting, and in any case use plenty of oil in working pump. To get greater power lengthen tube and decrease its diameter.—H. O., Glasgow.

[61136.]—**Screw-Cutting.**—The correspondent has not understood the rule of "J. H.," which applies to a leading screw of any pitch. For example, a thread of 2¾ to the inch would be in fractional form $\frac{4}{11}$, and the nut would gear properly every 4in. The matter may be grasped by him if he will divide his required pitch by that of his leading screw; if it will divide by 4 his nut will gear at any thread of leading screw. If double the number, will so divide at every second thread; if four times the number at every fourth, and so on.—H. O., Glasgow.

[61136.]—**Screw-Cutting.**—For external work run saddle back against back poppet, or stop, if you prefer it; then take distance to where thread is to terminate, and you will find if 1⅝in., and you are anyway smart, you will drop nut in right, unless you are running lathe too quick; 1⅝in. gives more time, and the same by longer distances. Internal work: Run tool in as far as it is to go, and mark it at face of work. Now run tool back with saddle until it is just clear about ¼in.; then take distance from face of work to mark on tool, if 1⅝in., 2⅝in., or 3⅝in., you can scarcely go wrong by keeping lathe in motion, provided you run back poppet up to a stop against saddle as before—a bit of wood I use; and with a little practice this is all that you need mark, provided you occupy the same time in running saddle back every time, because you can scarcely do that in the time occupied in leading screw revolving ⅛in.; therefore, you could not drop nut in at ⅝in. in cutting screw. It is in only exceptional cases that I mark anything else.—ONE OUT OF WORK.

[61139.]—**Chromic Acid v. Bichromate.**—On title page of "E. M." an advertisement states chromic acid is 20 times as strong as bichromate solution. What I want to get at is, is this borne out by the experience of any of your subscribers? What will a given weight of chromic and sulphuric acids do? What are the best proportions to use? Mr. Bottone says chromic acid 1, water 2, sulphuric acid half by weight. Now, at this rate I am able to compare: bichromate solution saturated 14 pints costs 2s. 1½d., and does for a certain purpose 30 hours' work. Chromic acid solution, 14 pints, would cost 5s. 1¼d., and so, price for price, it should do same work for about 70 hours, and if it is 20 times as strong as bichromate, then 20 by 70 equals 1,400 hours of work. Of course, I know all advertisements are to be taken with a grain of salt; but does the experience of any of your readers come anywhere near this—say, half, or a quarter the time?—W. W. N.

[61140.]—**Stains on Marble.**—I think that if the stains are not marks in the marble itself, the following will remove them:—Two parts of soda, one of powdered chalk, and one of pumice stone; sift through a fine sieve, and mix into a paste with water. Rub this well on, and wash off with softsoap, and then polish with a soft cloth.—BROSCENICUS.

[61141.]—**Screw-Cutting.**—If "Chaser" knows how to cut the threads he describes with single train, why run double one? However, if 20 and 80 will cut two threads, 20—80—40—80 will cut 12 threads; consequently $\frac{20—80}{50—80}$ will cut 13 threads, and $\frac{20—80}{70—80}$ will cut 15 threads.—ONE OUT OF WORK.

[61141.]—**Screw-Cutting.**—Pursue usual rule for single train, viz., mandrel wheel = threads per inch of leading-screw × say 10; screw-wheel = required pitch × say 10. For $\frac{1}{19}$in. pitch you would have mandrel 20, screw 190, which last you would split into 95 × 2, making your train $\left\{\begin{matrix} 20 & 30 \text{ drivers} \\ 60 & 95 \text{ driven} \end{matrix}\right\}$. For the 60 and 30 you may substitute any wheels of same ratio; but you cannot dispense with 95 and 20. I find simplest form of calculation to be—say, for $\frac{1}{13}$in. pitch, 13 ÷ pitch of lead screw (2) = 3¼ × 2:—Train: $\left\{\begin{matrix} 20 & 40 \text{ drivers} \\ 65 & 80 \text{ driven} \end{matrix}\right\}$; the first pair represent 3¼, the second pair represent 2. The position of drivers is of no consequence.—H. O., Glasgow.

[61143.]—**Launch Engine.**—The cut-off is usually spoken of as at the portion of stroke of engine, which is a simple way of expressing it for that cylinder; but it is in reality the proportion of

its capacity at which steam is cut off. So, if you increase length of cylinder, but cut off at same length of travel of piston, it is clear that is a less proportion of the cylinder's capacity, and consequently a greater amount of expansion takes place, with a consequent saving of fuel in proportion to power. In the cases given, expansion with 5in. stroke is 1·5 time, and with 6in. would be 1·8. The effect of the proposed alteration would be an addition to present power of about $\frac{1}{8}$th for same amount of steam. This is due to increased piston speed = + $\frac{1}{5}$ decreased by average reduced pressure on piston = probably − $\frac{1}{13}$. Power is in proportion to area × speed × average pressure.—T. C., Bristol.

[61143.]—**Launch Engine.**—By increasing the stroke from 5in. to 6in. you would gain in power about a $\frac{1}{4}$H.P. You must bear in mind that you would use more steam by increasing the stroke; in your case, $\frac{2}{3}$ of 5 = 3·3 distance travelled by piston before steam is cut off. Now, by increasing the stroke to 6in. you have $\frac{2}{3}$ of 6 = 4, the distance travelled by piston before steam is cut off, consequently you will use $9\frac{3}{4}$ cubic inches of steam more every revolution. Instead of lengthening the stroke, and if your cylinder will allow it, why not bore it out to $3\frac{3}{16}$in.? It will be much cheaper, more economical, and will develop the same power as the extra inch in the stroke;—all that you will require will be a new piston. To prove that by enlarging the cylinder's diameter less steam is used, we will take the 3in. by 6in., point of cut-off 4in., area of cylinder 7in., then 4 × 7 × 2 = 56 cubic inches per revolution, and 56 × 300 × 60 = 1,008,000 cubic inches per hour, which divided by 1728 = 577 cubic feet used per hour. Now, take the cylinder as $3\frac{3}{16}$in. diameter × 5in. stroke—area = 7·9; point of cut-off in this case will be 3·3. Then 3·3 × 7·9 = 26·07 × 2 = 52·14 × 300 × 60 = 938520; this divided by 1728 = 543 cubic feet per hour, so that enlarging the cylinder $\frac{3}{16}$in. you have the same power as you would have by increasing the stroke 1in., and at the same time you save 34 cubic feet of steam per hour.—ENGINEERING, MANCHESTER.

[61145.]—**Does it Boil?**—Boiling, or ebullition, means the rapid evolution of bubbles of vaporised liquid accompanied by movement of the mass of the liquid and a characteristic noise. The true physical definition of ebullition or boiling is this. "A liquid is in ebullition when it gives off vapour of the same tension as the atmosphere above it." Hence the temperature at which boiling takes place will vary with the atmospheric pressure. Water, for instance, boils at 100° Cent. or 212° Fahr. at an external pressure of 760mills. But under the receiver of an air-pump, water may be made to boil at any temperature between 0° and 100°. As to the production of vapour or steam, that occurs over a very wide range of temperature. Ice and snow are continually giving off vapour, even at temperatures below 0° Cent. This vapour or steam, however, is not visible unless it meets with colder air, when it instantly condenses to form the so-called "steam" as seen coming out of the spouts of our kitchen kettles. This is the explanation of the visible steam over the teacup. The steam given off by the hot water meets with the colder atmosphere, when it instantly becomes condensed into vesicles of water, and hence visible. The same reasoning explains the steaming of a fence on a sunny winter's day.—S. BOTTONE.

[61145.]—**Does it Boil?**—I put my query (p. 333), which was quite bonâ-fide, with a presumed belief that water sometimes became invisible and aëriform by a process other than boiling, and essentially distinct from boiling, and I desired to know what was the scientific account of this process. I appealed to common teaching in favour of the statement that water, when raised to the boiling-point (*pro re*), acquired a special capacity for becoming aëriform which it was considered not to possess below that temperature. The examination student, or the professor who gives him marks, may feel that the matter is entirely elucidated by saying that one case is "ebullition" and the other "vaporisation"; but, to my own mind, two grand scientific names no more constitute an explanation than two dishes make a pie. I inquire of myself, and of others, What is the nature of "vaporisation," if it is so to be called, and what is the essential distinction between this and ebullition, owing to which vaporisation takes place at all kinds of temperatures, whilst ebullition cannot begin until a certain temperature (according to pressure) has been obtained? I know that when a pool abates its level, the case is one of solution of water in air. Just as a lump of sugar dissolves at the bottom of a cup of tea, so a lump of water dissolves at the bottom of the atmosphere. Now, I want to find the courage, and have nearly found it, to tell myself that when the kettle is in that condition at which the expectant tea-maker asks, "Does it boil?" the case is still one of solution of a liquid in a gas, and that a cup of steaming-hot water has more affinity with the secretly evaporating pool, in regard to its physical condition and mode of forming vapour, than with the truly boiling kettle. My query, as it stood, has been so universally misunderstood, that the fault must lie in the querist who framed it. Nevertheless, I am eager to thank my two instructors, "Nun. Dor." and Mr. E. Conry, and would add some acknowledgment to the "F.R.A.S.' for giving attention to the case.—WEALD.

[61148.]—**Screw-Cutting.**—Twentieth part of 3in. at the fifth of a rev., 20—100—40, or $\frac{3}{4}$in. pitch. Twentieth part of 3in. at the fourth of a rev., 60 and 100 drivers, and 80 and 40 driven.—ONE OUT OF WORK.

[61148.]—**Screw-Cutting.**—Pitch of screws required: $\frac{1}{20}$ of 3in. = $\frac{3}{20}$in. which × by 5 = $\frac{15}{20}$ or $\frac{3}{4}$in. or $1\frac{1}{3}$ thread per inch, and $\frac{1}{20}$ of 3in. = $\frac{3}{20}$in. which × 4 = $\frac{12}{20}$ or $\frac{3}{5}$, or $1\frac{2}{3}$ threads per inch. See reply 61141 for rule, or take $\frac{1}{4}$in. and $\frac{1}{5}$in. pitches from your index plate, and drive your screw in each case three times as fast. Train for first: Mandrel 40, driving by means of two idle stud wheels 30 on same stud as which is 90 driving 40 on screw. Train for second the same, except screw wheel, which is 50; alter to suit size of lathe if required. Above is for $\frac{1}{4}$in, pitch lead screw.—H. O., Glasgow.

[61151.]—**Liquid Fuel.**—If "K. N. S." is near London, he can see the liquid fuel furnace at work, just as it has been for several years, at Hackney Wick; but he should refer to back volumes for illustrations. The creasote is usually supplied to the nozzle by gravity, being forced up a pipe by its own weight. Just as it reaches the top it is blown into spray by a powerful jet of steam and driven into the furnace as a sheet of flame. Probably some readers can give you actual dimensions to suit; but, although creasote, or the dead oil known generically by that name, has been used for years, the accounts we have heard lately about the economy of liquid fuel require to be taken with a considerable grain of salt. A lining of firebricks is not necessary, though it may be an advantage to some conditions. See the description of the Shipman steam-engine with petroleum furnace on p. 419, Vol. XLII.—SAML. RAY.

[61157.]—**Liquid Fuel.**—The good form of spray producer would be a short funnel shaped passage leading into the firebox high enough up to inject all over the bars, the shape being rectangular, corresponding with that of the firebox, and the slant of the sides sufficient for the sides if produced to describe a rectangle rather larger than that of the firebox. Towards the narrow end should be fixed the spray-producers. There are various forms; but several strong grids of metal-work with the openings not coinciding, and placed pretty close together, are a cheap and good form. Several thicknesses of strong galvanised wire netting placed one behind the other answers well for a time; but the zinc wears off the iron with the rush of the steam, so the layers should be made easily replaceable. I should suggest arranging the funnel to be removable, with a movable connection to a permanent steam nozzle, or else have a sliding shutter to close the end of it. The length of the funnel may be 3ft., and diameter at smallest end 1in. The oil-drip should not be less than 12in. from the steam jet. The firebox should be covered with asbestos knots, or pieces of broken firebrick (cinders soon pulverise) as closely as possible without absolutely choking up the air draft. A very little space will do for this latter, as the oil spray acts as a powerful steam-blast. Use as little steam at as high a pressure, and as dry, as possible.—EDWARD CONRY.

[61162.]—**Sewing Machine (Wheeler and Wilson).**—"Pestered Man" does not say a word about the top tension. If he will make this tighter, the machine will perhaps cease to pester him. The lifting of feed-bar has nothing to do with the top thread, and is only that the teeth can grasp the work before moving it forward another stitch. The thickness and stiffness of the work has more to do with the fault, and this hook should have a stout needle, large stitch, and sufficient tension to draw up the loop or work if white soaped, and the arm should be properly timed with the rotary hook. If not cured as above, ask again.—J. I. S.

[61166.]—**Engine for Boat.**—"Novice" is expecting rather too much from a boat 36ft. by 6ft., for it would take about 62H.P. to drive it at 12 miles = 10·4 knots per hour, and unless he is prepared to put in loco. boiler, forced draught, with closed stokehole and special engines, similar to those in a torpedo boat, the weight of engines, &c., would just about sink her, leaving nothing for fuel or passengers. About seven knots, say, eight miles per hour, is an outside speed for such a boat; even then she will have to be much stronger than he indicates by his weight.—GFYUNG.

[61166.]—**Engine for Boat.**—I have assumed your boat to have an immersed midship area of 6sq. ft., and to drive the boat 12 knots an hour it will require an engine of at least 15h.p. Taking your boiler pressure at 80lb., a compound engine to develop this power must have h.p. cylinder $6\frac{1}{2}$in. diam.; l.p. 11in. diam., with a stroke of 6in. For boiler I would suggest the marine return-tube type, 3ft. 6in. diam. by 5ft. 6in. long; firegrate area not less than $3\frac{1}{2}$sq. ft.; and total heating surface, 45sq. ft. This type of boiler would cost about £80. A vertical boiler would be cheaper, costing about £45 to £50.—ENGINEERING MANCHESTER.

[61169.]—**Safety Couplings.**—The hook-pole coupler has been in use for some years on several railways, and consists of a stick or pole with a hook at the end for lifting the shackle on to the waggon hook. No safety coupling has been adopted, nor, so far as I can see, is likely to be. I am afraid your correspondent has been misled by the newspapers.—NUN. DOR.

[61173.]—**Varnishing Fishing Rods.**—"Brown hard" spirit varnish, as used by French polishers, procurable at any oilshop, applied with soft camel hair brush in a warm room, will do the trick. It would be well to "paper down" the rods first with, say, No. 1 glasspaper.—S. BRETTON.

[61173.]—**Varnishing Fishing Rods.**—I do not think the querist will do much good with a shellac varnish, even if it is made with rectified spirit. (N.B.—Rectified spirit is out of place in making a varnish when methylated alcohol answers the same purpose.) I think it would be better to use stoving copal, and "stove" the joints of the rod; but possibly the best amber varnish, put on in a suitable temperature, would answer as well; or if shellac is used it should be just as French polish is put on. I think if I wanted to varnish a fishing rod I should try French polish, and do the work in the warm weather; but as a guess, I fancy the rod makers "stove" their work.—SAML. RAY.

[61177.]—**Plate Machine.**—This is just the very subject our estimable friend Mr. Bottone took so much trouble about a few months ago. See back numbers; can't refer myself, as last two vols. at the binder's.—S. BRETTON.

[61177.]—**Plate Machine.**—Yes; an 8in. disc will give a 1in. spark. For information as to mounting discs, both with and without central aperture, kindly turn to the first and second numbers of my "Electrical Instrument Making for Amateurs," in the ENGLISH MECHANIC, Vol. XLII. No. 1,086, p. 396.—S. BOTTONE.

[61178.]—**Electric Lamp.**—Cannot be satisfactorily done.—S. BRETTON.

[61178.]—**Electric Lamp.**—I have found that the difficulty can be overcome thus. Heat the glass (at the point where the breakage is) very carefully and gradually over a spirit lamp; when sufficiently soft, push it back from the platinum with the point of a knife till a little bit of the wire is uncovered: a very short end of this can be bent over so as to form a hook (not loop), to which any required attachment may be made, and all will be right.—TRY.

[61178.]—**Electric Lamp.**—I have frequently been able to solder a copper wire loop to the flush end of the platinum. To do this, hold a thin rod of solder in the flame of a spirit lamp; approach the lamp to the flame (having previously touched the platinum end with soldering fluid). As soon as the solder softens, rub it on the end of the platinum;—some will adhere. Allow the lamp to cool gradually. Now get a little globule of solder to adhere to the tail of a copper loop, shaped like Q; again warm both lamp and loop, bring them together, and the job is done.—S. BOTTONE.

[61178.]—**Electric Lamp.**—I have many times mended broken lamps as follows, provided a small portion, say, $\frac{1}{16}$in., projects beyond the glass. Scrape platinum clean with knife, cut two copper wires (No. 18) 3in. long, tin one end of each, make small soldering iron out of No. 4 copper wire, and quickly solder a wire to each platinum, using muriate of zinc. This done, select piece of tube (any material) large enough to slip over small end of bulb up to shoulder, passing the wires down centre. Rest the whole on a box of earth or sand (terminal end uppermost) to make a steady rest, and fill up tube with plaster of Paris. Leave 24 hours to set. Use copper wire for connectors.—W. W. N.

[61179.]—**Concrete and Cement.**—Concrete and cement made up with sea-water is liable to get damp in wet weather, and to "bloom" out with white powder on the surface in dry weather; also to break up in frosty weather. This is caused by the deliquescent salts held in the water, which cause the concrete or cement to absorb moisture from the air.—GEORGE EDWINSON.

[61179.]—**Concrete and Cement Plastering.**—Sea-water is not suitable for making concrete or cement, on account of the salts it contains. If your correspondent really wishes to make some of the best concrete or cement plaster he should use a saccharine liquid, not sea-water. A little sugar in the water—a decoction of malt, or probably

even treacle-water would answer; but the simplest arrangement will be to mix the mortar, cement, or plaster with water containing, say, 2oz. of sugar to the gallon. If any reader tries this, please report results whether favourable or not. It is an old dodge—goodness knows how old,—but is not much used nowadays, although there is no doubt that sugar-water enormously increases the strength of mortar.—SAML. RAY.

[61180.]—**Dynamo.**—I am rather doubtful whether you will be able to light six lamps with so small an armature. Try 2lb. No. 22 on the armature, and 8lb. No. 16 on the fields.—S. BOTTONE.

[61181.]—**To Mr. Bottone.**—The proportions given are fairly accurate.—S. BOTTONE.

[61182.]—**Lead Hammers.**—Add the antimony wrapped in lead to the rest of the lead whilst in a molten state, then stir all well together.—GEORGE EDWINSON.

[61182.]—**Lead Hammers.**—If this querist cannot manage to get what he wants in any other way, he can melt some lead and add old types to it until he thinks he has made the lead hard enough. The types will probably contain metal which will improve the lead hammer. If "W. M." wants only a few heads he should get some tea-chest lead, melt it, throw in a little bit of tallow, and stir briskly. The dirt will rise and can be skimmed off, when the antimony, or the old type or stereo-plate is added by degrees, the lead being raised to a red heat as it is called; for if merely at fusion temperature it will simply vaporise the antimony, as you have found. If you use old type, you will avoid much of that difficulty.—SAML. RAY.

[61189.]—**Precipitating Gold Chloride.**—The solution of cyanide of potassium to dissolve chloride of gold should be a strong one. Perhaps yours is too weak. When the chloride is dissolved in distilled water, there is frequently a small quantity of white precipitate at the bottom. The pale straw-coloured gold solution is to be poured off from this, then the strong cyanide solution gradually added, stirring with a glass rod. A brown precipitate should be formed, and the cyanide should be added drop by drop until it produces no further effect.—BOBADIL.

[61189.]—**Precipitating Gold Chloride.**—You probably mean potassium cyanide, not "gold cyanide." Gold cyanide is not easily precipitated from a solution of gold chloride by amateurs. You have prepared the gold chloride rightly. It should be dissolved in distilled water in the proportion of 5 fluid ounces of water at least to 1 of the chloride. Add the solution of potassium cyanide with much stirring until a precipitate begins to form, then leave it at rest for several hours. Again stir well, and leave at rest. The precipitate forms slowly, so you must be patient with it. The battery process of forming the solution for gilding is much the more convenient and economical for amateurs. Next to that is the solution made by throwing down the gold as an oxide with calcined magnesia, washing the pp. and dissolving in a solution of potassium cyanide.—GEORGE EDWINSON.

[61192.]—**Colouring Gun-Stock Fittings.**—One portion of your gun furniture should be blued, the other case-hardened; the butt, or heel plate, and guard should be blued; the trigger-plate, triggers, and lock-plate should be case-hardened. First, get as good a polish as you can on all the parts. For blueing, make a rough sheet-iron box, say, 8in. square; just cut the sheet-iron, and double over the ends. No rivets required. Next fill your box with powdered charcoal; now put the box on a good fire, stir up the charcoal now and then till you find it is partly ignited. Then put one of your articles into the centre of the charcoal, so as to be nicely covered from the air; but, first, before putting the article in, rub it over with a piece of rag or tow dipped in dry powdered lime. Every seven or ten minutes lift it out with a pair of tongs; don't keep it longer in the air than you can help, and every time you take it out brush it over with the dry lime—you must be quick about it. The first blue you will get fades; go on till you get the second blue, which should be rich dark, bordering on black. When you have obtained the desired colour, stand by to cool, then oil; any oil will do. There must be no grease on the things you want to blue. You did not say what kind of gun, so that I don't exactly know what kind of fittings you have. For the case-hardening you may use the same iron box as for the blueing. But do the blueing first, as the case-hardening may spoil your box if it be of thin iron. Proceed thus: half fill your box with bone-dust, lay all your articles in, then fill up the box with more dust; place your box in or on the fire, put some red coals on top; keep a good fire. Forge or kitchen fire will do; any fire where you can get plenty of heat. Let the box remain in fire till the whole is a good red heat, bone-dust and all. Now lift your box off the fire, and quickly turn the contents into a pail of cold water, they are now case-hardened. You have only to dry and oil the articles. They should have a nice mottled appearance. If you cannot get bone-dust, get some bones, burn them in the fire, and pound them up. But if neither can be got at, get some old boots and scraps from a shoemaker, put the leather on the top of a fire till well burnt; now powder, and use as you would the bone-dust. For my part, and I have had years of experience, I prefer the leather—I think it gives a better colour than the bone-dust. If you case-harden your lock-plate, mind you take off all the posts: and of the lock case-harden only the base-plate. Write again if you have any difficulty. You have not given your address, so I cannot send the tool until I know.—ARMOURER.

[61195.]—**Damage by Woodworms.**—Try soaking the woodwork in paraffin oil if turps has failed entirely. Are you sure that the wood was well soaked in turpentine?—GEORGE EDWINSON.

[61195.]—**Damage by Woodworms.**—A bad piece of wood does infect another; cut out all the bad pieces where this can be done without damaging the appearance of the furniture, substituting new and sound wood. Where this is inconvenient, soak the parts affected for a week with common petroleum. I have found this effectually stops the little game.—S. BRETTON.

[61195.]—**Damage by Woodworms.**—If you can get any oil (even paraffin) thoroughly into the holes you will kill the boring insects, but that is not easy. As a simple remedy try forcing lard into the holes until full, and then heat the furniture sufficiently to melt the lard. The really effective remedy would be to put the woodwork into a chamber from which the air can be thoroughly exhausted.—NUN. DOR.

[61195.]—**Damage by Woodworms.**—Make up a strong solution of corrosive sublimate, and if you have nothing else to do, squirt it into the holes with a very fine syringe. Or you may go over the woodwork several times with a rag well soaked in the solution; but be very careful with it, as it is a deadly poison. If well applied, the worms will be instantly killed, and the wood will be free of them until it drops to pieces. This is also a valuable method for preserving skins against moths.—R. E. F.

[61196.]—**Staining Leather.**—Staining leather is really dyeing leather, and "F. K." should therefore use the aniline dyes, and refer to an article in your last volume, p. 431, and to p. 388 in same volume, where he will find full particulars. Those pages are in Nos. 1110 and 1112, which appeared only a few months ago.—NUN. DOR.

[61198.]—**Induction Coil.**—This coil, if well-wound, should give about ¾in. spark.—BOBADIL.

[61198.]—**Induction Coil.**—If your coil is really carefully insulated, it should give from ½in. to ⅝in. spark.—S. BOTTONE.

[61200.]—**Work Done by the Heart.**—The following daily diet is sufficient for an adult man:

Albuminous food	3·5oz.
Fats	3·1oz.
Starch	10·7oz.
Salts	1·0oz.
Water	5 pints.

It is estimated that a man produces in the 24 hours over 2½ millions of units of heat, which are lost by the skin and lungs, and in heating the ingesta and the air breathed. The strange part about it is that if the heat value of such a diet be calculated, it does not nearly equal the heat given off by the body.—R. E. F.

[61200.]—**Work of Heart.**—The average weight of so-called solid food consumed by an adult doing ordinary work is from 40 to 60oz. According to W. Blyth, the diet of an English soldier consists of 12oz. meat (one-fifth bone), 24oz. bread, 16oz. potatoes, 3¼oz. of milk, 1·3oz. sugar. Such a diet, being equal to 266gr. nitrogen and 4,718 carbon, will provide sufficient energy for internal work, and also 300ft.-tons external work. Dr. Parkes' calculations, based on Dr. Frankland's experiments, show that the energy to be obtained from 1oz. of different foods in their usual condition is as follows:—Cooked meat, 106·2; bread, 87·5; oatmeal, 130; potatoes, 33; cabbage, 13; eggs, 67·3; milk, 26·9; cheese, 149·9ft.-tons. The work of heart is only part of internal work; respiration and various other expenses of energy must be also allowed for. The total internal work of body being estimated at 260ft.-tons (Blyth), this, with 300 to 340ft.-tons external work (a good day's work), make 600ft.-tons, the equivalent of which must be obtained from food. It must not be forgotten that many conditions must be taken into account in these calculation—e.g., digestion, individual, &c.—KENSINGTONIAN.

[61206.]—**Clothing.**—I would recommend this good housewife with the long name to consult the mistress of the nearest National or Board-school. Since needlework was made compulsory in elementary schools, cheap little books on sewing and cutting out have been published; a school teacher could, therefore, advise "J. C." where to find the instructions she needs to enable her to carry out her most praiseworthy wish to shape the garments of her little cusses.—A SCHOOL MANAGER.

[61206.]—**Boy's Clothing.**—My wife gets a good pattern old coat, vest, or trousers, takes it to pieces, and uses the parts as patterns for the new clothes; or she will get a garment, take it to pieces, cut out paper patterns of the same shape as the pieces, and keep these patterns in stock. As the boys grow she makes sufficient allowance for the growth by cutting the parts larger than the patterns.—GEORGE EDWINSON.

[61209.]—**Psychological.**—This query is addressed to "Garrison Gunner"; but as I am personally acquainted with the wonderful case referred to by Mr. T. Edge (details of which are given in last month's *Nineteenth Century Review*), I take upon myself to offer an opinion, and it is that there is a great difference between the case of his friend "wholly given up to drink," and that referred to. "The patient in the Salpetrière" was insane, and the insanity was of such a frightful type that neither I nor any of my collaborateurs in the Paris hospitals ever saw anything to equal it. On the other hand, the craving for intoxicants is associated oftener than not with persons who are perfectly sane. They (the intoxicants) may be said to produce temporary insanity; but that is very different from the "wonderful case." In a word, the one could not be held as a precedent for the other, and as far as I know, mesmerism has not as yet cured a drunkard.—B.SC., Plymouth.

[61209.]—**Psychological.**—By all means try the effect of mesmerism with your friend. If anyone can be found who can mesmerise him, and who will take trouble with the case, and use patience, the cure will have every chance of success. If Mr. Edge has time at his disposal, he would do well to try to mesmerise his friend himself; and let him try at least six sittings of an hour each, on six consecutive days, before he comes to the conclusion that he cannot do it. If no one can be found in the patient's circle of acquaintances able to mesmerise him, I would say seek out a man who is known to have the power, and who does not exhibit it for gain. If such cannot be found, apply to a professional mesmerist. There is no doubt whatever of the possibility of cure by this method, and, curiously enough, I was talking last week to a man of some note as an investigator, who told me that exhaustive experiments were being made at present in Paris, which had already established the fact of the possible cure of drunkenness by mesmerism, and also the power of mesmerising from a distance. I shall be glad to give Mr. Edge any help I can, and hope he will let me know the result of his experiments. In case of difficulty in obtaining a mesmerist, I would advise Mr. Edge to write to the Secretary of the Society for Psychical Research, or, if in London, call at their office (I think it is in Southampton-buildings), and ask for Mr. Frank Podmore, who, I doubt not, would be able to recommend him to the right place.—GARRISON GUNNER.

[61211.]—**Planing Machine.**—If my advice is worth anything you will have your driving as simple as possible, and with equal speed in return as in cutting—the rest to the leg is very welcome. If driven by power you might have a quick return. I fitted one as follows to a small machine:—A slotted link pivoted at one end to frame outside driving-wheel, and the connecting-rod pivoted at one of sundry holes between this and end of link, to vary the throw. The crank-pin of driving-wheel slid in the slot of the link, and that completed the affair; but, of course, a block in slot would have been better.—T. C., Bristol.

[61213.]—**Engine Query.**—You must have a good bit of play in the motion bars. If you will make a rough sketch of piston and rod, and connecting-rod and crank, you will notice that (as they are not in a straight line except at end of stroke) when the crosshead is making the in stroke in back gear, it must necessarily be pulled against top bar and thrust against bottom bar in the out-stroke. When the engine is in forward gear all the motions and strains are reversed, and so the reverse action is shown on the bars as you note. A simple chalk sketch will make it clear.—T. C., Bristol.

[61215.]—**To Mr. Bottone.**—I may not reply to this query, as the reply would be an advertisement. Will you kindly refer to the "Sale" column for my address, and communicate to me personally, when I will do what I can for you? The lamp gave about 5c.p., and required 2 volts.—S. BOTTONE.

[61219.]—**Gold Solutions.**—To keep these in working order always use an anode of pure gold slightly larger than the article to be gilded; also add a small piece of potassium cyanide to the solution occasionally. Your solutions become spent for want of sufficient pure gold and free cyanide to dissolve the anode.—GEORGE EDWINSON.

[61219.]—**Gold Solutions.**—Reading this query between the lines, as it were, permit me to ask

whether the troubles of the querist do not arise from the simple fact that he has taken much of the gold out of the solution after "four or five times" using? Probably if he put a piece of gold into his solution and kept it there while the battery was working he would not experience any difficulty. I have always heard from electro-platers that strong solutions work best, and in nickel-plating it is almost a sine quâ non to surround the article with anodes of nickel, so that the solution may be kept fully charged.—NUN. DOR.

[61219.]—**Gold Solutions.**—It will be difficult to fix upon the fault in "Puzzled Jeweller's" solution, but there are three methods which might be tried to get the desired results—(1) An article with a pale deposit, after being brushed, should be immersed in the bath again for an instant, and immediately plunged into boiling water. This should result in a fine gold colour. (2) A solution worked at a lower temperature than 130° Fahr. invariably yields a pale deposit. The best colour is got when the solution is rather above than below this temperature. (3) Whenever a gold solution gives bad results as to colour, the best and simplest remedy is to evaporate it to dryness; re-dissolve the dried mass in boiling distilled water, and add a little cyanide. There is no expense in this operation so far as the gold is concerned. Last of all, keep the solution in any large enough vessel other than a corked-up bottle. The act of pouring it out of the latter stirs up the impurity which gathers through time. In a suitable vessel with a lid to keep out dust, the impurity will lie at the bottom.—BOBADIL.

[61223.]—**Balancing Millstones.**—For true running it is not only necessary that there should be the same weight each side of a diametrical line, but also that there should be the same weight above a horizontal line through top of cockhead on each side of a diametrical line, and also a similar—not the same—balance on the lower half. If this were so, stone would be in both running and standing balance; if not, it is clear the centre of gravity of one-half is higher than the other half. Some stones have means of lowering the loading or raising it as required. If stone is out of balance, spindle will soon begin to wobble; hold a piece of chalk against it when running, and it will mark the heavy side.—T. C., Bristol.

[61224.]—**White Metal.**—I have not tried this for toe brasses, but have sometimes repaired them with ordinary solder, and they have run fairly well. The great secret to make the toes last is to have ¼in. hole drilled in bottom, but not through, by ⅜in. to ½in.; never mind side grooves; this prevents them heating.—T. C., Bristol.

[61227.]—**Model Boiler.**—You must really give us some dimensions, as well as describe the shape; an 8-gallon pot might be any depth or diameter. I should, in any case, recommend you to sell it for the value of the metal, and procure new brass with the money.—T. C., Bristol.

[61228.] — **Lantern Transparencies.** — I always use lampblack ground up with pallette-knife on a glass slab, with gold size and turps.—S. BRETTON.

[61231.]—**Dynamo (Ten 20c.p.)**—TO MR. BOTTONE.—An A gramme, with Pacinotti ring armature, laminated, gives as good results as any for a machine this size; it is also easy of construction. My castings for this size machine stand 1ft. 1in. in height, and are 1ft. 4½in. long; armature, 4⅞in. in diameter, 2½in. wide; 4lb. No. 18 on armature; 8lb. No. 16 on fields for series wound; or 20lb. No. 20, if shunt-wound. If I am spared, I intend shortly to send a paper to the Editor for publication, referring specially to the ring armature type of machine.—S. BOTTONE.

Alloys of Lead and Tin.—A paper was recently published on the specific heat of alloys of lead and tin, by W. Spring (*Bull. Soc. Chem.*). At low temperatures, alloys of lead and tin behave as simple mixtures of their constituents, each element still keeping its specific properties; as the temperature rises, a molecular action takes place, the molecules of each metal being broken down into molecules of simpler construction. This molecular modification increases in rapidity with the rise of temperature, and at a certain point attains its maximum, when the alloy melts, and it is to what the author terms the simplification of the molecules of the metals when heated in intimate contact with one another, that alloys so frequently have a melting point situated below that of either of their component metals. After the alloy is fused, the molecular change becomes less active, and finally, at a certain temperature varying with the composition of the alloy, ceases altogether; the alloy then once more behaves as a mixture of the component metals, each, however, having a more simple molecular structure than that of the separate metals at the same temperature. On cooling a melted alloy, an inverse action takes place.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last S. Bretton has replied to 60514.

60655. Strength of Type Metal, p. 162.

QUERIES.

[61232.]—**Bracelet Snaps.**—Will any of "ours" kindly tell me how the snaps or catches on gold and silver bracelets are soldered on, so as to retain their elasticity? I can get them on all right, but they are, of course, as soft as can be through the heat in soldering, and are consequently no use as snaps. I have tried ready-made snaps, and have made others myself, but with the like result. My solders are fusible at a fair heat, and are not extra hard.—PUZZLED JEWELLER.

[61233.]—**Permanent Way.**—Can any of our railway correspondents inform me what kind of permanent way is used for the railways on the Continent—the French, German, and Belgian particularly? Do they use the double-head rails and cross sleepers, with chairs and wood keys, the same as are generally used in England? I should also be glad of any information as to the same in the United States of America. What is Mr. Webb's system like of the L. and N.W.R.?—A. W. M.

[61234.]—**Bursting Pressure.** — Would "T. C., Bristol," or some other of our intelligent readers, kindly help me to find bursting pressure that I can produce by the following means? I have a screw, 1¼in. diam. in the bottom of the thread, and four threads to an inch; lever, 4ft. long; inclined plane, one in twelve. Plain figures will oblige—NON-CONFIDENT.

[61235.]—**Telegraph.**—Will Mr. Bottone, or some electrician, assist me in the following difficulty? I have erected a line wire of copper between two buildings, 50 yards apart, with earth plates of galvanised corrugated iron, 24in. by 18in., and galvanised iron wires leading from same, soldered to plates. Upon trying the circuit with one Leclanché, No. 2, I was surprised to find the bell would not ring, so I put galvanometer in circuit, which gave a slight deflection, proving there was a current passing, so I added two more cells, making three, coupling them first in series, then parallel; but still the galvanometer gave the same deflection in each instance. I then attached a common iron wire from each wire leading from earth plates, which rang the bells beautifully, proving the fault to be in the earth current. The plates are buried 6ft. deep, and the earth is saturated with moisture after the rain we have had. Of course, if there is a second wire for return, all will be right; but why am I obliged to put one, and why will not sufficient current pass through plates, as in other telegraphs?—CONQUERED.

[61236.]—**Colliery Winding Engines.** — Could any of your correspondents inform me if there are any winding engines (pairs) working expansive, and at what part of stroke they cut off?—CROXHALL.

[61237.]—**Lathe.**—What is the largest diameter in cast iron that can be turned with safety on a 7½-centre engineer's screw-cutting lathe, with gap to take in 30in.? Have asked several in the trade, and all gave different replies.—P. O. J.

[61238.]—**The Brown-Allan Relay.**—Will some electrical corespondent kindly give through these columns a detailed description of the above form of relay?—ANNESUIR.

[61239.]—**Circular Saw.**—I have a small circular saw to work in lathe; but with a long cut it buckles very much from heat, caused by friction, I believe. What diam. should the shoulder on spindle bear in relation to diam. of saw? Also, ought guide to be longer than diam. of saw? I am a novice, and an answer from one experienced would greatly oblige—WOODWORKER.

[61240.]—**Microscopical.**—Will some reader kindly solve the following problem for me? What diam. must a 5in. tube be to give the same field as a 10in. tube with an internal diam. of 1⅝in., the eyepieces having the same magnifying power, notwithstanding the different focal distances, 5in. and 10in. respectively? I am presupposing that the field given is in proportion to the diam. of the field lens of the eyepiece.—H. J. P.

[61241.]—**Climate for Chronic Catarrh.**—I have been suffering three years from this. The symptons are: continued discharges through the nose and into the throat, pungent, yellow, and extremely offensive. I have tried hospitals, doctors, physicians, without success; the winter weather especially keeping the nose in a continued state of inflammation, cold succeeding cold. There is also continued and excessive expectoration, indoors and out. I am in weak health, being a student of meditative and sedentary habits, using the head a great deal, but not the physical man. I must put a stop to it, if I have to go to the antipodes. Can anyone recommend a climate that does not aggravate nasal complaints? I thought California was the place; but have heard from a resident that they have continually cold west winds and fogs along the coast; and inland too hot, except for natives. Has Nelson Co. New Zealand, a good reputation for an even, temperate climate? Any information will be of inestimable service, if coming authoritatively.—NECESSITOUS.

[61242.]—**Canvas for Diagrams.**—Can any reader tell me how to prepare a sheet of canvas for drawing diagrams on with chalks, same as on a black-board? I have seen a lecturer use a portable screen, which appeared to be made of black canvas. Any information will much oblige—J. B.

[61243.]—**Failure of Amalgamation.**—Will some of our practical friends kindly assist me? I cannot get my zinc rods or plates to resist dilute sulphuric acid, even when the battery circuit is not complete. It is not for the want of mercury. A ½in. rod broke through the other day, almost by its own weight, through being saturated with mercury; yet it gives off hydrogen in abundance when placed in the cell. I have used the various tests mentioned in Mr. Sprague's "Electricity," and lead seems to be the substance mostly present. This is accounted for by its being made in lead chambers. I have changed the place I buy the mercury from, and have tried three fresh respectable firms for the acid, but my difficulty still continues. It is not caused by the mixture heating when mixed, because I always mix them over night and allow to cool for next morning. To see how dilute it really would act on the zincs, I made a solution of 1 of acid to 40 of water; still the hydrogen came off in abundance—in fact, with three Smee cells the place in ten minutes was unbearable, circuit not complete either. A sample of "pure" did show a little nitrous acid on testing; but, supposing this is causing the mischief, how am I to get rid of it? It seems almost impossible (at least, so it seems to me) to buy acid without it. Any help will greatly oblige—M.M.I.SC.S.

[61244.]—**To Tell the Age of Eggs.**—(See from *La Nature.*) Has anyone from the country tried this? They have more opportunities than we Londoners.—R. S. T.

[61245.]—**Saccharine Matter in Mortars.**—Has anyone tried it?—R. S. T.

[61246.]—**Wrought-iron Castings–Aluminium added to Wrought-iron.**—(See *Engineer*, p. 443, 3rd Dec., 1886.) Can anyone give further particulars? After reading the article I came to the conclusion that wrought iron is semi-faced, and then aluminium added, which acts as a flux. Am I right?—R. S. T.

[61247.]—**Hot-air Motor.**—TO MR. J. SEAL.—Having partly finished one of your hot-air motors, I should like to know the best or most suitable size to drill the port or air passage from cylinder A to D? Also if the cylinder D should be in any relative size to A? If so, what?—W. S.

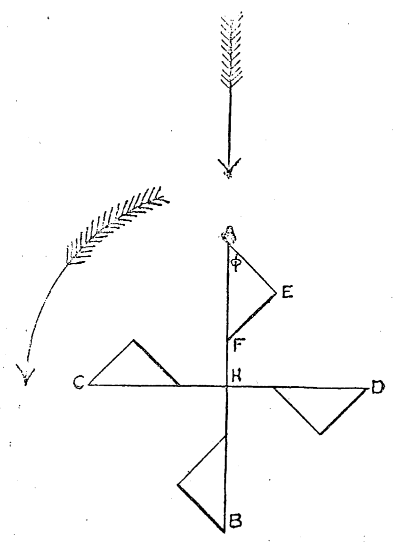
[61248.]—**Electrotyping.** — I wish to be able to deposit copper on to the surface of a gelatine photo.? I believe such is done. Any information regarding this process, electro-depositing on gelatine, will be thankfully received.—T. M. P.

[61249.]—**Boiler for Boat.**—I have a model compound engine, with cylinders ⅝in. and 1⅜in. by 1in. stroke. Will some reader kindly give me a description of boiler, and best way of heating the same?—STEAM.

[61250.]—**Telescope O.G. for Photography.**—Wishing to utilise two telescope object-glasses for photographic purposes, as a species of doublet, the one being a 4in. of 62in. focus, and the other a 2⅜in. of 42in. focus, at what distance apart should the lenses be mounted, and which lens should be posterior? Is it likely that there will be much difference between the visual and chemical foci?—J. C. H.

[61251.]—**Boiler.** — Could anyone kindly give the dimensions of a boiler for a double-cylinder engine, cylinder 2in. bore, 3½in. stroke? Also the best way of heating the same?—F. S. R.

[61252.]—**Windmill.** — Will some kind reader of "E. M." help me out of a difficulty? I wish to construct a horizontal windmill after the following manner, and would like to know whether or not the mill would work? If not, why? On each of the four ends of the cross, A, B, C, D, I affix a triangular plate of sheet iron, having the side A E equal to E F. The general direction of vanes



will be seen from the figure. The whole is to turn on its centre H, while H itself is permanently fixed. It appears to me that if we had a wind pressure of x power blowing in the direction of the straight arrow the mill would have a rotary motion in the direction of bent arrow equal to $2x \sin \phi$, provided the angle A is within certain limits.—MILLER.

[61253.]—**Electrical.**—Will any kind reader inform me if there is any method of registering the strength of a rapidly varied electric current?—H.

[61254.]—**Combination Machines.**—Some time ago I saw in a paper a firm advertising milling attachments for planing machines. I wrote to them on the subject, but they declined giving me any information. If any reader could tell me how to make such an attachment I should be much obliged.—A. F. SHAKESPEAR.

[61255.]—**Embrocation.**—Can anyone give me a good prescription for an embrocation for exciting the action of the liver? I had one some years ago, but have unfortunately lost it.—A. F. SHAKESPEAR.

[61256.]—**Hand Planers.**—Being engaged in building a new planer with the latest improvements, I should be much obliged to any reader answering the following questions:—(1) Have the capstan handles of the English machines any real advantage over the crank handles and reducing gear of the American and German machines, or are they only perpetuated from a conservative idea? (2) Have ⊥-grooves any advantage over dovetailed ones? The former are certainly more difficult to make, and necessitate a heavier table, as they cut into the metal more. (3) Is weight a necessity—i.e., must a machine 30in by 16in. by 12in. capacity weigh about 11cwt.? Why should it not weigh about 5cwt. or 6cwt.? (4) Is there any objection to the Haas machine with the clutch reversing motion? (5) In machines where the bed is about 1½ft. or 2ft. longer than the table, I have found a tendency in the bed to wear hollow. Is there any necessity for the bed to be longer than the table?—A. F. SHAKESPEAR.

[61257.]—**A New File.**—A file has lately come under my notice which claims the advantage over other files of being able to be ground on an ordinary grindstone, and of being easily repaired. The file is composed of pieces of steel ground at the edges to an angle, and strung on a rod of square steel. Can anyone tell me if such a tool has been tried in England, and with what results? I understand that the file will cut as much in a day as an ordinary one will in two days, and is easier to drive. Is this possible?—A. F. SHAKESPEAR.

[61258.]—**Organ Manual Couplers—Swell to Great in Octave and Sub-octave.**—Will some reader kindly favour us with a sketch (side view) showing the general principle of the action of above movements from key tail to pallet chest on a simple and effective plan? I may say that I have "thought it out" from an amateur's point of view; but as these movements entail a considerable amount of work, and should be constructed on sound principles to be really effective, I wish to obtain information from a higher source before proceeding. The clear space from underside of chest to suface of key tail, great organ, will be, say, 14in.—W. W.

[61259.]—**Induction Coils.**—Will Mr. Bottone and "Bobadil" kindly tell me how they calculate the length of spark obtainable? Also, in planning a spark coil, how they arrive at the sizes of the various parts in order to obtain maximum efficiency? Would there be any advantage in using two condensers—one in the primary circuit and one in the secondary?—MICKY DOOLEY.

[61260.]—**Dip for Brasswork.**—I want to dip the goods in, and on taking them out to get a black colour for lacquering.—BROSCENICUS.

[61261.]—**Mirror Galvanometer.**—I intend constructing an astatic mirror galvanometer, and purpose winding the four coils on brass bobbins. Will so doing affect the delicacy of the instrument in any way? What are the essential features of a galvanometer for measuring capacity?—MICKY DOOLEY.

[61262.]—**An Electrolytic Estimation.**—A current gives 1 to 5c.c. of electrolytic gas per minute; the time required to deposit the metal, 1 to 5 hours. What is the strength of the current in ampères and volts?—R. T.

[61263.]—**Electric Units.**—Are the "practical electro-magnetic units" at page 237 Sprague's "Electricity" correct modern units? I fancy an international committee made some alterations. If so, kindly state which have been altered.—R. T.

[61264.]—**Safety Valves.**—I shall feel obliged to any of your readers for helping me to find blowing-off pressure. 1⅞in. diam. of valve, 2½in. length of fulcrum, 13½in. length of lever; weight of ball in pounds, 28.—LONDON BRUM.

[61265.]—**Loss of Magnetism.**—Could any reader tell me why a machine suddenly loses its magnetism for a minute or two and then regains it again? I have known it in the Edison-Hopkinson and Bürgin machines, the Edison-Hopkinson being a shunt-wound machine, giving off 320 ampères and 105 volts; the Bürgin also being shunt wound.—ONE ANXIOUS TO LEARN.

[61266.]—**Induction.**—Can any of "ours" inform me of any ready means of preventing or lessening the induction between two telephone wires erected across country on ordinary wooden poles for a distance of about 20 miles? It is the induction from one wire to the other that I refer to, not that from any exterior source. The trouble is that one hears so plainly all that is spoken on the other wire. Is there any means of twisting the wires that would be beneficial? To simply make one revolve round the other would, I imagine, be of no service if in the same direction throughout.—C. F.

[61267.]—**Iron Poles.**—Which of the two following iron poles would be most likely to stand the strain (wind, snow, &c.) imposed upon housetop telephone standards: (1) 20ft. length of circular tube, 2½in. diam. (internal) and ¼in. metal, making 3in. ex. diam., (2) two 20ft. lengths T iron, bolted back to back?—C. F.

[61268.]—**Soldering Lamp.**—Shall be glad if any of "ours" can recommend me one that can be used for soldering wires on housetops in windy weather—one that can be readily lighted.—C. F.

[61269.]—**Gramme Dynamo.**—I am about to make one, to be able to light four 5c.p. lamps well, and also for general experimental work; but, before doing so, would like the opinion of some of our correspondents versed in this matter. As regards the proposed dimensions and methods of construction, the F.M.'s are four in number; the plain part for winding wire on is 4in. long by ¾ diam.; the pole-pieces are 1¼in. thick, into which the F.M.'s are screwed, and 3in. broad; diam. of space for armature to revolve in, 4⅝; shaft to carry armature, 8in. between bearings, ⅝ diam., turned down at each end for bearings to ½in.; the armature to be made with a core of soft iron wire or a number of thin iron washers, internal diam. 2¼in., external diam. 3½in., and 3in. wide. I would much prefer the latter method but for the difficulty in obtaining the iron washers; the armature to be wound with No. 20 c.c. wire, 16 sections. Please give probable length of each section, and total length, weight, and resistance of wire to be used. The F.M.'s to be wound with No. 16 c.c. wire, crowded towards the centre to obtain uniform magnetisation; please give weight and resistance. It may be said that the F.M.'s are not large enough in diam. I may say these I already possess. It is required to be driven by foot-power. Any hints as to the actual construction of the armature and commutator gratefully received.—R. A. K.

[61270.]—**Coil.**—Will Mr. Bottone or "J. W. B." kindly answer query 60818 of Nov. 5th, as I am in the same hole with one myself? Description as follows: Primary, two layers 16 d.c.c., shellac varnished, three thicknesses of Corbridge paper well varnished over same to divide primary from secondary; secondary, 3lb. 26 s.c., each layer being well insulated with rosin, and one layer of paper, as described in Dyer's book; on top of this is 2oz. of 38 s.c.; condenser is 50 sheets of foil, 4½in. by 5in. The longest spark I can get without condenser is 1-32in., and with it is ⅛in., with three quart bichromate cells. Please state main fault. "J. W. B." advises to rebuild. I have done this three times, and get the same result each time. I have also watched queries very closely, but find none relating to my own difficulty. Any information will be esteemed a great favour.—J. B. PC.

[61271.]—**Electric Bell Circuit.**—A friend of mine has an electric bell communication from the house to the stables, a distance of about 200ft. The battery (Leclanché) is connected thus: The carbon is joined to "earth" at one end, the push to "earth" at the other end, and bell between push and zinc. Is this correct? Should not the earth be used as the return wire, and not the positive wire? At any rate, the arrangement seems faulty, because the bell frequently fails to ring. Will some electrical correspondent say whether this method of interposing the earth in circuit is theoretically correct, as a treatise on electricity in my possession says that when not in use the electricity resides in the positive wire (in this case the earth) as a static charge? Is this so?—H. B.

[61272.]—**Trains on Greenwich Line.**—Can any of your readers inform me why on the South-Eastern line from Greenwich, Westcombe Park, &c., to London Bridge the trains run from left to right instead of right to left, as on other lines? What one would naturally expect to be the down line is the up line, and the up line the down line. —OBSERVANT TRAVELLER.

[61273.]—**Saddle Boiler.**—I have a saddle boiler for heating house. It works about six coils from base to top floor, and I have found a great quantity of air in pipes. Have opened air-valves about once a week. Have been told should not require opening only once every three months. Would someone please tell me the probable cause and the regular times the valves should be opened? Also if it has any injurious effect in letting air off every week? The air completely stopped circulation on one occasion, having not been opened for a few weeks.—F. H. R.

[61274.]—**Cell.**—Wanted, a suitable portable cell for testing wires, circuits, &c., something of the Leclanché type, but were the liquid is prevented from slopping about. Is there anything really suitable in the dry battery line?—FIX.

[61275.]—**Coppering Carbons.**—I have just been trying to electrotype some carbons with copper in order to form a connection to use them for a Leclanché battery; but find that after the electric action has been going on for the space of a few hours the sulphate of copper begins to deposit itself in a kind of muddy form, which easily comes off. The apparatus I use consists of a jam pot containing saturated solution of sulphate of copper, and also porous pot, which contains sulphuric acid diluted with ten parts of water, in which is placed zinc rod. Both solutions are kept level. Will some reader please explain cause of muddy deposit?—J. W. J.

[61276.]—**Solar Parallax.**—To "F.R.A.S."—Can you oblige me by giving the rule for finding the distance of the sun, knowing the horizontal parallax? In the issue of Dec. 3rd you give the distance as 92,359,000 miles. Please say whether the value of the solar parallax given by Mr. Gill in 1877 as 8·783″ is not considered the most reliable yet attained, and whether from this the mean distance of the sun is not deduced as 92,660,000 miles?—S. FORD.

[61277.]—**Multiplex Copying Ink.**—To MR. W. C. HALE.—I have tried your recipe for a graph given in the issue of Dec. 10, and find it to answer well. I used a multiplying ink made by Judson's, but find that I cannot readily clean the apparatus. I understood the impression to come off with sponge and cold water. This entirely fails in my case. Will you kindly say how you clean the graph?—S. FORD.

[61278.]—**Hot-air Motor for Organ.**—Would Mr. Audsley add to his valuable and useful information by suggesting a good motor (of the hot-air description) for use where neither water nor gas is available? Would he also give the scale and size of his double mouth flute?—C. C.

[61279.]—**Rhea Fibre.**—I am deeply interested in the experiments made on this fibre, as related by "Urtica" in letter 26585, and should be glad to know where I can obtain a sample of it spun into thread, twine, or cord? It will be useful for driving small machines where now gut or silk bands are used.—GEORGE EDWINSON.

FOR lecture experiments, Herr F. C. G. Müller recommends a thermometer containing sulphuric acid blackened with sugar, as it is readily seen; sulphuric acid expands regularly, and has a coefficient of expansion three and a half times greater than that of mercury.

CHESS.

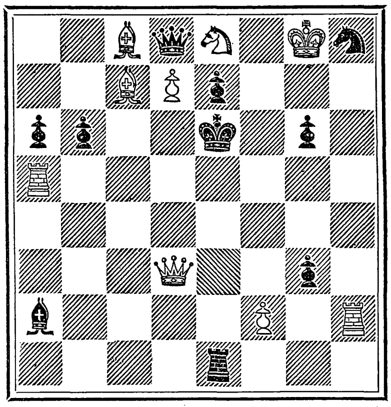
PROBLEM MXXIII.—BY J. P. TAYLOR.

Black.



White. [9 + 10

White to play and mate in two moves.

SOLUTION TO 1,021.

White.	*Black.*
1. B-Q R 2.	1. Anything.
2. Q mates accordingly.	

(Three variations.)

NOTICES TO CORRESPONDENTS.

CORRECT solutions to 1,021, by J. Rowland Turner, W. Hewson-Kilber, F. Krasser, Link, J. Mackenzie; to 1,020, by Link (but second move is B-R 5).

W. DUFF.—1. K-R 2 will not do for 1,021, on account of 1. Kt-Q B 6 (ch).

H. BALSON.—Thanks for games.

W. HEWSON-KILBER.—Name entered for A and B. It considerably detracts from the value of a problem for the first move to be either a take or a check.

H. HOSEY-DAVIS.—We have entered your name for both Tourneys.

AS fourteen have entered for Tourney A, and fifteen for B, we shall be prepared to start with the first Tourney Problem next week. All who have not paid the entrance fees are requested to do so. The regulations will be the same as before, except that solutions must be received within twelve days of publication of the problem. All the principal variations must be given. Additional marks will be scored for the discovery of second solutions and of duals (but not of duals in two-movers). Marks will be deducted for mistakes in solutions, and for incorrect solutions. The first six two-movers published will be common to both Tourneys A and B. We shall be glad to enter any more names in either Tourney up to the time of publication of solution of first Tourney Problem.

AS the Game Correspondence Tourney is nearly concluded, having lasted about eighteen months, we propose starting another (the fourth) in February next. The number is limited to 12, and there are now five vacancies. Entrance fee, £1, the total amount constituting prize money, to be divided (in proportion to the number each wins) among the six who win the greatest number of games. Each competitor plays two games with two opponents simultaneously. Drawn games reckon ½.

Failing Axles.—Of the 238 axles which failed during the first nine months of this year on our lines, 147 were engine axles—viz., 130 crank or driving, and 17 leading or trailing; 20 were tender axles, two were carriage axles, 63 were waggon axles, and six were salt-van axles; 29 waggons, including the salt-vans, belonged to owners other than the railway companies. Of the 130 crank or driving axles, 91 were made of iron and 39 of steel. The average mileage of 85 crank or driving axles made of iron was 233,057 miles, and of 39 crank or driving axles made of steel 223,933 miles. Of the 164 rails which broke, 79 were double-headed, 83 were single-headed, one was of the bridge pattern, and in one case the pattern was not stated; of the double-headed rails 49 had been turned; 31 rails were made of iron, and 133 of steel.

A NOVEL method of measuring the deflection of railroad bridges has been tried in Russia, and is thus described by the American *Engineering and Mining Journal*:—An iron pipe 1½in. in. diameter was carried along the outside of one girder. From this pipe, on each abutment of the pier, and at five intermediate points at each span, vertical pipes of the same diameter branched out. Inside, and near the top of each vertical pipe, was fixed a graduated ¾in. glass tube, the iron pipe being cut away on both sides. The zero divisions on the tubes were all the same distances above the flange of the girder. Before the bridge was loaded, the apparatus was filled with water, the tops of the upright pipes covered over, and the water was then drawn off until it stood at zero in each gauge. On the bridge being loaded, the deflection could be read with ease.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 332, *Strand, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Tuesday evening, Dec. 21, and unacknowledged elsewhere:—

A. J. S. COMPTON.—Rev. R. Swift.—King, Mendham, and Co.—Jawler.—B. T.—Not Known.—A. J.—T. O.—Tiler.—J. R. L.—Mensuration.—Barilier.—J. W.—W. J. T.

W. BUTTERWORTH. (Presumably you were attended by a medical man, and he would know whether there is any possibility of removing the mark. We think any alleged remedy would leave quite as objectionable a mark.)—R. R. R. ("Simple and efficient" remedies are desired by all; but tonsilitis is a troublesome complaint, for which it is often necessary to extirpate the tonsils. Consult a medical man.)—W. GARDNER. (We do not know, but should think it scarcely likely, as it is too old an invention. See Hints No. 5.)—ANXIOUS. (To what does the number 61170 refer? The only remedy for down draught is to secure a sufficient up-draught, or to put something on the chimney-pots which will prevent the downward suction. Boyle's cowls and similar inventions, by creating a permanent up-draught, prevent the smoke from adjoining chimneys finding its way down into rooms. Impossible to answer before.)—C. A. W. (What you describe is known as the magneto-telephone (Bell or Dolbear), and in its best form is made with horse-shoe magnets. Your failure is probably due to the fact that the diaphragm is too far away from the magnet, or the latter is not strong enough. A battery is easily inserted in the circuit. If the two telephones are connected by two wires, you can surely put a battery on one. See the back volumes from Vol. XXIII. onwards.)—F. W. S. (You can obtain a diagram of the Joy valve-gear from the patentee, or find it in several back numbers. Applied to a marine or vertical engine, it is illustrated in No. 806, and in No. 954 it is shown as fitted to a locomotive. 2. The numbers from 1050 to 1067 contain articles on the exhibits at the Inventions. 3. Of course. The L. and N.W. compound was illustrated in perspective in No. 1052; in elevation in No. 953.)—CARLISLE. (The standard wire gauge was given in No. 1101, and Stuo's can be obtained direct from the firm or found in most of the pocket-books.)—F. E. W. (Presumably you mean ventriloquism. It is an art that requires considerable aptitude and a large amount of practice. Procure a little sixpenny manual on the art by Hardy, published by Warne and Co., Bedford-street, Covent-garden, W.C.)—A. J. POOL. (In all probability they are spoiled. You will possibly find a remedy on p. 201, No. 1049, or in the back volumes by consulting the indices.)—H. A. SMITH. (You might succeed by mixing extra gum with the ink and adding finely-powdered coke. Use a quill pen, and stir the ink at each dip.)—E. G. W. (Whittaker and Co., White Hart-street, Paternoster-square, publish a "Grammar of Volapük.")—LEVER. (You may soften it slightly by warming it; but if it is vulcanised it has probably become permanently hard.)—T. L. H. (Can be done with dry compressed air stored in a reservoir, or with carbonic acid, as used by the soda-water bottlers. You must have a reservoir weighted to give the required pressure.)—B. ROLSTON. (Directions for erecting sundials in No. 924, in other back numbers, and in the cyclopædias.)—R. S. THOMPSON. (You can take photographic enlargements by following directions frequently given in our columns, or you can redraw by the use of the "squares"—that is, pieces of cardboard with silk threads stretched between so as to form squares; or, if the original is not valuable, you can rule squares in pencil over that, and then larger squares on the paper on which you wish to reproduce the larger picture. It is easy to draw then.)—ANXIOUS TO KNOW. (Similar queries have been answered over and over again as far as they can be. See the series of articles commenced on p. 1 last volume. The cotton is not sufficient insulation.)—A. H. (Answered not long ago. The copper can be deposited in the letters by the electro-process, or be brought out by dissolving the zinc from the surface. 2. As to filling up the letters, you can use sealing-wax, heating the plate so as to melt it; or mix the pigments with copal varnish and allow it to dry.)—W. S. C. (We do not know who could do such work for you, and the question should really be put into the Wanted Column of advertisements. It will be necessary for you to say what is meant by a semi-conducting plate.)—A SMITH. (By "pincat" we suspect you mean tincal, a commercial name for crude borax. Felspar is a constituent of rocks or rock itself, and consists of silicate of alumina combined with silicates of potash, soda, or lime. Orthoclase is a common potash felspar forming about 40 to 45 per cent. of granite. Albite, oligoclase, Labradorite, Anorthite are names of well-known felspars.)—JAPANNER. (Apparently you require to do what would seem to be impossible. If the labels are stuck to the plates while the latter are cold, the expansion of the metal when heated will naturally tend to split the labels off. The remedy is to transfer whatever appears on the labels to the metal itself, as is done in many cases now, and then you will have no trouble. If you can show that what you want has already been accomplished, no doubt some of our readers will help you; but at present you appear to ask for an invention.)—GLASS GILDER. (A method of gilding on glass was given so recently as No. 1082, about a year ago, and there are other methods in back volumes—see No. 891, p. 157. Probably the simplest method of gilding is to use a solution of chloride of gold rendered alkaline by the addition of soda. The reducing solution is proof spirit saturated with marsh gas, and we presume you know that the glass must be chemically clean. You can gild with the prepared "golds" in the usual way.)—666. (Query quite inadmissible; for friends of dealers might give their names as firms which "deal honestly.")—LONDON BEUM. (Consult a work on mensuration.)—WILLIAM SIMMONS. (The address was given in the number for July 28, 1865. We have no further information. See Hints No. 4.)—H. J. (Try Metzler, Great Marlborough-street, W. See p. 56, No. 1095.)—ALKALI. (It consists simply of apparatus by means of which a jet of sand is forcibly directed against an object by means of steam or air. See p. 235, Vol. XVI, and pp. 314, 437, Vol. XXVII.)—NOVICE. (You will find a variety by consulting the indices; but if you wish to understand the principle of secondary or storage batteries, see p. 279, No. 949. A simple and easily-constructed accumulator was described in No. 1016, p. 28. 2. See makers' lists for the cost of frictional machines.)—BELA BUCKEN. (The use of the Daniell battery for electric lighting has been under discussion recently. See p. 240 ante. 2. For Schanschieff battery see pp. 26, 257, last volume. 3. For nitrate of soda cell see pp. 320, 435, Vol. XLII.)—G. M. S. (Certainly not; it is a powerful antiseptic. 2. The clean metal has the effect of neutralising acid and precipitating what may be termed the "fat" of the oil.)—W. S. C. (Certainly it is, if he has the apparatus—a machine which costs about £30 to £50; but it would not be worth his while, as he can buy what he wants more cheaply than he can make small quantities.)—SCIENTIST. (There is no experimental method known—it is a matter of faith or belief.)—W. WILSON, Liverpool. (By immersion in hot water or steaming—sometimes dry heat—and pressure.)—INQUISITIVE. (Query not definite. Do you mean by taking them off the cards, rendering transparent, and printing from them?)—A. J. (The factitious birdlime is made by boiling linseed-oil with a little resin. You have boiled it too much.)—J. A. (We do not know what you mean; but suspect you will find what you want in such a book as Main's "Astronomy," published by Crosby Lockwood and Co., Stationers' Hall-court, E.C., price 2s. There is no lack of works on astronomy.)—A. TISNER. (The electric gas-lighter referred to was illustrated in No. 1033. It contains a little static induction machine, set in motion by pressing the knob or spring.)—ONE IN DOUBT. (The French reed is used in the instrument named—that is, the same reed as is used in harmoniums. See indices for full information about construction.)—J. B. HALIFAX. (Not suitable to our pages.)—WM. SALOP. (We cannot make much out of your letter. Such work is usually done by templates; but there are machines nowadays.)—A PRESENT SUFFERER. (Any druggist can supply you with ointment of galls; but you should consult a medical man. Various remedies have been suggested in back volumes.)—J. H. REID. (We cannot publish your letter. We regret to say we have had other complaints, and shall not allow the people concerned to advertise again. We have sent them your letter, and if they do not at once refund the money we advise you to communicate with the police.)

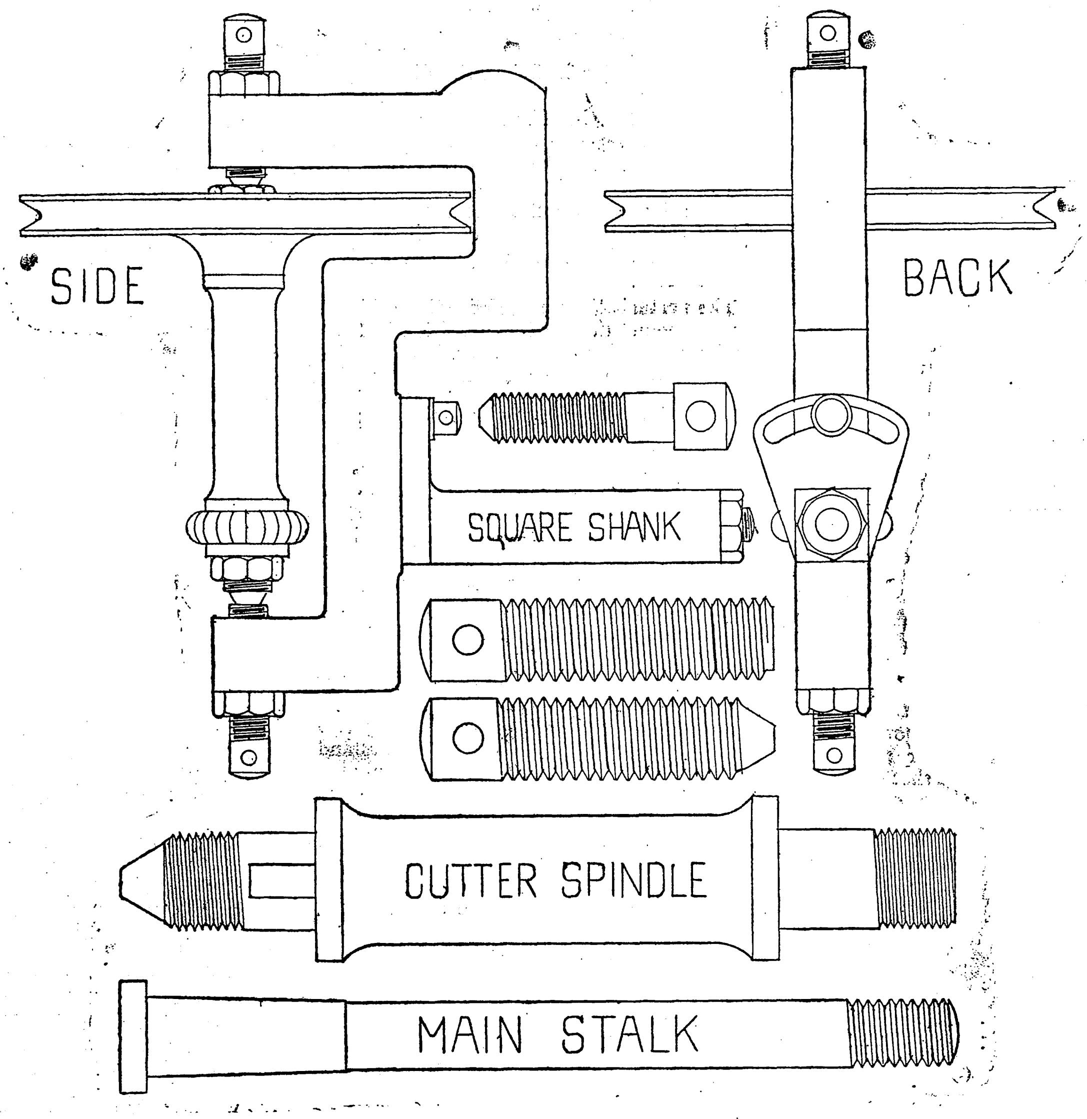
PROFESSOR HELMHOLTZ has shown that it follows from Faraday's experiments on electrolysis that while a monovalent atom carries to the electrode one charge of electricity, a divalent atom carries two charges of electricity. For instance, when we electrolyse potassium chloride, we have each potassium atom delivering a charge of electricity at the one electrode, and each chloride atom delivering an equal charge of electricity at the other electrode, all monovalent atoms, carrying with them an equal charge of electricity, which we may call the unit charge. When, however, we electrolyse magnesium chloride, we have two atoms of chlorine set free for one of magnesium, and consequently, while each chlorine atom carries its unit charge with it, the magnesium atom carries two units of electricity to the electrode. In fact, electrolysis proves that differences of valency mean differences in the electrical charge on the atom.

IT has for some time been stated that electricity may be used in soap and bleaching works, and now the *Electrical World* says:—M. Rotondi has discovered that by the employment of suitable vessels it is possible to effect the saponification of oils by the electrolysis of an emulsion of the oil in a concentrated solution of sodic chloride. This, at least, is the nature of the process so far as can be gathered from a not very lucid description in one of the French technical journals. During the process it is said that caustic soda, free chlorine, and glycerine are formed, and it is suggested that at bleaching works it would be found economical to prepare chlorine by this process in order to obtain the soap and the glycerine as by-products. It is also suggested that as the process requires practically no supervision, it would be practicable to employ in this way at night steam power already in use during the daytime for other purposes.

The English Mechanic
AND WORLD OF SCIENCE AND ART.
FRIDAY, DECEMBER 31, 1886.

UNIVERSAL CUTTER-FRAME FOR USE IN THE LATHE.

THE accompanying illustrations show a cutter-frame of substantial proportions, which is used in the slide-rest for cutting wheels, grooving taps, squaring nuts, and many purposes of a like nature. Those beautiful wheel-teeth cutters, made by the Brown and Sharpe Machine Company, of America, can be used in first-rate style in this cutter-frame.



The drawings, having been made carefully to scale, will show all dimensions correctly. The side and back views show the complete cutter-frame. The details are all drawn twice as large. The principal piece is an iron casting, the form of which is shown in the side view; it has a uniform section $1\frac{1}{8}$in. square. The shank is forged of $1\frac{1}{8}$in. square iron, with a piece bent up at one end, as shown in the back view, pierced by a segmental slot to allow the spindle to be canted over. It is useful to cant the cutter out of perpendicular for several purposes— for example, when cutting worm wheels. The shank has a hole bored through to clear the $\frac{1}{2}$in. steel stalk. The stalk is a piece of $\frac{1}{2}$in. mild steel rod, with one end upset to form its head, and about $1\frac{1}{2}$in. of the rod below the head is swelled slightly, so as to make a taper fitting both in the casting and in the mouth of the hole through the shank.

The cutter spindle is made of 1in. round steel, and has two collars $1\frac{1}{4}$in. diam. jumped up on it—one to form a shoulder for the cutters to abut against, the other to serve the same purpose for the pulley wheel. Two $\frac{5}{8}$in. cone-ended screws, one $\frac{3}{8}$in. clamping screw, five octagon nuts, and the pulley wheel complete the materials required.

The cutter spindle is $6\frac{1}{2}$in. long, one end pointed, the other countersunk. The two screws which form the bearings of this spindle are shown, enlarged, just above it: one is pointed, the other countersunk. The cone on the spindle and that on the screw have the points taken off to allow the spindle to be readily removed from the frame. The extreme points do not serve any useful purpose; and if not rounded off, the spindle would necessarily be about $\frac{1}{4}$in. shorter. The threads on the spindle are $\frac{3}{4}$in. diam. One takes an octagon nut to hold the pulley, the other a similar one to hold a cutter. There is a mortise hole through the spindle to take single tooth fly-cutters; these are held by the octagon nut and a washer.

The pulley wheel is made of wood mounted on a metal centre piece. It is shown without fair-leader pulleys, as this particular spindle is driven by a band coming horizontally from pulleys at the back of the lathe. Fair-leaders are easily added, to guide a band from above, by drilling and tapping a hole through the upper part of the frame casting where the lump is shown, and screwing in $\frac{5}{8}$in. pins on each side to carry the fair leaders.

The simplicity of this cutter frame, and the completeness of the illustrations render further explanation unnecessary.

THE PROGRESS OF ASTRONOMY IN 1886.

IF nothing startling or sensational has occurred in connection with Astronomical Science during the year which has just ended, 1886 has not closed without leaving a record of much valuable work, accomplished both in practical and theoretical astronomy. We propose, then, according to our annual custom, to give here a short précis of the most noteworthy additions to our knowledge of the heavens which have been made during the past twelve months, and of such cognate matters as may be held to be interesting to astronomers generally.

Everyone is familiar with the investigation of the motion of the fixed stars in the line of sight which has been carried on by the aid of the spectroscope by Huggins and Seabroke, and much more thoroughly at the Royal Observatory at Greenwich. The observations thus obtained have been discussed by Herr Homan for the purpose of determining the direction of motion of the Solar system in space; as also the rate at which it is travelling. Taking first the Greenwich stars, he finds that they indicate that the apex of the Solar motion lies in R.A. 21h. 20m. 24s. and Dec. 41·2° N., a point upon a line joining and σ Cygni, at a distance of nearly two- hirds of the way towards th e last

named star. Discussing the observations of Huggins in like manner, he finds that the point towards which the Sun seems to travel lies in R.A. 20h. 38m., and in 69·7° North Declination; while lastly, the very few of those made by Seabroke give us the resulting position of this point as R.A. 18h. 35m. 12s., and Declination 13·6° North, which places it in that blank region in Serpens, west of ε and ζ Aquilæ. It will be noted that all three of these points differ pretty widely from those previously determined from the proper motion of the stars by Herschel, Argelander, Struve, Mädler, Airy, and Dunkin, which latter were all situated in Hercules; the two Greenwich astronomers placing it at the apex of a practically equilateral triangle, whereof λ and μ Hercules formed the extremities of the base. Homan adopts 18·6 miles per second as the most probable rate of movement of the Solar system in space as derived from the spectroscopic indications of stellar approach and recession.

The additions to our knowledge of the physical structure of the Sun and his surroundings derived from the observations of the Total Solar Eclipse of August 29th are but meagre. The person whose name was most prominently mentioned in connection with the English expedition to the West Indies neither saw nor did anything. Mr. Maunder and Father Perry were somewhat more fortunate; while Prof. Tacchini succeeded in showing that certain prominences seen on the sun's limb during totality can not be rendered visible by the spectroscope after the eclipse is over. He also observed the spectrum of Prof. Young's "flash," tracing it to a considerably greater height than that to which it had previously been seen to extend.

In connection with this eclipse, perhaps this will be the most convenient place to mention that Capt. Darwin's photographs would appear to have set at rest the question of the possibility of photographing the Corona of the uneclipsed sun. We mentioned last year (Vol. XLII. p. 352) that Mr. Woods was experimenting on this subject in the Southern Hemisphere. We are now in a position to add, with purely negative results. Captain Darwin, however, by a series of negatives taken before, during, and after the eclipse, has shown quite conclusively that the Corona cannot be photographed under ordinary circumstances at all. Disappointing as this result is, it was the means of eliciting a letter from Dr. Huggins, which, for dignity and impartiality, formed the strongest possible contrast to the utterances of another scientific man (we are bound to admit of much inferior reputation, though) on the explosion of his hypothesis of the terrestrial origin of the corona itself.

Although made some time previously, Prof. Langley's observations on the temperature of the Moon's surface have only been published during the last year. He comes to some conclusions so remarkable as almost to throw doubt upon the trustworthiness of the instrument he employs—the "bolometer"—whose hypersensitiveness is so excessive as to render it susceptible to the slightest and most distant change of temperature. This must, as it seems, introduce a large element of uncertainty into the determination of the source of the heat rendered perceptible by its indications.

There is very little new that is of interest to note in connection with the components of our Solar System. The great Red Spot on Jupiter, which has for some years formed so conspicuous a feature on his surface, has been, in a strangely blanched condition, systematically observed by the possessors of large telescopes during his apparition of the past year. Seven new members have been added to those already known to exist in the rings of planetoids which revolve between Mars and Jupiter, thus bringing the number up to 260. Palisa had the honour (?) of discovering five of these; while Luther and Peters (more venially) only found one a-piece.

No less than six comets have made their appearance in the heavens since the 1st of last January. The first three were, singularly enough, all discovered by Brooks at the Red House Observatory, Phelps, N.Y.; *a* was seen on April 27; *b*, three days later; while *c* was detected on May 22nd; Winnecke's periodical comet (*d*) was picked up at the Cape on August 20th; while on Sept. 26th Finlay, at the Cape Observatory, found *e*. Finally, Barnard, at Nashville, U.S., and Hartwig at Kiel, independently discovered the sixth comet (*f*) on the nights of Oct. 4th and 5th respectively. The last-named object is visible to the naked eye after sunset, as we write, although it has passed its brightest phase, and is diminishing in splendour.

Gore's new star in Orion, the discovery of which he announced last year (ENGLISH MECHANIC, Vol. XLII. p. 351) turns out to be merely a variable one with a period of about a year. At the beginning of July, 1886, it had diminished to the 12½th magnitude; by October 29th it had increased again to the 8½th magnitude, and it attained its greatest brightness during the first half of December.

The perturbations caused in the orbit of Encke's comet during its apparition in 1878, by its proximity to Mercury, have enabled M. Backlund to make a fresh determination of the mass of that planet. It is considerably larger than any previously obtained, amounting, in fact, to 1-2,668,700th of that of the sun. Herschel gives the mass of Mercury as 1-4,865,751th; Chambers as 1-4,862,134th; and Newcomb as 1-5,000,000th; while Le Verrier and Von Asten (especially the latter) made it smaller still.

Early in the year, M. Loewy read a paper before the Académie des Sciences in Paris, in which he described a singularly ingenious method of determining the constant, and other elements, of refraction. In front of the object-glass of his telescope he places a prism with silvered faces, thus forming two mirrors. It is not difficult to understand how in this way the images of two stars at a great distance apart in the sky can be brought close together in the same field of view of a micrometer. If we suppose, then, that one star is in the zenith and the other just rising, it is obvious that refraction will very sensibly affect their apparent distance apart. Such distance is then determined, and may be called measure No. I. If, now, we wait until the first star has descended, and the second one risen in the sky, until their altitude is equal (when obviously the effect of refraction is at a minimum), the measured distance between the images will, of course, have altered: this we may designate Measure No. II. The comparison of these observations gives the means of determining the amount of refraction with great accuracy. The *sine quâ non* in this clever method of deducing the quantity sought, is that the planes of reflection for the two stars must be absolutely coincident.

The improvement in stellar photography continues, and it would really seem difficult to surpass some of the astonishing charts of certain rich regions of the sky produced by the MM. Henry in Paris. They have succeeded, too, in securing a photographic representation of a nebula near Maia, one of the Pleiades, an object theretofore unseen by any human eye, but which has since been observed both at Nice and Pulkova with the huge instruments in use there. They have further photographed the planets in a most remarkable way, their pictures of Saturn, exhibited at the Royal Astronomical Society, showing Cassini's division in the ring perfectly. And, lastly, amid other miscellaneous work of an equally marvellous character, they have photographed the satellite of Neptune in every part of its orbit. In this country, Mr. Common continues his excellent work, while the Observatories at the Cape and at Rio Janeiro are co-operating with the Brothers Henry in the production of definite series of star charts. We may add that Mr. Isaac Roberts, in this country, has also succeeded in the production of stellar photographs, which give great promise.

Perhaps the two most notable things in connection with the progress of meteoric astronomy in 1886, have been the establishment by Denning of a distinct shifting of the radiant point in the case of the Perseids, and by Denza and Schiaparelli of a similar shifting in the case of the Andromeds; and the establishment by Ranyard of the fact that the meteors of 1885, Nov. 27, instead of radiating from a point, seemed to issue from an elliptical area of considerable extent. It is eminently worthy of attention that the longer axis of the ellipse, as seen from Nice, was some 10° or 12° west of north; the magnetic deviation in the same direction in Europe being a fact familiar to all.

A contribution to Physical Science of the highest interest and importance has been made by Professor Simon Newcomb, of Washington, U.S., in the shape of the publication early in the year of the results of his elaborate and exhaustive series of experiments to determine the velocity of Light. His final conclusion is that light travels in vacuo at the rate of 186,326 miles per second, with a possible error of $\pm$ 18·64 miles. Assuming the velocity of light to be 186,326 miles in a second, and the earth's Equatorial radius to be 3963·29 miles, and further accepting Nyrén's value of the constant of aberration 20·492″, he obtains a solar parallax of 8·794″, which is 0·055″ in defect of that now generally adopted.

"Everything comes" (said Lord Beaconsfield, in "Tancred") "if a man will only wait"; a dictum once more justified by the completion of the object-glass of the Great Lick Equatoreal. The mounting has been undertaken by Messrs. Warner and Swasey, of Cleveland, U.S., for the modest sum of £8,750. Irrespectively of some future needful adjuncts, the instrument, with its mounting, dome, &c., has so far cost £34,347 5s., within a trivial fraction. Let us hope that the additions to our knowledge of the structure of the Universe will afford justification for the unselfish munificence which has provided such an unprecedentedly powerful engine for attacking the problem. No other advance in the construction of astronomical instruments has been made of sufficient importance to demand notice here.

In connection with the Bibliography of Astronomy, the opening of 1886 witnessed the publication of Professor Pritchard's "Uranometria Nova Oxoniensis," in which the magnitude of every star visible to the naked eye, from the Pole to 100deg. N.P.D. was given, as determined by the method of extinction, with the author's wedge photometer. Even admitting, what its author strenuously denies, that the coloured wedge does not afford unerring means of absolute determination, such a catalogue as that of the Savilian Professor must always possess very high value for differential measures of brightness, and so afford great help to the observer of variable stars. A remarkably useful little book to the amateur possessors of equatorially mounted telescopes has been produced by Messrs. L. Clark, F.R.A.S., and Herbert Sadler, F.R.A.S., under the title of "The Star Guide," containing, besides the coordinates and descriptions of nearly 600 objects, excellent lists of test objects, and information on selenography and other subjects of interest to the student.

Three Star Catalogues have been issued during the past 12 months, to which we may

briefly refer. The first is the Pulkowa Catalogue of 3,542 stars for 1855! which, well done as it undoubtedly is, might and should have appeared many, many years ago to have been of much service to the working astronomer. Of the second on our list, the "Second Armagh Catalogue of 3,300 Stars for the Epoch 1875," we need only remark that it is fairly good. With reference to the third on "Astronomical Observations made at the Royal Observatory, Edinburgh," in which—to employ an expressive Americanism—Professor Piazzi Smyth "fools around" no less than 1,675 pages, "the least said the soonest mended." With the last month of the year that well-known serial, *The Astronomical Register* comes to an end after an existence, at once useful and honourable, of 24 years.

What Dr. Huggins so appropriately spoke of as "an infant Hercules," the Liverpool Astronomical Society, has long quitted its cradle, and developed a mighty adolescence, as astonishing as it must be gratifying to those to whom it owes its originally humble inception.

Death has, happily, been once more sparing in his visits to astronomers. Among the best known of those who have passed away may be mentioned Mr. C. G. Talmage, F.R.A.S., observer to Mr. J. Gurney Barclay, at Leyton in Essex, from whose observatory he issued three or four volumes of measures of double stars, &c. His scientific career commenced in the Royal Observatory at Greenwich, whence he was transferred to Mr. Bishop's Observatory in the Regent's Park. He was subsequently in France for three or four years, and on his return to this country went to Mr. Hind (with whom he had formerly worked at Mr. Bishop's) at the Twickenham Observatory, which was the successor of that in the Regent's Park. He left Twickenham in 1865 for Mr. Barclay's Observatory, which he directed until the date of his untimely death. The Rev. S. H. Saxby, who was an earnest and enthusiastic amateur, has also been taken from us. The death, too, was announced, at a very advanced age, of Mr. R. Potter, who was Professor of Natural Philosophy and Astronomy at University College in the days of our fathers, and in August died Dr. R. J. Mann, F.R.A.S., who, when in practice at Ventnor, many years since, wrote a very good little elementary work on astronomy. Of late years, after a lengthened sojourn in Natal, he mainly gave himself to meteorology. On one of his extremely rare appearances at the Royal Astronomical Society—it happening to be the annual one—he was made a scrutineer of the ballot, and gave rise to much subsequent unpleasant discussion by actually taking the whole of the balloting papers away with him when he left Burlington House! Among the deaths, too, we must chronicle that of the Rev. James Pearson, of Fleetwood, who for many years carried on a series of investigations on the tides, accumulating a great store of valuable information with regard to those in his own locality. Another astronomer belonging (like Mr. Potter) wholly to a past generation has gone. We refer to General Boileau, who died in November, at a very advanced age. Very many years ago he was head of the Observatory at Simla. Finally, we may say that the only foreign astronomers of any note whose deaths remain to chronicle were Professor Dorne, of the University Observatory at Turin, and A. Wagner, of the Observatory at Pulkowa.

SUBMARINE BOATS.

SUBMARINE boats are a much older invention than is generally conceived; but they are now coming prominently forward, because there is a useful field for their employment, and also because modern devices have rendered it possible to construct vessels which can be propelled safely beneath the surface of the water. Who first suggested the idea is not known; but it seems well authenticated that in the reign of James I. a Dutchman named Drebbel designed a boat which was actually propelled by twelve oars under the surface of the Thames, the air being revivified by some liquor, the composition of which Drebbel kept a secret. The Marquis of Worcester, in his "Century of Inventions" (1663), refers to a similar invention, and there is a record that a man named Day sank with his submarine boat in Plymouth Sound in 1774. It is, however, to Robert Fulton that we are indebted for the first definite ideas on the subject, for so long ago as 1801 he descended to a depth of 25ft. in the harbour of Brest, and demonstrated the fact that his "plunging boat" could be trusted to take himself and three companions under the water and return to the surface in safety. This boat was named the *Nautilus*, and when beneath the surface was moved 500 yards in about seven minutes, by two men turning the "engine," while Fulton regulated the position of the boat. On one occasion the boat remained beneath the surface for nearly six hours; but nothing in the shape of effective warfare was accomplished when Fulton was persuaded to lend his services to this country, though he did by way of experiment blow up some old vessels with torpedoes. Fulton published his work on the subject, "Torpedo War and Submarine Explosions," in 1810, at New York, in which he shows that a system of harbour defence based on stationary and movable torpedoes is the surest, quickest, and cheapest plan for protecting maritime cities against the naval forces of an enemy. In 1860 a submarine boat was made in France, in which compressed air was utilised for working the propelling device, and also for expelling the water taken in to produce submergence; but this vessel, too, does not seem to have been a success. A submarine boat has, however, been used for some time by the Pacific Pearl Company in carrying out their fishing operations; but it is not intended to serve as a torpedo boat, being flat-bottomed, with "doors" in the bottom, through which the oysters can be collected. Toselli's submarine exploring vessel, which we illustrated in No. 1,017, p. 57, is a fairly perfect device for diving, but has no means of propulsion; it is, in fact, an elongated diving-bell, with reservoirs of compressed air and two or three stories. Much attention has been devoted to the subject of submarine vessels in Russia, and many experiments were made in that country about twenty years ago; but no practical device of the kind was produced. The inventions of Denayrouse and Fleuss, which disclosed a method of carrying sufficient air to enable a man to breathe either in the ways of an exploded coal-mine or beneath the water, gave an impetus to the search for a submarine boat, and modern inventions in connection with electricity have helped to place the scheme on the road to ultimate success. A few years ago two submarine boats were built at Liverpool from designs by Mr. Garrett, who employed chemicals to revivify the air and render it respirable over and over again; but the most successful of these boats was lost off the Welsh coast. Since then Mr. Nordenfeldt has turned his attention to the subject, and has lately demonstrated that boats can be propelled for a few hours under water, although not with sufficient accuracy for torpedo work. As mentioned on p. 321 ante, a large and powerful vessel is being built from his designs, and will probably be ready for trial in the spring. Meantime Prof. Tuck is progressing with *The Peacemaker*, which we briefly described on p. 82 ante, and which has since been astonishing those who have witnessed her performances in the Hudson River. Both Nordenfeldt and Tuck employ steam for driving the propeller, the former carrying the heated water in reservoirs, the latter using the Honigmann caustic soda (or potash) boiler. Last week further trials were made with the modern *Nautilus* in the Tilbury Docks. That is a cigar-shaped vessel, 60ft. long by 8ft. in diameter, with a short raised deck in the centre, through which a conning tower projects, and provides access to the interior. The vessel is built of steel plates $\frac{5}{16}$in. thick, with 3 by 3 by $\frac{1}{2}$in. frames 1ft. 9in. apart, and is estimated to be strong enough to withstand the pressure of 50ft. of water. The boat is fitted with two screws, each driven by an Edison-Hopkinson motor at about 750 revolutions, the current being supplied by 104 secondary cells; but owing to the comparatively confined space of the dock, no trials of speed were made. The method of sinking and raising the vessel was designed by Mr. A. Campbell, and consists in a simple method of decreasing or increasing the displacement without affecting the weight of the vessel. This is accomplished by means of four horizontal cylinders on each side of the hull, which can be thrust outwards into the water, or drawn into the hull. The cylinders work through watertight sleeves, and can be moved either by hand or by screws worked by gearing from a shaft, so arranged that corresponding cylinders on each side are pushed out or withdrawn simultaneously. It will be readily understood that if the vessel with water-ballast tanks full and the cylinders within the shell-sinks to the bottom, the extra displacement which can be obtained by thrusting out the cylinders will bring her to the surface, while the tanks will enable her weight and trim to be regulated. Besides a rudder of ordinary pattern, the *Nautilus* has a horizontal fin or rudder for guiding the vessel or preventing a tendency to rise or dive, thus keeping a uniform depth below the surface. It is said that the air contained within the vessel is sufficient for a two hours' submarine trip with a crew of six; but no doubt if other vessels of the kind are constructed, either compressed air will be carried, or some means will be adopted for revivifying the air, as men engaged in such work as submarine torpedo warfare will need clear heads, and must run no risk from air heavily charged with carbonic acid. A patent has recently been secured in this country by Mr. C. D. Goubet, of Paris, for a submarine torpedo boat in which equilibrium is maintained by a pendulum acting through a horizontal bar on a clutch that actuates one portion of a double-action pump, which displaces water from one or the other of two reservoirs at the ends of the vessel. Water-ballast tanks assist in the submergence of the boat, and the motor is driven by electricity supplied from storage batteries. The screw propeller is movable, so as to be capable of giving the vessel an oblique direction in any sense in relation to the vessel's axis while having a regular continuous rotary motion. The vessel can thus be guided without a rudder, and can perform various evolutions. The torpedo is placed at the after part of the vessel, and is connected to an insulated wire wound on a drum. The crew enter an opening at the top closed by a dome, and sit on a compressed air reservoir from which air is taken and moistened by being caused to pass into the water compartments, whence it is discharged by a pipe into the dome. The vitiated air is constantly expelled by an air-pump. The torpedo vessel is fitted in front with a cutter or spike which can be projected forward several feet; it is worked by a lever, and serves to cut torpedo wires or nets. An obturator tube serves to discharge signal cartridges which, on reaching the surface, explode, and thereby give an indication to the ship with which the torpedo vessel is connected. A special arrangement enables this vessel to be propelled also by means of oars. We are not aware that any trials have been made with this vessel, or whether one has been constructed; but we may rest assured that it is only one of many patents which will be taken out for vessels and machines adapted to submarine navigation for the purposes of warfare.

LORRAIN'S IMPROVEMENTS IN ELECTRIC TELEPHONY.

THE improvements which Mr. J. G. Lorrain, of Norfolk-street, W.C., has introduced in connection with electric telephony form the subject of a patent. The object is to construct a long-distance system of electric telephony, and to overcome or avoid the difficulties produced by induction. The invention consists of an instrument capable of acting either as a transmitter or as a receiver. When acting as a transmitter it fulfils the usual function of a transmitter in telephony—namely, that of producing under the influence of sound-waves rapid variations of current in a conductor or

system of conductors; and when acting as a receiver it fulfils the usual function of a receiver in telephony—namely, that of producing under the influence of variations of current mechanical vibrations of the air or sound-waves similar to, and uniform with, those which actuate the transmitter. In carrying the invention into effect, the patentee employs an instrument which consists essentially of two conductors and a screen. The two conductors are arranged in proximity to one another, and the screen occupies a position between them. In one form of the instrument the two conductors are fixed, and the screen is movable. In another form the screen is fixed, and the two conductors are movable. In a third form the screen and one of the conductors are fixed, and the other conductor is movable. In a fourth form one of the conductors is fixed, and the other conductor as well as the screen is movable. The patentee prefers to attach the movable part or parts of the instrument to a diaphragm serving the usual purpose of a diaphragm in telephony; that is in order to concentrate or increase the effect of the sound-waves upon the movable part or parts when acting as a transmitter, and when acting as a receiver to concentrate or increase the effect of the movable part or parts upon the air so as to produce sound-waves or air-pulsations. The said conductors may be arranged in any convenient manner. One convenient manner of arranging them is in spirals or coils, and such spirals or coils may be flat, straight, or annular. The several parts of the instrument are so disposed with regard to one another that when in action the extent of surface of one conductor exposed to or screened from the other will vary according to the vibrations of the movable part or parts.

When used as a transmitter the instrument is connected up in such manner that one of the two conductors shall be in circuit with a battery, or other source or reservoir of electricity, so that a current shall pass through this conductor; and the other conductor is connected to the main circuit. When used as a receiver, the instrument is so arranged that one of the conductors is in connection with the main circuit and the other conductor is closed upon itself by putting its two ends in electrical connection with each other. For convenience of description, that conductor is called the primary through which the current from the battery or other source or reservoir of electricity is passed, and that the secondary one which is connected to the main circuit—that is in the case of a transmitter; but in the case of the receiver that is called conductor the primary which is in connection with the main circuit, and the secondary the one which is closed upon itself. By the term "main circuit" is meant the circuit connecting the two stations between which telephonic communication takes place, and which may consist of any of the usual forms of circuit—such, for example, as a metallic circuit or a line and earth circuit. The action of the invention is as follows:—Let us take the case where the two conductors are fixed and the screen, in this case attached to a diaphragm, is movable. The sound-waves impinging on the diaphragm of the transmitter will cause the screen to vibrate in such manner as to vary the amount of surface of the secondary conductor exposed to the inductive influence of the current in the primary conductor, and so vary the energy of the induced current transmitted through the main circuit. The variations of current passing through the primary conductor of the receiver will cause variations in the current induced in the secondary conductor, and these variations will cause the screen to move in unison with such variations, and so cause vibrations in the diaphragm which will produce sound-waves similar to and uniform with those which actuate the transmitter. From this description the action of the invention in the case of the other forms of instrument will be readily understood. In all these forms the effect is the same, whichever parts are fixed and whichever movable—the amount of the one conductor screened from the other will vary with the sound-waves in the case of the transmitter, and with the electric undulations or variations of current in the case of the receiver. To increase the inductive action of one coil upon the other, the patentee sometimes employs a core or cores or mass or masses of iron or other magnetic material (but preferably iron); and such a core or mass is called an "intensifier." To gain increased effect the several parts of the instruments are sometimes multiplied for the purpose of transmitting signals, instead of actuating the transmitter by means of sound-waves, tapping on the diaphragm where such exists, or tapping on the screen itself is sufficient.

Figs. 1 and 2 show diagrammatically one form

FIG. 1.

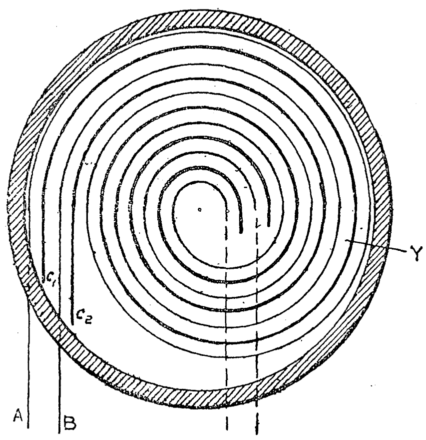


FIG. 2

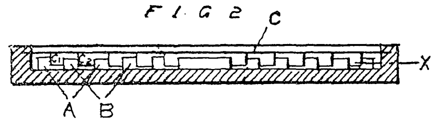

of the invention. The primary coil A and the secondary coil B are formed of thin ribbons of metal wound each in a flat spiral as shown. C is a vibrating diaphragm having attached to it the screens c^1 c^2, which interpose more or less between the primary and secondary coils as the diaphragm vibrates. Sometimes in this form of instrument the patentee dispenses with the second screen c^2, and replaces it by a fixed strip of iron acting as an intensifier. Fig. 1 is a sectional plan on line X, and Fig. 2 a section on line Y. These figures show the instrument as a transmitter. In practice the patentee prefers to use two instruments at each station, one connected up as a transmitter, and the other as a receiver; but he sometimes uses only one instrument at each station; and when this is the case employs a switch, which, when the instrument is to be used as a transmitter, places the primary conductor in circuit with the battery, and connects the secondary conductor with the main circuit; and which, when the instrument is to be used as a receiver, places the primary conductor in connection with the main circuit, and closes the secondary conductor upon itself.

ASTRONOMICAL NOTES FOR JANUARY, 1887.

With the advent of a New Year we shall, in accordance with a now annual custom, give such an explanation of the various tables of which these Notes are made up as shall enable the amateur observer to employ them intelligently and beneficially. To this end we append, wherever it seems necessary, numerical examples worked out at length; and in the case of the lists of Occultations of Stars by the Moon, and of the times of the Greatest Eastern Elongation of Saturn's Satellites, furnish illustrative woodcuts of the methods of measuring the position angles at the disappearance and reappearance of the stars, and of the position of each of the satellites, at the times given in our tables respectively.

In the table which immediately follows, the second column gives, for every fifth day, the instant which should be shown by a clock at Greenwich, regulated to exhibit Mean Time, when the Sun is due South or on the Meridian, and a sundial marks 0h. 0m. 0s. What is called "The Equation of Time" in the almanacs, or the amount to be added to—or subtracted from—the instant of Apparent or Solar Noon, is calculated for the Meridian of Greenwich, but may, without any practical error, be employed for any other station in the United Kingdom; inasmuch as Valentia is only 41m. 23s. West of Greenwich, and the variation in the Equation during one hour is only 1·18sec. on January 1st—a quantity which further dwindles to 0·37sec. by the 31st of the month; and, notoriously, no sundial ever constructed can be read with anything like this amount of accuracy. Columns three and four give the Right Ascension and Declination of the Sun when a Mean Time clock at Greenwich marks 0h. 0m. 0s.; while column five shows the Right Ascension of the Meridian, or Sidereal Time, at the same instant.

The Sun.

Day of Month.	Souths.	At Greenwich Mean Noon.		
		Right Ascension.	Declination South.	Sidereal Time.
	h. m. s.	h. m. s.	° ′ ″	h. m. s.
1	0 3 46·69 PM	18 47 4	23 0 39	18 43 17·08
6	0 6 3·64 „	19 9 3	22 30 9	19 2 59·87
11	0 8 8·55 „	19 30 51	21 48 35	19 22 42·65
16	0 9 58·76 „	19 52 24	20 56 26	19 42 25·43
21	0 11 32·18 „	20 13 40	19 54 17	20 2 8·21
26	0 12 46·77 „	20 34 38	18 42 52	20 21 50·99
31	0 13 41·00 „	20 55 15	17 22 58	20 41 33·77

The last-named quantity (the Sidereal Time at Mean Noon) is very often required by the observer for the instant of Local Mean Noon at his own station, and this may be obtained by the addition of 9·8565 seconds for every hour (and proportional parts for minutes and seconds) of Longitude when the place of observation is to the West of Greenwich, and by their subtraction when it is East. For example: What is the Sidereal Time at Mean Noon at Armagh on January 6th? Armagh is 26m. 35·5s. West of Greenwich; so we say 60m. : 26m. 35·5s. : : 9·8565s. : (what we shall find to be) 4·37s. We see from our table that the Sidereal Time at Greenwich Mean Noon on January 6th is 19h. 2m. 59·87s., and if to this we add, according to the precept (Armagh being West), 4·37s., we obtain 19h. 3m. 4·24s. as the Sidereal Time at Armagh Mean Noon on the date specified. Or let us take a station like Canterbury, which is 3m. 28s. East of Greenwich; then, as before, we say 60m. : 3m. 28s. : : 9·8565s. : 0·57s. If, then, we wish to know the Sidereal Time at Canterbury Mean Noon on January 26th, we simply subtract 0·57sec. from 20h. 21m. 50·99s., with the result that we find it to be 20h. 21m. 50·42s.

At 8 p.m. on January 2nd the Sun is said to be in Perigee; in other words, the Earth is in that part of her orbit which approaches the closest to him, and his apparent angular diameter is at its maximum. Accepting Newcomb's determination of the Equatorial Horizontal Solar Parallax (8·848″) and Colonel Clarke's measurement of the Earth's Equatorial Radius (3963·296 miles), there is, at that instant, an interval of 90,842,922 miles between the centre of the Sun and that of our own Globe. Days, and almost weeks, now pass without the appearance of any perceptible spots on the Sun's surface, whence it would appear that we cannot be far distant from a minimum period.

The Moon

Enters her First Quarter at 20·5 minutes after Noon on January 2nd, and is Full at 10h. 32·3m. on the night of the 9th. She will enter her Last Quarter at 3h. 22·0m. p.m. on the 16th, and be New at 3h. 1·1m. a.m. on the 24th.

Day of Month.	Moon's Age at Noon.	Souths.
	Days.	h. m.
1	7·1	5 29·6 p.m.
6	12·1	9 19·0 „
11	17·1	1 8·6 a.m.
16	22·1	5 41·0 „
21	27·1	9 57·9 „
26	2·4	2 0·1 p.m.
31	7·4	5 33·5 „

The Moon will be in Conjunction with Saturn at 11 p.m. on the 9th; with Jupiter at 3 a.m. on the 17th; with Mercury at 8 a.m. on the

Occultations of (and near approaches to) Fixed Stars by the Moon.

Day of Month.	Name of Star.	Magnitude.	Disappearance.	Moon's Limb.	Angle from N. Point.	Angle from Vertex.	Reappearance.	Moon's Limb.	Angle from N. Point.	Angle from Vertex.
			h. m.		°	°	h. m.		°	°

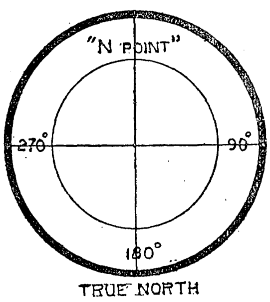
23rd; with Venus at the same hour on the 25th; and with Mars at 11 o'clock at night on the same day.

The following table gives the approximate Mean Time at which the stars whose names it contains will disappear and reappear at the Moon's Limb as viewed from Greenwich, and the points on that limb at which the phenomena will occur as seen in an inverting telescope. As probably everyone knows who will read these lines, the Moon travels from West to East through the sky. Hence, in her passage over such stars as lie in her path, her Eastern limb occults them, and they reappear at her Western limb. The "Angle from North Point" in our table means the arc included between the star when in contact, and that point of the Moon's limb cut by a circle passing through the North Pole and her centre. The "Angle from Vertex" is measured from a point where a circle through the zenith and the Moon's centre cuts her limb. The former is employed with the Equatoreal; the latter with the Altazimuth instrument. In the familiar case of the measurement of double stars, the initial point of the circle of reference is the true North—or bottom—of the field of view of the micrometer, and the angles are measured thence in the directions North following, South following, South preceding, and North preceding back to North again, or in a direction opposed to that of the hands of a watch. In the case of Lunar Occultations, however, a precisely opposite method is adopted, and angles are measured from the true *South* point of the Moon's limb, absurdly called the "North Point," because it is at the top of the field of view in an inverting eyepiece. Moreover, the direction of measurement is changed, too, and follows the same course as do watch-hands in their diurnal revolution. A diagram will make



this intelligible. The outer circle in the one above represents the field of view of a telescope, while the inner one may be conceived to show the Moon's disc with the angles as measured marked round it. We may add that the "North Point" and "Vertex" of the Moon coincide for the instant that the Moon is on the Meridian, but diverge widely when she is far to the East or West of it, as anyone may see by bisecting her image by a plumb-line at the time of her Transit, and again three or four hours afterwards. In the case of "Near Approaches," we give the *true* point of the Moon's limb to which the star most closely approximates; and we do so because she is so comparatively close to the earth, that while she may pass clear of the star as seen from Greenwich, she may pass over it as viewed from other stations in the British Islands. For example: If we suppose that, as regarded from the Royal Observatory, her South limb just passes North of a given star, she may well occult it to an observer in Yorkshire, and *vice versâ*. As we have said above, it is the Eastern or advancing limb of the Moon at which stars disappear, and as from New Moon to Full Moon this is dark, disappearances between these phases occur at the dark limb and reappearances at the bright one—a condition of things precisely reversed between Full and New Moon again.

Mercury

Is a Morning Star throughout the month, and from his great South Declination is about as badly placed for the observer as he can be. He rises, however, soon after half-past 6 a.m. at the beginning of January, so that he may possibly be glimpsed above the S.S.E. part of the horizon before sunrise about this time. His diameter remains pretty constant during the month at a very little over 5".

Day of Month.	Right Ascension.	Declination South.	Souths.
	h. m.	° ′	h. m.
1	17 20·5	22 24·5	10 37·4 a.m.
6	17 50·7	23 22·2	10 47·9 „
11	18 22·7	23 53·7	11 0·1 „
16	18 55·8	23 54·8	11 13·5 „
21	19 29·8	23 22·8	11 27·8 „
26	20 4·4	22 15·6	11 42·6 „
31	20 39·4	20 31·8	11 57·8 „

Starting thus from the most Southerly part of Ophiuchus, Mercury travels across Sagittarius and into Capricornus. He does not, however, approach any conspicuous star in either of these constellations.

Venus

Is an Evening Star, but is barely visible before the end of the month, when she may possibly be caught twinkling close to the horizon, over the S.W. by W. part of it, after sunset. Her practically circular little disc increases imperceptibly in diameter from 9·8" at the beginning of January to 10·2" by the end of it. She is wholly destitute of interest as a telescopic object, though, at present.

Day of Month.	Right Ascension.	Declination South.	Souths.
	h. m.	° ′	h. m.
1	19 18·0	23 13·2	0 34·7 p.m.
6	19 45·1	22 23·4	0 42·0 „
11	20 11·8	21 16·6	0 48·9 „
16	20 38·0	19 54·0	0 55·4 „
21	21 3·6	18 16·9	1 1·3 „
26	21 28·8	16 26·9	1 6·7 „
31	21 53·4	14 25·4	1 11·6 „

It will be seen, from the above ephemeris, that the path of Venus during January lies across Sagittarius and Capricornus, and terminates in Aquarius. As in the case of Mercury, the part of the sky through which she travels is free from conspicuous stars.

Mars,

For the observer's purpose, is now quite invisible.

Jupiter

Is a Morning Star all through January. As he does not rise until between 2 and 3 o'clock in the morning on the 1st, nor even on the 31st until half an hour after midnight, crossing the Meridian on those days at 7h. a.m. and 5h. 33·2m. a.m. respectively, we shall defer our ephemeris of him until next month. He is in quadrature with the Sun at 4 a.m. on the 25th.

Saturn

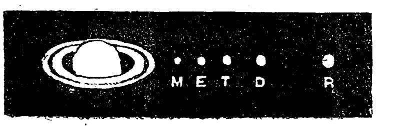
Is visible all night long, and, coming as he does into opposition to the Sun at 2 p.m. on the 9th, is most excellently placed in every way for the observer. The slight closing up of his ring

system will be perceptible to anyone who remembers the aspect of Saturn in 1885, and it will be noted that the South Pole of the planet now covers Cassini's division, and even barely projects beyond the ring A. His equatorial diameter is 18·4″ at the beginning of January, and increases to 18·6″ during a few days of the second week of it—only, though, to return subsequently to its pristine dimensions.

Day of Month.	Right Ascension.	Declination North.	Souths.
	h. m.	° ′	h. m.
1	7 25·1	21 49·1	12 39·7 p.m.
6	7 23·3	21 53·2	12 18·3 „
11	7 21·6	21 57·9	11 56·9 „
16	7 19·8	21 1·1	11 35·5 „
21	7 18·1	22 4·8	11 14·1 „
26	7 16·5	22 8·4	10 52·8 „
31	7 14·9	22 11·8	10 31·7 „

The short retrograde arc indicated by the above ephemeris begins at a point somewhat to the East and just to the South of δ Geminorum, towards which star Saturn is travelling, and to which he approaches so closely as to be in the same telescopic field with it at the end of the month.

The table (p. 383) gives the approximate times at which the five inner satellites of Saturn will be at their Greatest Elongation East of the planet and visible at Greenwich, and is intended to enable the student to identify them. The subjoined diagram (drawn to scale) shows the exact positions which they severally occupy at the times specified.



Titan is so prominent an object (shining as he does as a star of the 8th magnitude) as to be visible in the smallest telescope; while Iapetus describes so large an orbit as to be easily identified, especially when at its brightest to the West of the planet. Hyperion is hopelessly beyond the optical power of any of those who will be likely to employ these Notes; and even Mimas is invisible in any instrument less than one of between 6in. and 7in. aperture.

Uranus

Is a Morning Star; but as he does not rise until after midnight at the beginning of January, and between 10 and 11 p.m. at the end of it, we shall defer our ephemeris of him until March. He is in quadrature with the Sun at 2 a.m. on the 3rd.

Neptune

May still be well seen during the earlier hours of the night, but should be looked for as near to the time of his meridian passage as is convenient.

Day of Month.	Right Ascension.	Declination North.	Souths.
	h. m.	° ′	h. m.
1	3 33·7	17 24·4	8 49·0 p.m.
6	3 33·4	17 23·4	8 29·0 „
11	3 33·1	17 22·7	8 9·0 „
16	3 32·8	17 22·1	7 49·1 „
21	3 32·7	17 21·7	7 29·3 „
26	3 32·5	17 21·6	7 9·5 „
31	3 32·4	17 21·6	6 49·7 „

From which it will be seen that Neptune continues in a blank part of the sky some $6\frac{1}{3}$° South, and very slightly to the West, of the Pleiades.

Shooting Stars

May be looked for on the nights from the 1st to the 3rd inclusive, and again from the 15th to the 19th.

Greenwich Mean Time of Southing of Seventeen of the Principal Fixed Stars on the Night of January 1st, 1887.

Star.	Souths. h. m. s.
α Andromedæ	5 18 22·97 p.m.
α Cassiopeiæ	5 49 51·47 „
β Ceti	5 53 39·11 „
Polaris	6 33 27·51 „
α Arietis	7 16 19·58 „
α Ceti	8 11 44·72 „
α Persei	8 31 35·36 „
γ¹ Eridani	9 7 58·80 „
Aldebaran	9 44 33·77 „
Capella	10 23 22·20 „
Rigel	10 24 7·58 „
α Leporis	10 42 42·99 „
α Orionis	11 3 57·88 „
Sirius	11 54 56·50 „
Castor	12 42 1·93 „
Procyon	12 48 0·68 „
Pollux	12 53 0·71 „

Were the stars rigidly and absolutely "fixed," any given one would South 3m. 55·91s. (or 235·91sec.) sooner every day, as indicated by a clock regulated to show Mean Time. This is so nearly true with a large proportion of them that, for our present purpose, we may assume it to be accurately so, and to find the Greenwich Mean Time of Transit of either of the stars in the above list for any other night in January we have only to multiply 235·91sec. by the number of days which have elapsed since the beginning of the month (i.e., by the day of the month − 1), and subtract the result given in our table. For example: At what hour will α Arietis South at Greenwich on the night of January 11th, 1887? 11 − 1 = 10 and 10 × 235·91sec. = 2359·1sec., or 39m. 19·10sec. If, then, we take 39m. 19·10s. from 7h. 16m. 19·58s., we get 6h. 37m. 0·48s. as the Greenwich Mean Time of Southing of α Arietis on the night of January 11th. This differs 0·14sec. from the actual instant of Transit—a nearly inappreciable result. This discrepancy would, however, have been greater in the case of Polaris, though so slowly does that star cross a wire that it might even then be neglected. Let us now suppose, though, that we wish to ascertain the Local Mean Time of Southing of any one of the stars in our table. This we may do by subtracting 9·8565sec. for every hour of Longitude (and proportional parts for the minutes and seconds) when our station is West of Greenwich, and adding that quantity when our Longitude is East. For example: At what hour in Dublin Mean Time will Capella South in that city on the night of January 1st, 1887? Dublin is 25m. 22s. West of Greenwich; so, as in the example computed under the head of "The Sun" above, we say as 60m. : 25m. 22s. : : 9·8565s. : 4·17s.; and subtracting this quantity, according to the precept (Dublin being West), from 10h. 23m. 22·20s., we get 10h. 23m. 18·03s. as the instant when Capella will be on the Meridian of the observatory of that city. Had we been dealing with a station having East Longitude, like Dover or Yarmouth, the quantity found by proportioning must, of course, have been added to the time given in our table.

SIMPLE EXERCISES IN TECHNICAL ANALYSIS.—XVIII.

By an Analytical Chemist.

Olive Oil.

(239.) On account of the high price of olive oil, and the importance of the uses to which it is applied, its analysis deserves special attention. The young analyst should make himself familiar with the physical properties of the several varieties found in the market. Indeed, in the examination of oils there is often a great deal of time saved by a judicious exercise of the eye, the nose, and the tongue. Opportunities for studying the taste, odour, and colour of the several oils, and varieties of oils, in the market should be sought, therefore, by all who desire to attain proficiency in this branch of analysis.

(240.) Olive oil when pure and fresh is almost free from odour; but in inferior qualities the smell is rather unpleasant. The taste is agreeable and free from that fattiness which characterises the oils of animal origin. The colour is greenish yellow; but the green is often more strongly marked in inferior samples.

(241.) *Sp. Grav.*—Unfortunately, authorities differ as to the limits for genuine oils, and the published figures of experienced analysts have so far shown that some of these limits are slightly in error. As the test is of some importance, and as it is desirable that future standards should be adopted in the light of wider experience, our results are given in full:—

Sp. gr. ·913	1·5 per cent.	(adulterated)
·914	6· „	„
·915	18· „	„
·916	39· „	„
·917	27· „	„
·918	2· „	„ } (adulterated)
·919	3· „	„ }
·921	2· „	„ }
·927	1·5 „	„ }

Those marked "adulterated" were found to be so by other tests, although when the gravity even slightly exceeds ·917 the purity of the sample is very doubtful. The gravity test alone, however, should never be relied upon, for samples are occasionally met with of a correct gravity produced by a judicious addition of oils lighter and heavier than the particular kind it is intended to counterfeit. Indeed, it is very desirable to bear constantly in mind that correct conclusions about oils can only be arrived at by a consideration of the results of several tests, such as those described in Art. 216. Many mistakes are made by placing too much reliance on one or two tests, however rigid their nature, unless such tests are sufficient to determine the suitability or unsuitability of an oil for a particular purpose. Even pure oils vary so much in quality that they occasionally fall without the recognised limits of a certain test; but show no other indications of adulteration.

From the above table the limits of ·914 and ·917 would appear to include the majority of genuine samples.

(242.) *Rise of Temperature.*—The figures given in tables showing results by this test vary somewhat, owing to the different conditions under which the test is performed. Some analysts weigh both oil and acid, some the oil alone, some take no precautions that the acid is of the correct gravity (1·845), and all do not use the same proportions of oil and acid, nor make the experiment in the same kind and size of glass vessel. An analyst with long experience can construct a comparative table for himself; but, wanting this, he must be dependent upon those supplied by Maumené (the originator of the test), Allen, and others. In large laboratories, it will probably be found more convenient to measure both oil and acid as described in Art. 218; and, as the densities of oil do not vary very much, the proportionate weights of oil and acid will be approximately constant. The advantage of using the same vessels in all experiments is that the same amount of heat is absorbed by them.

So far as my own experience goes, I have found that 25 per cent. of the samples of olive oil gave a rise of temperature of from 65° to 69° F; and *twenty-five* per cent. a rise of from 72° to 76° F. These represent two qualities—the lower figures the kind known as Lucca, the higher figures the inferior kind sold as Gallipoli. For the latter, the lowest rise obtained was 73° F., while the specific gravities of the several samples lay almost without exception between ·915 and ·916. But although the gravities were so uniform, the rise of temperature varied considerably, and reached as high as from 84° to 106° F., while the gravity did not exceed ·916. When the rise of temperature amounts to 84° it indicates adulteration; when it goes above that and approaches 106°, adulteration is certain; and when the gravity is not excessive tke adulterant used is probably colza oil. In one instance the rise of temperature was 116° F., and the gravity ·921, indicating poppy-seed or cotton-seed oil as the adulterant. This test is the more valuable in the case of olive-oil, since the rise of temperature of any of the adulterants ordinarily used is higher than that of the pure oil itself.

(243.)—*Solidifying Point.*—Olive oil begins to solidify at or above the freezing point. Some analysts observe the temperature at which the fat becomes solid, others that at which the fat begins to deposit. As it is not easy to determine the temperature at which a

fat is entirely solidified, we think that the latter method is to be preferred. It is always necessary to lower the temperature below that at which the oil begins to solidify for the purpose of ascertaining whether the bulk of the oil is or is not changed into fat within a few degrees of that temperature. Unless this is done, the fat deposited may be due to the presence of an adulterant having a higher solidifying point. The temperature at which the oil becomes clear again is also observed, as it usually helps to check the solidifying point. Rape, lard, nut, and poppy oils, especially the two latter, prevent the deposition of fat until the temperature falls below 30° F. If no fat is deposited before 20° F. is reached, adulteration may be suspected.

There is one other remark necessary in connection with this test. In cooling, as much oil as can be spared should be used. The temperature should be lowered gradually, and the oil constantly stirred the while. If the temperature be made to fall very rapidly by means of such a mixture as ice and salt, the fat will not be deposited until the temperature falls considerably below the correct solidifying point. A good plan for oils that solidify above the freezing point is to place the bottle in an ice-chest near a block of ice for a night. For olive oil this answers very well.

(244.) *Elaïdin Test.*—Olive oil, being non-drying, is converted into a firm, yellowish, white solid by this test, which gives fairly uniform results when applied as described in Art. 220. There are other ways of applying it, but this we have found answers very well in general practice. Two things have to be particularly observed: (1) the colour of the solidified mass; (2) its consistency. The time required for complete solidification is also of importance, and should be observed whenever possible. But it varies in the same oils according to the temperature at which the experiment is performed, and is longer when applied in the way recommended here—so long that some oils require to stand overnight. The time for solidifying is considerably increased by the presence of drying oils, such as poppy and nut, and to a less extent by the semi-drying cotton-seed oil. Any variation from the colour or the consistency would indicate adulteration. Rape or colza changes the colour more or less to orange red, according to the quality and quantity of the adulterant.

(245.) *Acidity.*—The amount of free acid should always be determined in olive oils, especially when they are to be used for lubricating. It is determined as described in Art. 230 (*d*), and when calculated as acetic acid varies from 0·03 to 0·64 per cent. Samples quite free from acid are rarely met with. Oils with the smaller amount of free acid attack copper, those with the higher amount much more so. The latter are quite unsuitable for the lubrication of delicate machinery. The acidity increases with the age of the oil, and in consequence of this, ordinary olive oil is growing more and more into disfavour as a lubricant.

(246.) To test the action of the oil upon copper, a few drops are placed on a sheet of copper the surface of which has been newly cleaned by rubbing with fine emery paper. The sheet is then placed horizontally (oiled side uppermost) in a clean white porcelain basin and left for twenty-four hours. The sheet is then tilted so that the oil may drop into the basin, and by means of a few drops of ether, the adhering oil is washed off the sheet completely. If the oil attacked the copper, the recently-covered part of the surface will be brighter, and the oil will have a distinct green colour. The fact will be more evident if there be added to the oil in the basin two or three drops each of acetic acid and solution of potassic ferrocyanide, to form the reddish brown precipitate of ferrocyanide of copper. The copper is affected by the oil in proportion to the amount of free acid in the latter.

(247.) *Colour Tests.*—With sulphuric acid, as in Art. 230 (*e*) olive oil forms a clear yellow clot; a violet shade would indicate cotton-seed oil, and a green or slaty shade colza. When violet shades are produced, the rise of temperature with sulphuric acid is usually very high.

(248.) In addition to the above, other colour tests may be applied in particular cases; but the purity of a sample can be determined from them alone. The viscosity test is also useful; but more will be said of it in connection with lubricating oils.

Other special tests, which would be out of place here, will be found in the textbooks.

(*To be continued.*)

LIQUID FUEL.

THOSE who believe that petroleum is to be the fuel of the future have the courage of their opinions, and lose no opportunity of advancing its claims. On November 10th two papers "On the Use and Transport of Liquid Fuel," by Messrs. G. B. Nicholl and J. Gravell, incorporated and taken as one, were read before that admirably-managed society, the North-East Coast Institution of Engineers and Shipbuilders. With the latter portion of the paper—that on the carriage of petroleum in suitable steamers—we do not propose to deal; we shall confine our attention to Mr. Nicholl's statements. He spoke in somewhat general terms of the efficiency of petroleum as a steam generator compared with coal. He sets it down as being competent to evaporate in practice twice as much water per pound as coal can evaporate. But in doing this he multiplies the theoretical efficiency of coal by ·7, while he uses ·9 as a factor in dealing with petroleum. This he justifies on the ground that the combustion of the latter is perfect, while the combustion of the former is not; and also on the assumption that less air is required to burn petroleum without smoke than will suffice to secure the smokeless combustion of coal. This, we think, postulates rather too much; yet we are content for the sake of argument to concede that a ton of petroleum will do as much work as two tons of coal. In this country the cost of petroleum is, of course, fatal to its adoption. It costs as much for freight alone in any north-country port as coal would cost per ton. We have not yet heard that the crude oil can be sold for the price of coal, and its value, whatever it may be, must be added to the freight. If we set the cost of petroleum against that paid for coal, say at Aden, then the comparison is more favourable to the petroleum. But there is a point to be considered which is quite as important as cost; and that is that crude petroleum is not burned in either steamers or locomotives, and it does not appear that it can be so burned. The risk is too great. Crude petroleum is a very composite material. It is really a mixture of a great many hydrocarbons of different specific gravities and igniting points. At one end of the scale we have the benzines—excessively volatile, giving off a gas highly explosive when mixed with air; and at the other end the dead tarry oils which have a comparatively high flashing point and evolve little vapour. We are told a great deal about the working of steamers on the Caspian and the Volga with petroleum, and of its use on South Russian railways. On examination, however, it appears, first, that coal is at prohibitive prices in these regions, and that it is not crude oil that is burned at all, but "astaki"—namely, the dead oil or refuse left in the stills after the crude oil has been refined. It is clear, then, that the supply of suitable oil fuel depends not so much on the oil wells as on the demand for the refined oils; for it would not pay to refine oil and throw away the better portion merely to get as fuel what is now a waste or by-product, of no value whatever. Those shipowners, then, who contemplate fitting up their steamers for this kind of fuel will have to reckon with the possibility of being unable to get astaki when they want it, save at an extravagant price. Furthermore, a ship sailing from England must find astaki here in sufficient quantity to take her, say, to Alexandria, where she can get her further supply to take her to Bombay, let us suppose. At Alexandria we may grant that it will be cheap enough, but what will it cost in England? Obviously the economical course to pursue would be to take coal in her bunkers sufficient to carry her to Alexandria, and fill up there with astaki. But it seems to be generally conceded either that a petroleum-fitted boiler will not do at all for coal; or that the superior advantages of petroleum cannot be realised with a coal-burning boiler. In the course of the discussion on Mr. Nicholl's paper, Mr. J. A. Rowe pointed out that, as no soot was produced, it would be possible to make boilers with much smaller tubes than are now used, so that the total heating surface could be augmented by 50 per cent. This is probably a sound argument; but every sea-going engineer knows that a small tube marine boiler cannot be used with coal.

Mr. Nicholl touched very lightly on the objections to the use of liquid fuel at sea. We do not want it to be supposed that we are in any shape or way opposed to the innovation. On the contrary, we are desirous to see petroleum a success, because there can be no doubt whatever that it is in many respects a most admirable fuel. But, on the other hand, we should not do our duty by our readers if we did not point out the difficulties which stand in the way of its adoption, and thus probably save some shipowners and engineers from loss and annoyance. We have no hesitation, therefore, in calling attention to facts which seem to be readily overlooked or forgotten. They ought to be kept prominently in view in order that they may be overcome. We have already pointed out that crude petroleum cannot be used without peril. This is due to the penetrating powers of the oil. Joints in tanks which are perfectly watertight will pass petroleum freely. The utmost care and special workmanship are needed to make petroleum-tight tanks. Again, all the space above the liquid, as the tanks are emptied, is full of vapour, which will explode like gunpowder if mixed with air and ignited. In the few cases where petroleum has been used at sea the water has been admitted to the tanks. The oil keeps on the top, and the water follows it up, so that there is no space for gas. A very small mistake in dealing with such a fuel as this may entail a possible catastrophe. With astaki, as we have already explained, the case is different. Again, nothing is certainly known as to the true evaporative efficiency of astaki. Mr. Nicholl cites some old experiments of Favre and Silberman on petroleum refuse, which give its theoretical efficiency as 19,794 units, that of coal being 14,000. But "petroleum refuse" is a wide term, and we are not certain that Favre and Silberman ever tested the astaki of commerce. Astaki has the great advantage that a tank will hold it without leaking if it will hold water. No one has said one syllable as to the action which underwriters on the one hand, and the Board of Trade on the other, are likely to take in the matter. Will the former underwrite at ordinary rates? and will the latter grant passenger certificates to steamships burning liquid fuel? These are most important questions, which will have to be answered before any considerable advance can be made in the use of liquid fuel.

There is, furthermore, an objection which may seem small, but is, nevertheless, of considerable importance—namely, the noise produced by the combustion of petroleum. Each furnace makes a thundering roar which must be heard to be realised as regards its magnitude. It is possible that this may be got over. It has not been got over yet. All the systems of burning astaki or petroleum used with success up to the present time are based on Aydon's method, patented many years ago. That is to say, the oil is blown into the furnace in the form of spray by a jet of steam. It has been found highly advantageous, if not essential, that this steam should be first superheated, and the loss of the steam—or rather of the water which it represents—must be made good either on such systems as those patented by Mr. Kirkaldy, or by Mr. Jones, of Liverpool, or else there must be a separate boiler to supply the steam for injection. Of course, these things are not insuperable objections; but they complicate the question. To us it appears that it would be far better to use compressed air than steam. This might be readily obtained by working a compressing pump off the back levers of the main engine, just as the air and circulating pumps are worked now. While the engines were standing steam might be used. We are sorry to see that Mr. Arnison, who certainly knows better, during the discussion on Mr. Nicholl's paper, referred, without contradicting it, to the statement that the boiler of the steamer *Ryde* evaporated 41lb. of water per pound of petroleum. In which case it is clear that each pound of the oil must have had a practical thermal efficiency of about 41,000 units, or, say, twice the theoretical efficiency of any oil yet tested, and he made matters worse by saying that this was "apparently accounted for by the utilisation of the hydrogen liberated from the steam used for injecting the oil." Now when hydrogen is burned with oxygen the result is water, and the energy developed in the form of heat is precisely the same, neither less nor more, than that expended in separating the steam—water—into its component gases. Put chemically, the heat of combustion is simply equivalent of the heat of dissociation; consequently there is absolutely nothing to be gained in the way Mr. Arnison seemed to suppose.

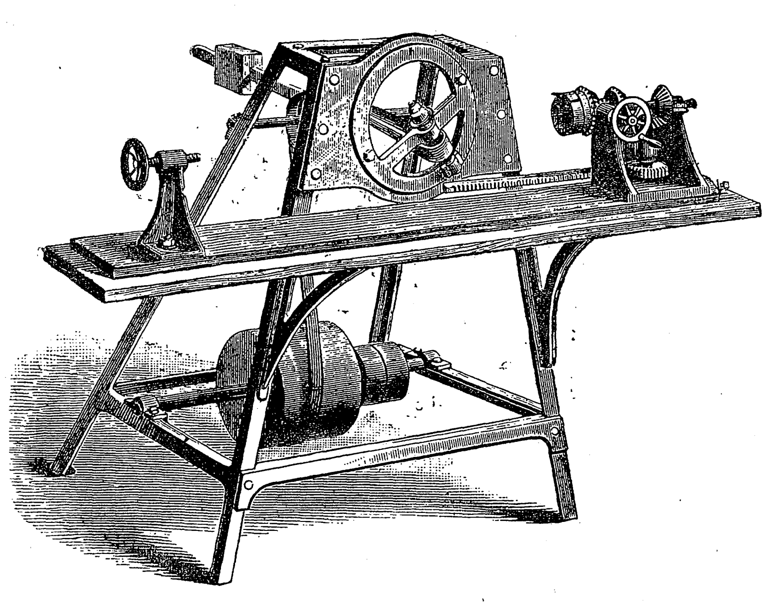
We have no doubt but that many more papers on the subject of liquid fuel will be read in the immediate future. We would direct the attention of intending readers to the points we have raised. Nothing is to be gained by passing over objections in silence. Everyone knows now that petroleum can be burned and steam raised with success. The points on which information is lacking do not refer to steam raising, but to its concomitants—such, for example, as the safety of astaki; the action of underwriters; the proper method of storing the oil; the effect of very intense temperatures on boiler plates; the probability of disaster as a result of the failure of any part of the apparatus; the means of taking the astaki on board—in fact, what we now want is information concerning those details on which the success or failure of the whole scheme depends. The soundness of the principle

may be freely conceded. The shipowning world has yet to be shown how the principle is to be carried out in practice to the best advantage. On this point next to nothing is known, and for this reason it ought to be easy to write a most interesting paper on this subject: that is to say, provided —which we doubt—that there is really sufficient information for the purpose available anywhere.—*The Engineer*.

LATHE FOR TURNING SPIRALS.

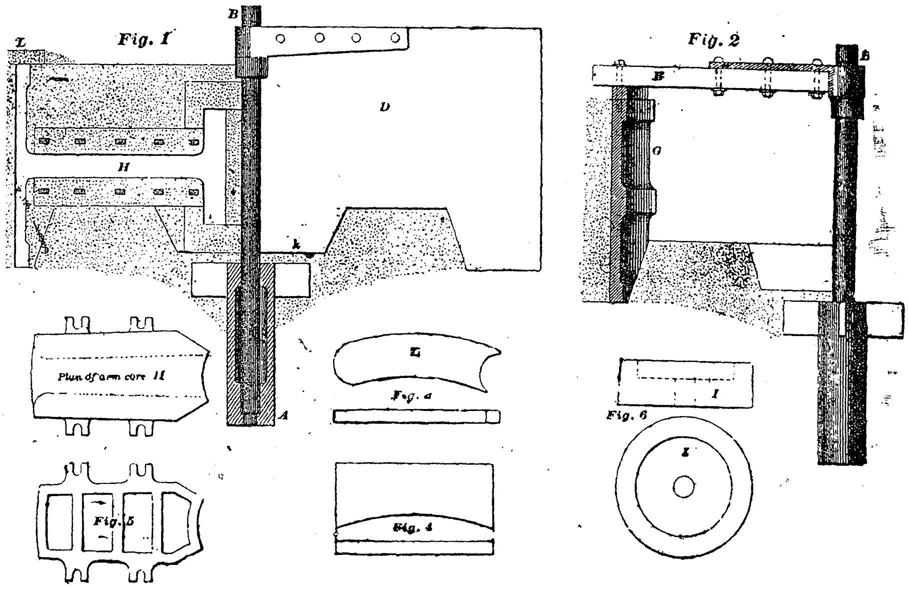
THIS machine is adapted for cutting spiral twist mouldings or forms on the exterior surfaces of turned work, such as stair balusters, newel posts, and the like, whether it be cylindrical, or tapering, or curved, and irrespective of the diameter or length of the work. The frame of the machine is made with a vertical front, to which the face plate is fixed. Fitted snugly, but movably, to the face plate is a frame, in which is journalled the spindle carrying the cutters, which may be formed to work beaded, fluted, or other forms in spiral twists of any pitch on balusters or posts. The spindle may be set at any desired angle with the horizon by turning the frame, but the cutters will always operate at the centre or axis of motion of the cutter frame. The spindle is driven by a belt passing over a tightener, and leading to tight and loose pulleys on a shaft driven in any convenient way. The main workbed of the machine is fixed to brackets secured to the main frame, and the carriage holding the head and tail stocks is laid loosely on the bed. The tail stock may be freely swung on the bed to carry the work to and from the cutters, and, at the same time, the carriage is free to be moved along the bed to feed the work along in front of the cutters. The headstock is fixed to the carriage, while the tail stock is adjustable along the carriage to accommodate the length of the work. In the head stock is journalled a live spindle, which holds one end of the work. On the inner end of a shaft journalled at right angles to the spindle is fixed a bevelled pinion, which meshes with a gear fixed to the head block. At the outer end of the shaft is a hand wheel, by turning which motion is imparted to the spindle and its connected parts.

On the spindle are placed two bevelled pinions, either of which may be engaged by a gear fixed to



a vertical shaft journalled to a cross bar of the head stock, and to the lower end of this shaft is fixed a gear wheel, which engages with a rack bar held to the bed in such a manner that it may be adapted to engage gear wheels of different sizes, to govern the speed of rotation of the spindle and work, in accordance with the diameter of the work and the pitch of the spiral mouldings to be cut. Operating the hand wheel with the right hand causes the work to be turned and the carriage to be moved forward, while the left hand is free to press the work to the centres by pushing the carriage inward.

After the first spiral cut has been made in the work, from the head stock toward the tail stock, the carriage is swung backward to carry the work away from the cutters, when a dividing wheel on the spindle is turned around a distance of one or more notches and held by a latch. The work is then fed along the cutters for making the second spiral; this is repeated as many times as may be necessary to go around the work. It will be seen that spirals may be cut upon tapering work for the whole or any part of its length, and upon cylindrical or curved work. By properly arranging the cutter spindle and turning the hand wheel in the reverse direction, left-hand mouldings may be cut. This invention has been patented by Mr. George Wood, of 4724, Main-street, Germantown, Philadelphia, Pa.—*Scientific American.*



MOULDING FLYWHEELS.*

THE following explanation of the method, and the direction for using all the appliances for moulding flywheels, as adopted by the Hartford Engine Company, are given for the purpose of assisting those who contemplate rigging up for casting flywheels.

The method here explained, but with a few slight changes in the appliances, is the same as that used for casting large flywheels in the Algers Iron Works, South Boston, 20 years ago.

My experience in this class of work leads me to believe that this method is the simplest, surest, and most correct way for obtaining a uniform thickness of rim. In a flywheel 12ft. in diameter with a face 36in. wide which I made by this method, I found that the unequal weights in the rim were inappreciable, and the wheel was very nearly balanced. I also remember casting a wheel 9ft. in diameter with a face 26½in. wide, which, when cast, was so well balanced that the owner of the wheel claimed the turning of the same to be unnecessary.

By this method the hub and arms are made of dry sand cores, and the rim up to 48in. wide is made in green sand. In moulding wheels with a 72in. face I have obtained excellent results by using loam outside and green sand inside of the rim; but yet, for wheels having faces over 48in. wide, I consider it to be a better and easier plan to mould the inside and outside of the rim in loam, or at least loam should be used for the outside and that part inside of the rim lying underneath the arms.

* By "FOUNDRYMAN," in *American Machinist.*

The appliances used for moulding flywheels are illustrated in the annexed figures, in which similar letters denote the same part of the appliances. A represents the gudgeon or centre. This centre, as shown in Fig. 1, is placed in the floor sufficiently deep to give 1in. or more clearance between the upper face of the centre A and the lower edge *k* of the sweep D. The centre A should also be placed in an exact vertical position, and then firmly secured. The wings cast to this centre will prevent it from turning. Place the shaft B into the centre A, and on this shaft slip the sweep D, adjusting the latter to a suitable height for the rim of wheel. In swinging the sweep D around the shaft B, its edge *k* will form a surface on which the hub core I is to be placed; the edge *l* will form a surface on which the arm cores H are to be laid, and the edge *m* will sweep a surface which is to hold the cheek and the bottom of the segment G of the rim pattern. After these surfaces have been formed, and the bed is well made up, the sweep D is removed. Now (see Fig. 2) place on the shaft B the arm E to which the segment G is attached. Place a flask cheek in position, and ram up the outside of the rim.

When this is done, lift off the flask cheek, dress and blacken the mould. Next (see Fig. 1) slip the bottom hub core I over the shaft B, and place it in an exact central position, in which also its upper face will be even with the bank made by the edge *l* of the sweep D, and ram the sand firmly around it. Now place the arm cores H in position, with equal spaces between them, and do not allow these to strike the segment G. Ram up the inside, and when this is finished dress up with blacking those ends of the arm cores which meet in the centre of the wheel, and hang the same in a fire in order to dry them. Finish the outside, black, and close on cheek. Cover rim with cores L, and with as many risers as desired. Slip the upper hub core over the shaft B, secure it in a central position, and then remove the shaft or spindle B. Fill the gudgeon A with sand, to prevent the iron from flowing into it, and set centre core. See that the holes for pouring gates are all right. Lay bars on top of mould to secure everything, cover these bars with a large plate, load it with weights, and then pour the metal.

Fig. 3 represents the covering core L, and is used for covering the rim, as shown in Fig. 1. It will be readily understood that by shaping the ends of this core, as shown in Fig. 3, its core box can be used for any size of wheel.

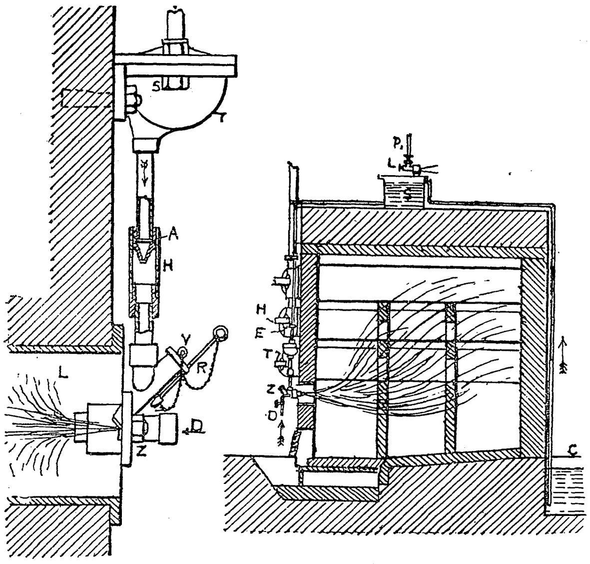
Fig. 4 represents a board used for holding the segment G in its place while ramming the inside of mould.

Fig. 5 represents a core iron, and is used in the arm core H. Its lugs are allowed to project beyond the core, so that the two parts of the core can be readily bolted together, which will be appreciated in moulding large wheels; for with this arrangement greater security will be obtained.

Fig. 6 represents the lower hub core before it is placed in position.

STEAM VAPORISER FOR BURNING COAL TAR.

IT is certain that we shall before long succeed in increasing the industrial yield of petroleum, and in reducing the cost of carriage in a large measure, through shipments in vessels provided with tanks. This fuel will then be able to compete with coal for the heating of boat and locomotive boilers. The residua from distillation espe-



erally will offer serious advantages over coal in certain applications, owing to their great heating power, the ease with which they can be used, and the small space required to store them. As well known, this question is analogous to the problem of utilising coal tar for heating, and so vaporising apparatus can, with a few slight modifications, be applied to either of these products. Now, in view of the extraordinary fall that has taken place in the price of tar, many gasworks have decided to return to the use of this substance as a fuel for retort furnaces, after having discarded it for a few years.

But, in order to get rid of the inconveniences due to the abundant production of smoke that the burning of tar is accompanied with, it is necessary, before combustion, to project the liquid in the form of a spray, and to make as perfect a mixture as possible of its particles with the air. Under such circumstances, it burns normally with a white flame, and a great advantage may be derived from the heat that it develops. In order to obtain such a result, the Messrs. Koerting Brothers have devised an arrangement which is distinguished for the simplicity and accuracy of its operation. The apparatus that serves for burning the tar is very strong, and is entirely of iron. As for the vaporiser, properly so called, that consists essentially of a pipe through which the tar descending from above is led to the front of the furnace, in order to be converted there into a fine spray through a jet of steam projected obliquely. The fuel reaches the furnace after being mixed with atmospheric air. With this apparatus, the vaporisation of the tar is very complete, and, owing to the peculiar escape of the steam, there is no loss of fuel.

The annexed figure shows in section a four-retort furnace provided with a tar firebox, whose vaporiser is represented on a larger scale to the left. The tar is raised to the reservoir S, by means of a pump or aspirator, L. The heat that prevails at the point where the reservoir is located keeps the tar continually in a liquid state.

From the pipe E the tar passes into the cap T, which is provided with a semicircular sieve that can be easily removed for cleaning. This sieve holds back all the impurities that the tar contains. The tar afterwards flows through the tuyere A, the size of whose orifice varies according to requirements. In case this orifice gets obstructed, despite the action of the sieve, and after a somewhat extended period of service, it can easily be cleaned without taking the apparatus apart. To this effect, the socket H is raised, and this frees the tuyere, which can then be cleaned with a needle.

From the tuyere D the tar enters the vaporiser Z, which is fixed, through a short sleeve, in an aperture in the front wall of the furnace. The jet of steam that enters the furnace through the conduit D makes a very fine spray of the tar coming from above, and, moreover, introduces into the furnace with great force the quantity of air required for the combustion. It results from this that the combustion proceeds under exceptional conditions. On each side of the vaporiser there are dampers for regulating the entrance of the external air at L, so that the draught may be neither excessive nor insufficient, and so that no smoke shall be produced. The combustion is further regulated by the steam valve. In cases of a choking up of the vaporiser, which would be shown at once by a complete extinction of the flame or reduction of its intensity, the orifice of the apparatus is cleaned with the needle R after removal of the cover V.—*Revue Industrielle.*

LUMINOUS PAINT AND PHOSPHORESCENT MATERIALS.

THE sulphate of calcium, which is remarkable for its violet phosphorescence, and forms the basis of some luminous materials, has been analysed by M. A. Verneuil, who finds it to contain monosulphide of calcium 37 per cent., lime 50 per cent., sulphate of lime 7 per cent., carbonate of lime 5 per cent., with traces of silica, magnesia, phosphates, and alkalies. He also finds that it is a *coquille* shell which furnishes the lime used. M. E. Becquerel has made extensive researches on these luminous powders, and M. Verneuil has more recently followed up the subject. He gives the following process for preparing what he considers the most beautifully phosphorescent matter known. Twenty grammes of lime from the *Hypopus vulgaris* shell, calcined, is pulverised and intimately mixed with six grammes of sulphur and two grammes of starch. To this mixture is added drop by drop a solution containing half a gramme of subnitrate of bismuth, 100 cubic centimetres of absolute alcohol, and some drops of chlorhydric acid. When the most of the alcohol is evaporated by exposure to the air for half an hour, the mixture is heated in a covered crucible for twenty minutes to a clear cherry heat. This temperature is obtained easily by wood charcoal or a Perrot gas furnace. After pulverising the mass, it is again calcined at the same temperature for a quarter of an hour. If not too strongly heated, the product obtained is small grained, lightly agglomerated, and easily crumbled. A new pulverisation is to be avoided, as it tends to diminish the phosphorescence. The addition of sulphides of antimony, cadmium, mercury, tin, copper, platinum, cranium, zinc, molybdenum, produces a variation in the colour of the light, which varies from yellow green to blue green. Manganese produces an orange tinge. Sulphides of cobalt, nickel, iron, and silver diminish the phosphorescence.

MR. WILLIAM MCKENZIE, general foreman of the New York, Pennsylvania, and Ohio Railroad machine shop at Meadville, has invented a device for ejecting water from the cylinder of a locomotive. It is described as follows:—"The steam ports on either side of the locomotive are connected with a small pipe, to which is attached an automatic valve directly at the back of the saddle. When the locomotive is under steam pressure this valve remains closed, and opens the moment the pressure is shut off, thus allowing every drop of water that has accumulated in the ports to escape.'

AT Jebel Zeit, Egypt, the boring for oil has gone down 215ft., and nothing valuable has yet been reached. At Jemsah there are three separate borings, from one of which, at 125ft., is spurting good heavy petroleum.

THE steam yacht *Chic* is being fitted up in Greenock harbour with a Brush dynamo, for the purpose of pearl fishing in the South Australian seas, and when the ocean bottom is thus examined by the electric light there will no doubt be some wonderful discoveries made. The steamer *Hyæna*, belonging to the Liverpool Salvage Company, has also been fitted with electrical apparatus for diving purposes.

THE Madras Government is about to engage in the cultivation of jalap. The demand this year from the Madras Medical Department was 1,300lb., and only 400lb. could be obtained from private growers.

SCIENTIFIC NEWS.

THE death is announced of Prof. Theodor von Bamberger, the Austrian astronomer, at the early age of 46 years.

According to Prof. C. A. Young, of Princeton, N.J., the rotation period of Jupiter's red spot is 9h. 55m. 40·7s. $\pm$ 0·2s. The determination was made from eight observations in the spring of 1886, and shows that the period is slowly increasing.

At the annual soirée of the Associated Societies of Liverpool, Mr. Isaac Roberts exhibited a photograph of a portion of the Orion Nebula, in which twenty of the stars are represented by lines. Mr. Roberts considers that these are not stars at all, but planetoids, and that the lines represent their amount of proper motion during the 67 minutes of exposure. A note in the *Journal* of the Liverpool Astronomical Society for January deprecates so hasty a conclusion, as there are signs that the stars had been allowed to "run," and that the plate had slipped.

We understand that in connection with Prof. Dewar's course of Christmas lectures at the Royal Institution, arrangements have been made for introducing into the theatre a powerful beam of electric light equal in intensity to a sunbeam. The lectures, it will be remembered, are on "The Chemistry of Light and Photography," and this electric light beam will be used for photographic experiments.

At the recent meeting of the Institution of Civil Engineers, Prof. A. B. W. Kennedy read a paper on "The Use and Equipment of Engineering Laboratories." Prof. Kennedy believes that it is essential for a young engineer to obtain his practical training in the ordinary sense of the expression, in a workshop; but he is also aware of the fact that the practical training of the workshop is incomplete on its own ground. In an ordinary pupilage a young engineer has not much opportunity of studying such things as the physical properties of iron and steel, nor the strength of those materials, nor the efficiency of the machines he uses, nor the relative economy of the different types of engines, nor the evaporative power of boilers. He requires such experience as might help him to determine for himself, or at least to see for himself, how other people have determined, all the principal engineering constants, from the tenacity of wrought iron to the calorific value of coal, or the efficiency of a steam-engine, or the accuracy of an indicator spring, or the discharge co-efficient of an orifice. Prof. Kennedy thinks that this kind of practical experience can be gained best in an engineering laboratory in connection with some institution where technical instruction is given, and he asserts that in the matter of engineering laboratories, as a branch of technical education, England has really taken the lead, instead of being, as is too often the case in such matters, in the rear. The paper enumerates the principal subjects on which experiments might be carried out in engineering laboratories.

The telegraphs of this country, if we may accept statistics published in a foreign paper, compare favourably with those of the Continental countries. As regards the number of offices and instruments, we compare favourably with France (the latter, however, having more offices but fewer instruments), while in the number of staff we exceed the total of all European countries put together.

A system of automatically lighting trains by electricity is undergoing experiment in Glasgow, the inventor being Mr. Carswell, assistant engineer of the North British Railway. A central rail is in circuit with a dynamo which is used for supplying current to light the goods' yard at Queen-street Station, and as a train enters the tunnel it makes contact, and the lamps in the carriages begin to glow, being extinguished as the train leaves the tunnel, and consequently loses contact with the rail. In connection with this question of lighting trains by electricity, the Brighton Company are about to extend their experiments largely, and will make comparative trials with colza-oil lamps.

MM. Becquerel, Berthelot, Cornu, Mascart, Lippmann, and Fizeau, commissioners appointed to inquire into the protection of buildings from lightning, have reported to the

Minister of Instruction that it is indispensable for complete safety to have all iron roofs, doors, pipes, sashes, &c., carefully connected with the apparatus usually attached to public buildings as protections against electric discharges.

Compound locomotives are evidently to have an exhaustive trial on the London and North-Western Railway, as it is stated that the large number already in existence is to be still further augmented by thirty more now in course of construction at Crewe.

Mr. Stretton's "Safe Railway Working," which is a treatise on railway accidents, their cause and prevention, has just been issued by Messrs. Crosby Lockwood and Co.

A locomotive on the Northern and North-Western Railroad, Canada, has made an aggregate mileage of 190,554 without undergoing general repairs. After running 45,179 miles as a freight engine, her wheel tires were turned, and she was used as a passenger engine, running 145,375 miles without having so much as a pin, a brass, or a flue taken out. The engine was made at the Brooks Locomotive Works, Dunkirk, N.Y., and has 5ft. drivers, and cylinders 17in. by 24in.

The Audubon Society, which has been established in the United States for the protection of birds generally, and plumage birds in particular, has a goodly roll of members, for although the certificates were ready only in April last, the society now numbers more than 17,000 members.

At the meeting of the Royal Society of Edinburgh last week, Sir W. Thomson, the president, read a paper on the "Ring Waves Produced by Throwing a Stone into Water," in which he commented on phenomena in regard to the waves which have not hitherto been noticed and analysed—how the waves proceeding from the stone constitute a series of different wave-lengths and of different velocities; how each wave as it advanced becomes longer and gains in speed. The point to which he directed attention was the law of that progress and the place where a wave-length had a given value, in connection with which he gave a mathematical analysis of the problem, the result of which was that the velocity of propagation was proportional to the square root of the wave-length. Another paper by the president was on the waves produced by a ship advancing uniformly into smooth water. The general results of his investigation showed that the rate of propagation of the waves was equal to the component of the ship's velocity in that direction, and that if a point be taken in the ship's wake in the line of her motion, and the distance between that point and the point from which the waves take their origin be bisected, the tangents from the latter point to the circle whose diameter is the line between the point of bisection and the point first mentioned will form the limits of wave disturbance.

The last experiment in sending ova of salmon to Tasmania has proved successful, the development having been checked by means of refrigerating machinery. The eggs were hatched out in the colony, and some of the fry have developed into smolts, which have been captured in the Mersey a river running into Bass's Strait. The attempts to transport the sole to the United States have also, it is believed, been successful, and the American Government have promised to forward large consignments of ova of valuable species of Transatlantic *salmonidæ* to the National Fish Culture Association, in order to assist in developing the inland fisheries of the United Kingdom. Supplies of ova will also be sent by various Fishery Boards and other bodies for incubation, under the condition that the fry, when hatched out, shall be returned to their respective waters. The Association have lately been engaged in collecting ova from various parts, so as to extend the scope of their operations as far as possible.

The Lettsomian lectures will be delivered by Dr. J. Langdon Down on Jan. 3rd, 17th, and 31st, the subject being "Some of the Mental Affections of Childhood and Youth."

An ingenious piece of surgical mechanism, designed by Herr Rosenthal, was exhibited at the last meeting of the Odontological Society by Dr. Cunningham. The ramus and condyle of the lower jaw having been removed on one side, the other side became dislocated, and could not be kept in position. To the last molar of each jaw gold bands were fitted, to the upper of which a thick, slightly-curved wire was soldered. The wire fitted loosely into a tube soldered to the band round the tooth in the lower jaw, and although the arrangement does not admit of lateral movement the patient can eat with some ease, and the jaw on the other side is prevented from slipping out.

At a recent meeting of the Linnean Society, Mr. G. J. Romanes read a paper "On the Sense of Smell in Dogs," in the course of which he related his own experiments with a setter-bitch. His conclusions are that in the case of this animal she distinguished his trail from that of all others by the peculiar smell of his boots, and not by the peculiar smell of his feet. "No doubt the smell which she recognised as belonging distinctively to my trail was communicated to the boots by the exudations from my feet; but these exudations required to be combined with shoe-leather before they were recognised by her." The experiments further show that although a few square millimètres of the surface of one boot are amply sufficient to make a trail which the animal can individually recognise, the scent is not able to penetrate a single layer of brown paper. Furthermore, it would appear that in following a trail this bitch is ready at any moment to be guided by inference as well as perception, and that the act of inference is instantaneous. Lastly, the experiments show that not only the feet, but likewise the whole body of a man, exhale a peculiar or individual odour, which a dog can recognise as that of his master amidst a crowd of other persons; that the individual quality of this odour can be recognised at great distances to windward, or in calm weather at great distances in any direction; and that this odour is not overcome by aniseed.

Popular Science.—In the *Saturday Post* of October 23, 1886, a Greenock paper, the following appears: "*The Pressure of Steam.*—Steam, as compared to water, occupies 1,728 times as much space. A cubic inch of water will make 1,728 cubic inches of steam at atmospheric pressure. Now, if this steam is compressed into half that space, it will give double pressure, or 15lb. above the atmosphere; and then it will occupy only 864 cubic inches. If reduced again to half its volume, it will occupy 432 cubic inches, and will give 30lb. pressure per square inch. Reduced again to half the volume, the steam will occupy 216 cubic inches, and will give 60lb. pressure to the square inch. We can go on reducing in this way until we find that a cubic inch of water turned into steam, and compressed into a space of 3 cubic inches, will give the enormous pressure of 3,840lb. to the square inch." Greenock occupies a high position in regard to the science of steam; it is the birthplace of Watt, and it has turned out a greater horse-power of marine steam-engines than any other town of its size in the world. Notes about steam served out in the Greenock papers on Saturdays for Sunday meditation ought therefore to be worth reading. Let us take the above extract bit by bit. "Steam as compared to water occupies 1,728 times as much space." . . . Only at one pressure is this true, and that is not at atmospheric pressure; the relative volume is then, say, 1,648. "Compressed into half that space it will give double pressure, or 15lb. above the atmosphere." If we could have steam at that pressure, but still at the temperature of "boiling water," 212° Fahr., then might the pressure be as stated, but steam at twice the pressure must be at its own higher temperature, and therefore its volume must be more than "compressed into half that space." "Reduced again to half the volume . . . 30lb. pressure to the square inch." In addition to the temperature objection there is now an atmospheric objection to this statement. Pressures are stated either as above the atmospheric pressure or as including the pressure of the atmosphere, but the writer of the Greenock note seems to have now forgotten the atmosphere altogether. The pressure he has now attained by doubling is 60lb. gross, or 45lb. above the atmosphere, and not by any way of looking at it can it be 30. The note goes on doubling and doubling in this way, getting

$$15, 30, 60, 60 \times 64 = 3{,}840\text{lb. per square inch,}$$

instead of

$$15, 45, 105, 120 \times 64 = 7{,}665 + 15$$

As this Greenock note contains quite unconsciously so many common errors, its correction may prove useful.—*Engineering.*

LETTERS TO THE EDITOR.

[*We do not hold ourselves responsible for the opinions of our correspondents. The editor respectfully requests that all communications should be drawn up as briefly as possible.*]

All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, *332, Strand, W.C.*

All Cheques and Post-office Orders to be made payable to J. PASSMORE EDWARDS.

*** *In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks, a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

ORBITS OF SATURN'S SATELLITES AND MASS OF THE PLANET.—STELLAR PARALLAX. — VESICLES. — STARS VISIBLE FROM THE BOTTOM OF A WELL.—SOLAR PARALLAX.

[26630.]—I HAVE been reading—need I add with the greatest possible pleasure?—three of Professor Asaph Hall's masterly astronomical monographs which appear respectively as Appendix I. to the "Washington Observations for 1882," and as Appendices II. and III. to the volume for 1883—but which have only just reached this country. The first is on "The Six Inner Satellites of Saturn," and contains much that must be valuable to the students of the marvellous Saturnian system. Among the most popularly interesting details may be mentioned: that the five inner Satellites of Saturn move in sensibly circular orbits, and that their orbits are either actually in the plane of the ring, or so very close to it that they may be assumed to be in it; and that the mass of Saturn derived from the observations of Tethys, Dione, Rhea, and Titan $= \frac{1}{3478 \cdot 7 \pm 1 \cdot 10}$ (that of the sun being unity). In Appendix I. to the volume for 1882, the orbit of Iapetus, the outer satellite of Saturn, is discussed, and from the observations of its motion a mass of $\frac{1}{3481 \cdot 3 \pm 0 \cdot 54}$ for its primary is deduced. Perhaps I may note that the two previously best determined masses of Saturn are those of Bessel $\frac{1}{3501 \cdot 6}$ and of Le Verrier $\frac{1}{3529 \cdot 6}$. The last, but by no means the least, of Professor Hall's essays is contained in the second appendix to the "Washington Observations for 1883," and discusses the observations for stellar parallax made there. Four stars were observed to this end: 40 (o^2) Eridani, 6 B Cygni, α Lyræ, and 61 Cygni. Dismissing 6 B Cygni, which furnished a negative parallax! we have the parallax of 40 Eridani determined as 0·223″, which means that it is situated at a distance of 924,954 times the radius of the earth's orbit, a distance which light, travelling at the rate of 186,326 miles per second, takes 14·494 years to traverse. In the case of 61 Cygni its parallax would seem to be 0·270″, so that this star must be removed from us by 763,944 times our mean distance from the sun, and light must occupy 11·971 years in its journey. Lastly, in the case of Vega, Professor Hall found that its parallax was only 0·134″—in other words, that it is 1,539,290 times as far from us as the sun, or, say, 142,218,754,000,000 miles! and that the light by which we behold it to-night quitted it 24·121 years ago! It will be remarked that Mr. Hall's results are notably smaller than those usually given in tables in works on astronomy; but this does not shake his faith in their accuracy.

Let me thank Mr. Lecky for inviting my attention (in letter 26618, p. 368) to the solecism I committed in speaking of "vesicles" of water; when I meant what—for want of a better term, I may call—water-dust. "Vesicle" is, of course, the Latin *vesicula*—a little bladder—and used as I used it, a wholly misleading term. If Mr. Lecky has access to the *Transactions* of the Royal Society of Edinburgh, he will find in Vol. XXX. p. 337 a paper by Dr. Aitken, in which that gentleman maintains the thesis attributed by him to the younger Helmholtz.

In answer to the query with which the second reply (61101) concludes (on p. 373), the arc of the heavens visible from the bottom of a well depends simply upon its depth and diameter. Taking the first figures that come into my head, and supposing an imaginary well to be 40ft. deep and 3ft. in diameter, then would a circle of some 4°18′ diameter be visible from the bottom of it. Preserving the same diameter, and assuming the depth

to increase to 80ft., only 2° 9′ of the sky would be visible, and so on.

In reply to query 61276 (p. 377), the rule for finding the distance of the sun when his equatorial horizontal parallax is given, is of the most simple possible character. We have merely to divide the earth's equatorial radius by the sine of the parallactic angle. Here is the work. The earth's Equatorial radius, according to the latest determination of Colonel Clarke, R.E., is 3,963·296 miles; of this the log. is, of course, 3·5980565. First, let us take Gill's parallax, as given by Mr. Ford—8·783″, the log. sin. of this is 5·6292178. Then we simply subtract this log. sin. from the log of the earth's radius, thus—

3·5980565
5·6292178

7·9688387 the log of 93,076,210 miles.

Or let us use what I may term the Official parallax, or that given in the preface to the *Nautical Almanac*, 8·848″. The log. of which is 5·6524200. Then, as before, from

Log. of earth's radius	3·5980565
We take.................	5·6324200
And obtain	7·9656365

the log. of 92,392,450 miles.

Mr. Gill's parallax is certainly not at present preferred by astronomers to that of Newcomb, which is adopted in the *Nautical Almanac*, and given above. For myself, I regard the whole question as, to a certain extent, still *sub judice*, with a leaning in favour of the larger parallax. I really forget whence I derived the figures 92,359,000 miles. Quite possibly from some book that happened to be lying open on my table.

A Fellow of the Royal Astronomical Society.

HORIZONTAL WIND-POWER.

[26631.]—IF Mr. Vallance would send drawing, and you would be good enough to illustrate his windmill, it would be more understandable. I have long had a notion of the possibility of charging accumulators from a dynamo worked by wind power; but on ascertaining the average speed of the wind here on an average of 17 weeks, I find it is only seven miles per hour. The 14ft. diameter American mill shown at the Colonial Exhibition was stated to be 2H.P., with 18 miles of wind. Finding, therefore, that the average speed of the wind is so small, I have come to the conclusion that the game is not worth the candle. In America, also, I know that attention has been given to the question, and the conclusion arrived at is that the only practical way to use wind power for the purpose referred to is to let the mill pump water to a tank and then for the water to turn a wheel or turbine to actuate the dynamo. I need not say that this would involve great expense in the construction of tank, &c.. and I am sure it would be cheaper to employ a gas-engine to actuate dynamo than to rely on such uncertain power as is the wind. **B. Boothroyd.**

[26632.]—IF Mr. Brown will be so good as to read my letter on page 346 again, I think he will see that he has made the miscalculation, and not I. He will there see that I say "the sails are to be made of half a 14ft. yellow deal cut diagonally from ½in. on one side to ½in. on the other, which will make two sails, 2½in. thick on one side and ½in. thick on the other, and 9in. wide." Now, I did not say that each sail will be 14ft. long; because I thought every one who read and attended to what I had said would see that for a deal cut diagonally and making two sails would necessarily have the sail the length of the deal; so that the 600ft. I stated as the surface of sail exposed will be about right.

Now for the "strong resistance that has to be met on the side constantly pressing against the wind on the return side of the mill." The flat edge of each sail is about 2½ square feet, and this receives the full pressure of the wind when it is exactly at a right-angle to the arm, and going against the wind; *but only when in that exact position*, for when on either side of that, the wind is driving it in its course round the shaft. If not come up to that position the wind is pressing on the inside of the sail, and if beyond it, the wind is pressing on the outside, so that there is only one place in which the sail is doing no duty, but is driven against the wind. Now, the surface of the sail is about 2½ square feet, and if the wind presses 2lb. per square foot the resistance will equal 5lb. to be deducted from the duty of all the other sails. If Mr. Brown objects that there are five sails in a line, I reply that then all five only expose 2½ square feet, as they would be sheltered by the first sail of the five; in fact, the sails are so effective that if only one sail is on the mill it will run as if the whole were on it, which proves that the sails are efficient in almost every position of their course. In the portable mills we used for ploughing I have frequently put one sail only on to show spectators this.

With respect to the doubt as to the truth of my statement that the two mills have drawn seven ploughs at once, I think there are still alive a few witnesses who would confirm it; I know of two. But as this took place in 1844 or 1845, few are left who saw it, although I could give the names of 20 who did so.

I used the mills for six years on my farm at Bromich, between Lewes and Eastbourne, from 1842 to 1848, and I daresay there are many alive still who saw them. I also exhibited them at the Agricultural Show at Shrewsbury, and they were taken from the show yard to the trial ground, and set to work there in 1 hour and 10 minutes, proving their portability, and I then and there had one mill running with only one sail; I sold them there. Previously, in 1837, I drove an oil mill in Henfield Brooks by a large one, with sails 24ft. high and 6ft. wide, so that I think sufficient witnesses may be produced of the efficiency of the mill.

As to the staggering of Mr. Brown by the cumbrousness and ponderosity of the mill, I suggested what I believed to be a mill that will stand the effect of a violent storm, and I think this will do so; the weight is no objection. The cost of material is about correct, and as I have described it with as little labour bestowed on it as I could, I believe the total cost will not much exceed the estimate.

Mr. Brown seems to be very unfortunate in his endeavour to understand what he reads. Thus, in his letter on p. 303, he says (referring to Mr. Collingridge's account, p. 269), "The inquiries one would like to make of him are—What was the length of arm? what portion of it was occupied by the sail—length and breadth? and is it to be seen, and what did he drive with it?"

Now, each of these queries is distinctly answered by Mr. Collingridge on p. 346, where he writes: "Length of arm, 8ft.; sails, 7ft. high and 6ft. wide," and that his model gave off ½H.P. He then says that, not having room to put up a large mill, I have to be contented with steam power, its cost of fuel and attendance. And yet Mr. Brown says he has reluctantly *gone back* to steam. Why, he never departed from it—from want of room to erect a windmill. **Philip Vallance.**

SUGAR ANALYSIS.

[26633.]—WE are much indebted to Mr. Allen and Mr. Alf. W. Stokes for valuable notes on this question, and shall be glad if these gentlemen will favour us with further contributions. The subject is one of interest to readers—chemical, commercial, and medical.

To demonstrate the mere existence of grape-sugar is very easy, providing those "other substances" to which Mr. Allen alludes can be shown to be absent or can be excluded. Will Mr. Allen teach us the criterion by which these "other substances" can be shown to be absent or present in, say diabetic urine, and also the best means by which they can be excluded while the grape-sugar is left intact? Having often to examine for grape-sugar under these circumstances, I cannot but say that even Mr. Allen's book, which is the best we have on this subject, does not give us all the practical guidance we want. With regard to other sugars, Dr. Bodenbender says: "Many beets contain a substance which has the property of separating peroxide of copper from Fehling's solution as yellow hydrate of protoxide of copper, which, after being boiled some time with the reagent, becomes red protoxide of copper." What we want here to know is, What are these substances? How can we show them to be present or absent? How can we best exclude them when present, at the same time having our grape sugar intact? Then again, I do not find that by boiling it is always easy to separate the copper in any form that gives either a ready subsidence or a clear filtrate, or any colorimetric indication by which exact quantifications can be secured.

Some of these "other reducing substances" can be removed by adding a few drops of basic acetate of lead, shaking well and then filtering. To the clean filtrate add sodic sulphide so as to remove the whole of the lead added in excess, and then filter again. If we now quantify with Fehling's solution we have the reducing sugars plus other possible reducers which are not got rid of by the acetate of lead. Of these residual "other substances" some, again, are not destroyed by boiling with caustic soda, while the grape sugar is. If, therefore, we now boil a second portion of the filtrate with caustic soda, so as to destroy the reducing sugars, and then quantify again with Fehling's solution, it is clear that by subtracting this result from the previous one, we get the reducing sugars, apart from two sets of "other substances"—i.e., apart from those removed by basic acetate of lead, and those which survive after boiling with caustic soda. Unfortunately the dark colouration given by the reducing sugars under the destructive action of caustic soda, is a great drawback to the convenience of this process and the questions for our eminent analytical friends, therefore are. Can a better process be suggested? And how far do we, by our process, entirely free our grape-sugar quantification from errors introduced by other reducing substances?

I have been in the habit of preparing my own Fehling's solution with tartrate of soda and solution of caustic soda. Most books prescribe the potassio-tartrate of soda; but I understand Mr. Allen to lay down that whether the alkaline base be soda or potash, or a mixture of the two, makes no difference.

If Knapp's method be applicable in all cases, and his standard mercurial solution undergoes no change by keeping, while it is, at the same time, more delicate in its action, how is it that sugar chemists so very generally use Fehling's solution?

Mr. Stokes's letter upon the detection and quantification of grape sugar in diabetic urine by means of the ammoniacal copper solution, is very interesting. If he would favour us with the contribution which he so kindly offers, he would enrich the pages of our useful journal.

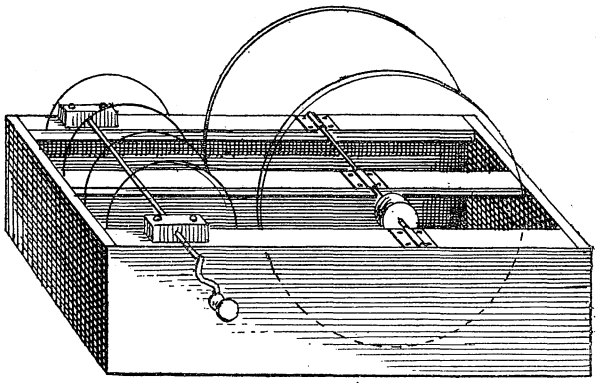
M. O. H.

NOTES UPON THE WIMSHURST ELECTRIC MACHINE.

[26634.]—THE following remarks may be of some use to those endeavouring to improve our knowledge of the properties of electric machines, as well as those of electricity, with relation to this particular phase of electric action. These notes having reference to a long series of experiments, I would just repeat, *pace* "Sodium" (see page 327, No. 60839), that any hole in a disc is extremely liable to end in a crack; but it is a great help to avoid this disaster that we round off the sharp edge of the hole with a nice fine piece of grindstone applied, say, cornerwise in the orifice, supposing that the piece of stone be right-angled. Also, why not turn the bosses with the lathe centres in the brass tube instead of going to the unnecessary trouble of fitting on an accurate mandrel? Memo.: An ordinary table leg and so forth wood-turner, is not competent to turn accurately, even if he tried; his lathe, so far as my observation goes, is not accurate enough; because if the ends are at all hollowed towards the centre, as there is a great temptation to do, then, when the cement which I have recommended dries in, the plate will be under a heavy pressure. Memo. 2: No wood-turner nor brass-finisher ever turns anything truly round, or flat, as far as my experience goes. I have hitherto used a washer of Drogheda linen, but intend to try a piece of the good upper leather from a lady's kid boot, as the real difficulty is that the disc usually has a bend somewhere in its circumference, and is rarely of a uniform thickness, which renders "Sodium's" proposed plan (see page 328, No. 60989) unavoidable. With reference to cracked discs, I always cover the crack with a strip of thin glass, say, 1in. broad, and Diamond Cement it; by this is meant the cement advocated by me in these pages. My reason for proposing a leather washer is that I think that by means of a thin and narrow chisel a wedge could be inserted to correct any slight inaccuracy. Now, then, I am of opinion that, seeing that the Wimshurst machine acts precisely the same in whichever direction it be turned (all the difference being that the electricity is not given off in the same place), Mr. Wimshurst is wrong in terming it a circuit from one side of the diameter to the other, and the way he fixes up his dischargers proves it, because he has to make one ball larger than the other to induce the electricity upon the superior one to strike at the little one first (same as the roughs do). Does he mean to assert that were I to shift the driving handle of his machine on to the opposite end of the spindle, and then to turn it in the opposite direction, that it would not work equally as well?—and this being so, what becomes of his imaginary circuit? Let us take and entirely cover the discs with tinfoil: we will then get no electricity; then divide this into sectors by narrow spaces, then it will be apparent upon working that we get little or none, because as these sectors recede from the brushes the electricity jumps back to the brush from whence it came. Next we widen the distance betwixt each sector, and thus succeed in carrying more away. Now, if we catch same by conductor or Leyden jar, as this accumulates it will reach a point of accumulation when it will jump from sector to sector "in the direction of the nearest brush," not necessarily back to where it came from. This being so, I maintain that the real circuit of this machine "is to the earth"; but the reason why it is advantageous to discharge as per Mr. W.'s design, is because advantage is taken of the simultaneous jumps of each side. Let anyone study a Leyden jar charging by placing two pieces of foil slightly pointed in connection with inside and outside, and, say, ½in. asunder; it will be observed that there will be a brush discharge from each to the other previous to the jump. All experiments with Leyden jars through various bodies show conclusively that there is a place of meeting

which is not at either inside or outside foil, but at a point somewhere between both. But this is enough for one dose, so I would observe that in order to obtain the longest jump it appears to me that we must use the smallest number of sectors which will work well without any preliminary charging, and this I would put at, say, 8 per disc, and in favourable conditions of the atmosphere, unless the machine be encased with glass. We cannot accumulate more upon a conductor or a jar than a quantity proportionate to the distance between each section as well as of the boss, nor can we use less than, say, 8 sectors, or there won't be a sufficient number of makes and breaks of contact with one sector whilst another one is passing same (which is absolutely necessary), as the speed cannot be increased to advantage presumably, because the rushing through the air carries off a large quantity, therefore it follows that increasing the diameter of discs is not attended with correspondingly good results, and reducing the number of the sectors lessens the quantity of electricity per revolution. Now, to lessen as far as I can see, at present, these defects, I have devised the following modifications as per diagram annexed; where A is an oblong box of pine, or any other kind of timber, to be dovetailed at the corners, and to have a central piece extending to the bottom as well. This might be all made of ¾in. stuff; the top edges to be thickened with pieces of some hard wood, say, boxwood, 2in. by 1in., from end to end, to be glued and sprigged securely in order to carry the bearings as before described at page 262, the object being to avoid—first, having any holes in the discs; secondly, any metallic body between the discs or in communication with them and the earth, the bosses being turned upon their own tubes, and a little shellac or vulcanite being dropped into the end of hole next the glass after being affixed so as to cut off the end of the axis from said glass. Say that the 4 discs as here drawn are 19in., I would make the bosses 2½in. long; then the driving-wheels would be 4, as shown; thus all could be easily got at when requisite, and a glass cover could be added by arranging four grooved standards attached to bottom pieces, also grooved, and an ornamental frame glazed and fitted on top, 4ft., to be left projecting, say, 1 or 2in. at bottom of standards to take into the corners of the box, so that it could be lifted on or off, and preferably the inside of said box to be cased with glass; but, if not, to have several coats of shellac varnish. I find it beneficial to use a larger area of conductor than any I have as yet seen upon any other machine.

There is another point to be considered as regards the behaviour of electricity, which I have not seen any allusion to in any work treating of these matters, but which must be carefully studied, more especially if one contemplates the making of a compound machine. I have already stated my opinion that the length of the spark is governed by the distance between the sectors as well as of these from the boss. Now, if a conductor and its points are in connection as usual, and we turn the driving handle, the electricity apparently accumulates upon the superficial area of said conductor. (Who gave the name of "Tensional" to electricity in this state, as it seems to me that it would be more correctly designated as "Compressed Electricity"?) If any body in connection with the earth be now brought close to a charged sector, of course it will give up probably the whole of its charge; but this by no means is the case if it be accumulating upon what is termed (curiously enough, it seems to me) a conductor or in a Leyden jar. We are accustomed to placing great reliance upon the attractive properties of "points" in connection with static electricity; but I conclude that I am making a point when I lay down this "apparently new to us law," that even with the aid of said points we cannot take away from any sector on to any insulated surface any more electricity than will leave upon the sector a quantity proportionate to its superficial area in an equal state of compression; therefore it follows that in order to increase the power we must look for a means of accumulating more upon a given area of sector in order to increase the compression of that upon the receiver. To make this apparent, we need only apply a knuckle below the comb during the process of accumulating, and when this reaches its limit the electricity will be seen jumping from sector to sector to the nearest brush. Thus I think that it follows that although a machine be made with numerous pairs of discs, unless the sectors be so separated as to insulate the increased quantity, as well as a largely increased area of receiver for the same, the desired result cannot be obtained, and I think that this is fully proved by the results as stated in connection with the powerful machine of Mr. Gray, and the (to me) disappointing result mentioned upon the last page of his book. As a step in the direction of increased energy of the electricity received upon the sectors, I have already pointed out in these pages that a fixed sheet of glass between the revolving discs as well as corresponding sectors upon the inside of "one" of the



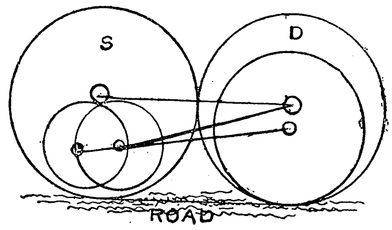
A

said discs (I have not as yet tried whether it will act well if both have sectors upon their insides, but can say that it won't answer to put any sector upon the central fixed sheet of glass.) I must again impress upon all experimenters my opinion that their receivers (conductors, as they are usually termed) are much too small for showing to advantage sparks therefrom—that is, if they are similar to those as shown in Mr. Gray's or Mr. Wimshurst's book. I find that in this arrangement the theory appears to be that there must be two metallic bodies passing each other having an insulating body which also possesses the property of developing electricity between them, one of these metallic bodies to be placed in communication with the earth. Now, I take it that as the one receives the one kind of electricity from the glass, so the other receives a proportional quantity by means of the brush from the earth. I also am aware that this electricity undergoes some change in its condition, which cannot so far be accounted for, seeing that it cannot be freely obtained off a sector in the neighbourhood of either a brush or a rubber; whereas, if the connection of either with the glass be broken, the electricity will fly to air from all parts speedily, unless, as in the case of a Leyden jar arrangement, the one condition of energy is balanced by the other. If this reasoning is correct, the following views ought also be so; but I have not yet had an opportunity to experiment in this direction. I take it that the glass between each sector is not so good an insulator as dry air, and that it does not contribute any appreciable quantity of electricity to the adjacent sectors, that being, in my view, a function confined to the glass immediately under the foils; therefore, I purpose to construct each disc as follows:—A in the diagram is to be a disc of, say, $\frac{3}{16}$ plate glass having a boss affixed as usual on its opposite side; B is one of the eight sectors (in this instance), cut of thin sheet glass; these may be firmly fastened on to the central disc by means of either strong paper and glue paste, or linen and the aforementioned cement, the foil sectors placed upon the surface as near to centre as the lines marked C. The outer dotted circle is merely to indicate the diameter, as all this intervening space is to be air. The proposed benefits would be that the difficulty from the liability of a disc to crack is much lessened, as any one of these can be readily replaced; it would be very much lighter, which is of great importance as we increase the diameter. It would allow of more suitable, thin and flat glass being selected, as well as of any part not possessing good electrical properties being rejected. Finally, even if it is found that the intervening glass is requisite, this method of making up discs by means of separate segments offers a means of making them much more balanced as to insure steadier running; and if a suitable template is made to run the diamond around, a defective one could be easily replaced. Although sheets of thin glass can be procured here as long as, say, 7ft., they cannot be got broader than, say, 40in., and vary much in the thickness of the different sides. If the air spaces are found to answer instead of the glass between these segments, then I would propose to substitute segments made of, say, stout tinned sheet iron; these would be well coated with shellac or other suitable insulator upon the edges and the inner faces. Upon working a disc machine quickly, it is clearly noticeable that there is a large quantity of electricity leaving the sectors before they reach the single line of points. When these are in the uusal position, it appears to me that it might prove advantageous to so arrange the receivers that they would either themselves or by means of their points take in more area of the circumference than this single line does; also, it would seem, judging by the strong odour pervading a room in which one of these machines is at work, that it ought to be a great improvement (independently of its use in keeping out damp air) to have the whole apparatus closely closed everywhere around its action with glass. Query.—Does its working purify the surrounding air, and is the odour healthy? I am inclined to think so.

Dec. 22. **A., Liverpool.**

TRICYCLES.

[26635.]—IN reply to "Gamma Sigma," page 347 (26603), if cycles ran on perfectly flat surfaces, it would make but little difference as to the size of wheels (excepting weight and rigidity); but most roads called smooth or "sandpapered" are simply a series of falls and projections, so that the larger a front steering wheel is compared to its driver, the less it strikes and jumps, saving loss of power by vibration. When a steering wheel is larger than its driver it simply runs in and out of the undulations, making but little vibration or loss of speed. The following rough sketch I hope will make it clear:—S steerer, D driver.



It will be seen by the sketch that although the front wheel receives its force from the tire of the back wheel in a line with the road, the weight of the rider on a 50in. axle makes the front wheel dig at projections more than if on a 40in. driver, unless, of course, the frame is made longer.

R. G. Bennett.

INDUCTION COIL.

[26636.]—I HAD the pleasure of seeing last week, at the Soirée of the Associated Scientific Societies at Liverpool, the famous coil which Mr. Marples recently referred to in your columns. With one bichromate cell (zinc immersed about 6in. by 3in.) it gave a 9in. spark! I hope that Mr. Higgs, the owner of the coil, will be kind enough to favour the readers of the "E. M." with a detailed description of this (as I believe) the most wonderful coil constructed.

Newport. **Benjamin Boothroyd.**

LIFEBOAT ANCHORS.

[26637.]—IT appears from the inquiry into the recent disasters at Southport, that lifeboat anchors pass over the stem head—I have seen several that do so—and that when a capsize occurs, the anchor, if suspended or on the ground, tends to prevent self-righting. May I suggest that if a strong eye were put on the stem, below water line, and the cable were rove through it from the head, and the bight then returned inboard ready for bending to the anchor, the anchor would then act as ballast, or tend to right the boat if capsized; and also the boat would ride easier to her anchor.

Vulcan.

ELECTROMOTIVE FORCE.

[26638.]—IN a query entitled "Accumulator" (61052, p. 311), "Torbay" made reference to a statement which appeared in the *Electrical Review*, to which that serial replied in the following manner:—

"ELECTROMOTIVE FORCE.—A correspondent to the ENGLISH MECHANIC quotes a passage from the *Electrical Review* as follows:—'When the external resistance approaches the internal resistance, the E.M.F. of the cells will be reduced, and if the external was made equal to the internal resistance, the E.M.F. would be but half that indicated when the external resistance was high. How is this? I thought that the E.M.F. of any cell depended solely on the materials composing the two plates, and the composition of the battery acid as representing electro-chemical actions of various kinds, each of which produced its own particular E.M.F.' The above statement is correct. 'Tor-

bay' confuses the full potential or E.M.F. on open circuit with the free potential when the battery is working. If he will measure the E.M.F. of a cell which is not connected up with any exterior circuit, he gets the full potential between its terminals; but if he joins the terminals up to a resistance equal to the internal resistance of the cell, he will find that only half the potential is free. If he proceeds still further, and short circuits the cell with a thick piece of copper wire, he will find the free potential between the terminals reduced to practically zero."

The *Electrician*, however, takes exception to this view, and in its number for Dec. 24th says:—"A Distinction *with* a Difference.—We were recently somewhat surprised to learn that in certain quarters which might have been supposed to be tolerably well posted up in such matters there exists a decided misconception as to the precise difference between the accepted significations of such everyday terms as 'electromotive force' and 'difference of potential.' We have always understood that electromotive force may be defined as *that which causes* a difference of potential; and this definition is not by any means a mere scholasticism, for the simple reason that in a closed circuit containing a single source of electromotive force, the latter has (or may have) only one fixed value, while the value of the 'difference of potential' depends upon the position in the circuit of the points between which this difference is measured, and may therefore have any number of different values from zero up to that of the E.M.F. itself; while at the same time all values of potential difference are caused by, and are proportional to, the E.M.F. Hence in a dynamo we speak of the 'difference of potential at the terminals,' or at the lamps, which is caused by 'internal electromotive force.' That an attempt should at this date be made to upset an established convention of so useful and convenient a character is, we think, decidedly to be deprecated. The following paragraph, which appears in a contemporary journal, has induced us to enter this protest:—'A correspondent of the ENGLISH MECHANIC quotes a passage from the *Electrical Review* as follows:—"When the external resistance approaches the internal resistance, the E.M.F. of the cells will be reduced, and if the external was made equal to the internal resistance the E.M.F. would be but half that indicated when the external resistance was high. How is this? I thought that the E.M.F. of any cell depended solely upon the materials composing the two plates, and the composition of the battery acid representing electro-chemical actions of various kinds, each of which produced its own particular E.M.F."' On this the journal referred to subjoins, 'The above statement is correct. The querist confuses the full potential, or E.M.F. on open circuit, with the free potential when the battery is working. If he will measure the E.M.F. of a cell which is not connected up with any exterior circuit, he gets the full potential between its terminals, but if he joins the terminals up to a resistance equal to the internal resistance of the cell, he will find that only half the potential is free. If he proceeds still further, and short circuits the cell with a thick piece of copper wire, he will find the free potential between the terminals reduced to practically zero.' For ourselves, we beg leave to assert that, in accordance with the views which we had thought to be universally accepted, the correspondent of the ENGLISH MECHANIC is perfectly correct in his assumption that the E.M.F. of the cell is a constant quantity, subject, however, to the influence of such secondary chemical reactions as may take place in the cell, and also to a certain slight extent depending upon temperature, but otherwise quite independent of the resistance of the circuit, both external and internal. The 'difference of potential' at the terminals of the cell is, upon the other hand, a function of the E.M.F. and of the external and internal resistance, and there is nothing in the correspondent's query to show that he was not perfectly well acquainted with these elementary facts. We trust that it is not proposed to speak in future of the 'free potential' of a dynamo machine."

Now, who shall decide when doctors differ?

E. M. F.

THE VALUE OF THE MICROSCOPE IN TRADE.

[26639.]—WE have all no doubt been struck with the amount of learning and research embodied in the papers by Dr. Royston-Pigott, and marked how well he illustrates the advances that have been made, from time to time, in microscopical knowledge; but in this short paper I purpose to dwell on another side of the question, and to show what infinite value the microscope is in trade; and of trades I venture to select that of brewing, because it will be apparent to all readers that a brewer without a microscope is almost analogous to a peacock without a tail.

To begin with, I will roundly assert that since the remarkable revelations of M. Pasteur, the brewing trade has been completely revolutionised, and that a man nowadays who does not know how

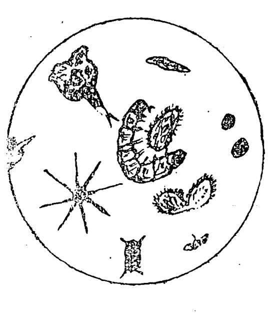


Fig 1.

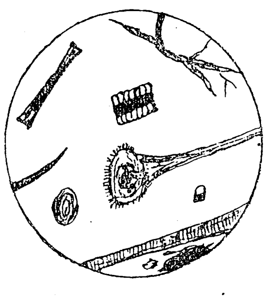

Fig II

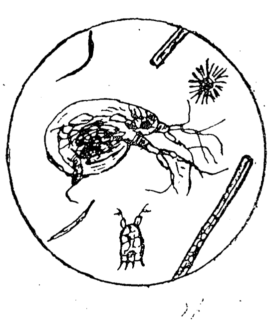

Fig. III

to use the microscope, and, in fact, is not an able manipulator of that fascinating instrument, does not come within the definition of "master brewer," and further, that science has so beautified the labours of the brewers, that they have been elevated above the level of empiric soupmakers to that of, at least, semi-professional men; and I doubt not but that "time's effacing fingers" will ere long entirely sweep away the old ignorant class of men who perhaps knew well how to wash a barrel, but had no idea of the influence of certain salts and organisms on the character of their malt extract.

Firstly, let us mention the value of the microscope in determining, indirectly, the purity of the air in the fermenting rooms, &c., and the important part it plays in the analysis of water; indeed, it is the custom in well-regulated breweries to examine the water frequently to detect any organic impurities, which play sad havoc with the produce. Figs. 1, 2, and 3 are specimens of some of the impurities that are often met with in water, and though probably well known to most of the readers of this article, yet there may be those to whom these minute forms of life, with such tremendous names (I will spare the reader these at least), are comparatively unknown. Fig. 1 represents some animalcula, Fig. 2 some vegetable organisms, and Fig. 3 the appearance of a drop of water containing both animal and vegetable organisms.

But by far the most important use of the microscope to the brewer is its value in determining the quality of his yeast, as it is all important that *Mycoderma cerevisiæ*, the type used, should be pure. The presence or absence of certain bacteria is of vital importance, as it is these foreign organisms that cause the unhealthy fermentations that used to perplex brewers so much; but which (thanks to such men as Pasteur, Huxley, Tyndall, Lister, Budd, and others) they are now learning to detect and remove. The germs most frequently found contaminating yeast, have already been described by me in these columns under the names of Bacterium lactum, B. aceti, and B. amylo-bacter, and it is these three that are familiar—too familiar—to most brewers. We now know that a healthy yeast cell should not be larger than $\frac{1}{2000}$in. in diameter, and as a micrometer is an indispensable adjunct to every brewer's microscope, the size is easily measured. We know that the absence of any vacuole in the cell denotes the plant to be too young, and not fit to induce a vigorous fermentation, and that the presence of more than three vacuoles and a shrivelled cell, at once points out the yeast to be too old. We learn from the presence of an undue amount of lactic and other ferments, when it is time a change of yeast was sought, and the "change" having arrived, we can examine it before using, and determine the age and quality of the purchase.

As this is intended for non-professional readers, I will not enter into any lengthy detail, but shall be happy to do my best to satisfy any correspondent. This is merely to show that, whilst the microscope affords a most pleasing recreation to many men, and a deep, life-study to others, its value to a trader is not the least of its uses. The growing taste for microscopical research amongst men is a sure sign of the intellectual age in which we live; and now that a good instrument can be purchased for such a small outlay, it behoves all men to get as deep an insight as possible, into "the wonders of the world around us." **D.**

TINNING A SOLDERING IRON—SALT IN THE LECLANCHE.

[26640.]—HOW do you tin a soldering iron? The simplest way is to make a hole, or cavity rather, in a brick, into which the beak or nose of the bit can enter, and then put the hot bit into the mixture of rosin and solder with which the cavity can be filled. Instead of rosin, the common chloride of zinc soldering fluid answers every purpose; but the copper should be filed clean before inserting. In America, I learn from one of the papers, this method is productive of great waste of time, though the writer who mentions it went "slowly downstairs" thinking of what a friend had shown him above—that is, a "new method" of tinning a copper bit. The hot "iron" was put in the vice (I beg pardon, "vise," the Americans know how to spell English so much better), and one side had two or three rubs with a mill file. The filed side was then touched with a bit of rosin held in one hand, while immediately following it came the solder, held in the other. The result was one side perfectly tinned. The process was repeated on the remaining sides, and the job reported done in less than 30 seconds. That is quick work, even for a Yankee; but did anyone ever experience any difficulty in tinning a copper bit—that is, I mean, anyone who knew the simple principle that the copper must be hot enough and clean.

Not long ago I saw in an American journal of popular science the extraordinary announcement, made editorially, that a correspondent had discovered that salt and water will excite a Leclanché combination, and that there is no necessity to use sal ammoniac. It will, perhaps, be "news" to this journal of popular science that the discovery was made years ago, and that in the first edition of Mr. Sprague's "Electricity" (1875) a paragraph commences, "Either common salt or sal ammoniac is employed, though others will answer." In Niaudet's cell common salt is used as a matter of course, but the ammonium salt is preferred in the Leclanché.

I have lately noticed a curious mistake in a well-known almanac, in the scientific summary of which it is stated that "the application of telegraphy for everyday purposes as a motive, *heating*, and speaking agent is coming more into use almost daily as fresh discoveries, inventions, or adaptations are constantly being brought out." After that we are told that Mr. G. Westinghouse has patented a new system which will reduce the cost of electric lighting by 95 per cent. That is good news. I hope I shall live to see it actually demonstrated. Jules Verne is not in it with some of his contemporary teachers. **Regel.**

MICROSCOPIC APPEARANCE OF GLASS AFTER PASSING OF INDUCTION DISCHARGE.

[26641.]—TWO years ago, when making some experiments with a large induction coil, I found that when a thin microscopical cover glass was placed between the secondary electrodes it was very quickly pierced by the calorific discharge. On looking at the glass a small roughened spot was seen around the point where the discharge had passed. When this is examined with the microscope (50 diameters and polariscope attachment), small blue crosses are seen over the field, and generally a few of larger sizes are to be made out. Is there any theory with regard to the formation of the above, or are they simply caused by air bubbles carried through the heated glass by the force of the discharge? **A. Beauchamp Northcote.**

CONCERNING THE LUMINIFEROUS ETHER.

[26642.]—AT page 310 our valued electrical correspondent "Sigma," while replying to a question concerning Ampère's theory of magnetism, indulges in an attack on the luminiferous ether, of which he writes in an exceedingly disrespectful manner. It is my purpose in this letter briefly to summarise the evidence in favour of what "Sigma" terms a "precious jelly," partly to see if "Sigma" can really attack the reasoning, and partly for the information of our readers, who might be misled by the remarks in reply to query 61033.

Excepting tidal energy, and the energy of such things as native sulphur, &c., all the energy at present existing on earth is due to the sun, and has come to us from that luminary. The energy which propels our trains, which drives the machinery in our factories, which warms us in our houses, which gives us power to act and think, all is due to the sun. In no merely figurative or poetical sense, but in the most rigid scientific truth, are we children of the sun; and thus curiously does modern science

show some slight foundation for what is probably the oldest form of religion in the world—the worship of the great ruler of the solar system.

The sun and earth are distant from each other 92 millions of miles, and hence the energy which we receive from the sun must have crossed this distance somehow. Two kinds of motion are known to us—motion of translation, in which matter itself travels, as when a bullet goes from a rifle to a target; and wave motion, in which there is no actual transference of matter, but where a state or condition travels. We have examples of this kind in water waves. The energy, then, must reach us by one or other of these two kinds of motion. Sir Isaac Newton imagined that light was an actual transference of matter, and upheld this view to the last, as also did Laplace. The phenomena of polarisation, however, and still more those of interference, finally overthrew the theory of luminous corpuscles, and rendered it evident that light consisted of waves of some kind. If waves can be sent from the sun to the earth, there must be some medium in which these waves travel; and we have next to find the properties of this medium as best we can. The velocity of transmission of light has been investigated in three different ways. Roemer determined the rate of transmission by observations on the eclipses of the moons of Jupiter. Fizeau measured the velocity by means of a toothed wheel, the distance traversed being about ten miles, and Foucault, by means of a contrivance which was a marvel of experimental ingenuity, managed to measure the velocity in an ordinary room. A very close agreement exists between all three determinations, and the velocity is three hundred millions of mètres per second. The rate at which a substance can transmit wave motion has been shown both by theory and experiment to be equal to $\sqrt{\frac{E}{D}}$, where E is Young's Modulus, and D is the density of the medium (a small correction has to be applied in the case of gases). In order to transmit wave motion at the rate of three hundred millions of mètres per second, it is evident that the elasticity of the medium must be enormous, and that D must be very small. The smallness of D can, moreover, be proved in another way, for astronomical observations show that the medium between us and the sun does not sensibly retard planetary movements, although it may have an influence on comets. The highest value of E in any ordinary material is $2{\cdot}139 \times 10^{12}$ dynes per square centimètre for steel; and even if in steel the density were only equal to that of hydrogen gas, the resulting velocity of wave motion therein would not nearly reach the known velocity of light. Hence we are compelled to conclude that the medium which transmits light and heat must be enormously more elastic than steel, and that its density must be very much less than that of hydrogen gas. This medium, then, whose properties are rather those of a solid or jelly than of a gas, is the luminiferous ether; it fills all space, it pervades all ordinary matter, no doubt packing itself away among the molecules, as sand in a heap of cannon balls. I do not by one iota underrate the difficulty of forming a definite conception of this substance which no human eye ever saw or ever will see, and which no human hand ever felt or ever will feel; but I am ready to go unfalteringly wherever scientific reasoning from experiment may take me; and the evidence for the ether is as strong as that for gravitation itself.

Not only has the theory enabled us to explain the most complicated cases of the interference of polarised light; but in at least one case it enabled Sir William Hamilton to predict the result of an untried experiment in double refraction, and the prediction was verified by Lloyd. Now "Sigma," I wait your reply, wishing you and all our correspondents and readers a very Happy New Year.

Wm. John Grey, F.C.S.

Christmas Day, 1886.

BALANCING A PULLEY.

[26643.]—WHAT are the best methods of balancing a pulley, or what practice do your readers recommend? There seems to be much diversity of opinion about the matter, and I should be glad of opinions on the following: Suppose the pulley is to be put in good standing balances, if a spirit level is not at hand, the balancing bars may be roughly tested by laying the mandrel on in the centre; if it rolls with the same apparent ease in either direction the bars are about level. After placing the pulley on, hold it still for an instant, and let go; but instead of letting it roll back and forth until it stops, check it a little until you get the oscillations down to about 4in. travel of the rim; hold the chalk in readiness, and as it rolls toward the right and stops, dash a small mark on the edge of the rim plumb over the centre; as it returns to the opposite stopping point mark as before. Make a central mark between these two, and that will be the light spot. Now attach the weights and test it by rolling down to a position horizontal to the centre, and let go. If it stands still, roll it to the opposite side, and if it will stand there also it is correct; but if it rolls *down*, the bars are low at this end. If you use cast weights, and find that of two sizes, between which there is very little difference, one is too light while the other is too heavy, give the preference to the light one, as it makes pulley nearer in balance when running.

T. P.

VACCINATION A PREVENTIVE OF SMALL-POX.

[26644.]—SEEING letter 26625, I should like to call your attention to one fact, and that is that you have not stated how many had the small-pox, because, if equal numbers took it, then the vaccinated must have died in greater numbers than the unvaccinated. One thing is quite certain, that those that were protected by vaccination were protected to such an extent that they died of small-pox.

There is another thing. The Government returns are just what doctors think fit to send in, which I know are always the truth, because they do get something out of it, and on that account are not likely to say anything against it.

Then, again, you say the vaccinated to the unvaccinated are as 19 to 1. Now, if there were 19 to 1 protected against small-pox, how is it that out of 899 that died 569 were vaccinated? What good was vaccination for them, and ought they died a little easier of it? You also state that 351 are not stated, 330 unvaccinated, taken together make 681; so that 681 taken from 899 leaves 218 vaccinated. If, then, out of 899 deaths 218 only are vaccinated, where do you get your proportion of 19 to 1?

There is only one way to tell what vaccination does for mankind, and that is to note how many cases of small-pox occur both of vaccinated and unvaccinated, and then if 19 times as many persons take small-pox that are vaccinated to those that are unvaccinated, and then only 1 dies out of each class, then I can understand that they are protected 19 times as much.

The fact is that if vaccination was in any way a preventive there would be no deaths from small-pox. I know this, I would sooner run the chance of small-pox than the chance of what might follow vaccination.

You say that you have seen it making very terrible work. I think that it makes no less in this country, when there is an epidemic, as well as in other countries. As to how many will die depends on the strength of the constitution and attention they get.

W. H.

TEMPERING AND DOCTORING STEEL.

[26645.]—ALMOST since the discovery of a method of convering iron into what is known as steel, those who are engaged in working it or in utilising it have had so-called "secrets," and much mystery has surrounded the subject. That there are different qualities of steel is well known; some require to be treated in one way, some in another, according to the nature of the metal and the purposes for which it is to be used; but for all practical purposes the art of hardening and tempering remains very much as it was. Much depends on the heat to which the steel is raised previous to quenching—very little on the solution into which the red-hot iron is dipped—water, oil, and mercury respectively serving all purposes when used with brains. A search through the back volumes, and in other treasures of applied science, will reveal the existence of a number of special tempering compounds, for which wonderful properties are asserted, but which as a rule fail to give the promised results, or if they yield them, do no more than can be done with others, more simple in their character or composition. The following "certain method" of tempering steel appeared recently in an American paper, and as whatever may be its merits it cannot fail to interest your readers, I send it for insertion: "Mr. James A. Peck, of Brewster, N.Y., mechanical engineer of the N. Y. Condensed Milk Co., gives the following method discovered by him, and which he uses with great success for tempering all kinds of tools, knives, razors, steel dies, and other implements. Take a suitable quantity of muriatic acid, dissolve all the zinc the acid will take. Prepare a tempering bath composed of one part of the above zinc acid, and one part water. Heat the steel according to its hardness. If high or hard steel, heat until just red, and then temper in the acid bath. If low steel, heat it as hot as you would to temper in water, then temper in the acid bath. After immersing in the acid bath, cool off in water. For lathe and planer tools draw no temper; but for other tools draw temper. Unlike water tempering, the colours that appear under this method give no clue to the hardness. By this process, steel is readily hardened to any desired degree, and may be made to cut glass like a diamond. If desired, an acid bath composed of two parts of muriatic acid and one part water may be used. Mr. Peck, however, prefers the zinc acid, as being more dense. A prominent advantage of this method of tempering is the certainty and excellence of its results. It never fails to yield the temper required. It can be relied upon for every description of steel or tool."

I do not think the use of chloride of zinc (the well-known "soldering fluid") is novel; but its value can be readily tested. Another method of treating steel, which has been reported on recently by S. L. Wiegand to the Franklin Institute, may also interest your readers, though details are wanting. It has reference to Adam Schaefer's compound for improving the quality of steel, which compound forms the subject of letters patent granted in the United States, No. 341,173, May 4th, 1886. The compound consists of rosin, linseed-oil, glycerine, and powdered charcoal, heated and intimately mixed in the proportions stated in the specification. It is used by heating the steel to a clear red heat, and immersing and coating it in the compound, and the steel is afterwards re-heated and hardened in the usual manner by quickly cooling it. Burnt cast steel is restored to its original condition, and the softer grades of steel acquire the properties of cast steel by being treated as above stated. Tools made from Bessemer steel, which is incapable of being hardened, are, after treatment with this compound and hardening, capable of cutting cast steel. Tools so treated possess a greater durability than before, and are capable of cutting castings which resist the best of ordinary cast-steel tools. The grain of steel exhibited by fracture of tools so treated as compared with the same material before treatment shows a difference analogous to that between fine cast steel and coarse or blistered steel. The compound applied to grey castings and malleable iron-castings imparts a degree of hardness to them superior to case-hardening. It is not attended in use with the unpleasant and deleterious fumes incident to case-hardening compounds, containing hydrocyanic acid, and is much less expensive. Specimens of different materials in their normal state and also as treated with this compound and hardened were submitted, properly labelled, which conveyed a clearer conception of the effect than could be stated in language. In order that the facility of application and its effect may be seen, a forge with fuel and bars of steel and other metal and a supply of the compound were submitted, by means of which the members who felt inclined, personally tested it after the close of the meeting. The compound has been introduced into practical use in many manufacturing establishments in this city (Philadelphia) with uniformly satisfactory results.

If any of your readers experiment in the directions indicated, a record of the results obtained would be useful to a wide circle of mechanics and others interested, if published in your columns. It is with the hope that such records may be forthcoming that I trouble you with this rather lengthy communication.

Nun. Dor.

PASSENGER TRAINS AND PARTING COUPLINGS.

[26646.]—I AM very glad to find that "Nun. Dor." is, like myself, in favour of some automatic indicator by which goods drivers may know when any part of their train breaks away. The plan he suggests is certainly simple, but is to my mind open to the following objections:—

1. Its efficiency depends entirely upon human intelligence, which is apt to fail.

2. The driver would have no reliable check upon the efficient coupling of his waggons.

3. Its adoption would impose additional work upon the already overtaxed guard and shunter.

4. The neighbourhood of every siding and junction would become far more intolerable than at present, and should the cord prove stronger than the whistle lever (and on goods engines all sorts and conditions of whistles exist) the driver would —but "Nun. Dor." can imagine.

I am not particularly in favour of an electrical device for accomplishing the end in view; but it has these great advantages: that if any waggon be uncoupled no line exists, and that the act of coupling completes the required check without extra labour.

Francis M. Rogers, F.C.S.

21, Finsbury-pavement, E.C., Dec. 23.

[26647.]—NO doubt the appliance suggested by Mr. F. M. Rogers (letter 26608) in your issue of 17th inst. would apprise the driver of a train of the fact of the vehicles breaking loose; but of what earthly use would that be in preventing the occurrence of an accident such as that on the Underground referred to by Mr. Rogers? The fact of the driver knowing his train had parted wouldn't prevent the hindmost part of it from running back when on an incline. Of what service, then, is the apparatus alluded to?

W. F.

PASSENGER TRAINS PARTING COUPLINGS.

[26648.]—Allow me to point out (see letter 26627, p. 370) that "an electrical contrivance" to warn a driver when his train has parted, is of no practical use. What is wanted for safety, is an efficient automatic continuous brake which will at once bring each portion of the train to rest.

Clement E. Stretton.

Consulting Engineer Amalgamated Society of Railway Servants.

306, City-road, London, E.C., Dec. 23rd.

G.W.R. EXPRESSES.

[26649.]—On Thursday, the 23rd December, I happened to be at G.W.R. Ealing Broadway Station, and I send a few notes on the running of some of the G.W.R. expresses, between 2 p.m. and 4 p.m., if you can find room for them.

(1) 2.15 p.m. n.g. express, ex Paddington, due Westbourne Park 2.18 p.m., arrived 2.25 p.m., dep. $2.32\frac{1}{2}$ p.m., passed Ealing 2.44 p.m. Load, equal to 9 coaches. Engine, 472.

(2) Up b.g. express, due Paddington 2.45 p.m., passed Ealing 3.17 p.m., arrived Paddington $3.22\frac{1}{2}$ p.m. $5\frac{3}{4}$ miles in $5\frac{1}{2}$ minutes, including the slowing into the terminus. Load, equal to $9\frac{1}{2}$ coaches. Engine, Sultan.

(3) 3.0 p.m. b.g. ex Paddington, passed Ealing 3.11. Load, 10. Engine, Warlock.

(4) N.g. up express, due Paddington 3.30 p.m. and Westbourne Park 3.25 p.m., passed Ealing 3.45 p.m., arrived at Westbourne Park 3.51 p.m. and Paddington 3.57 p.m. Load, 11 coaches. Engine, 570.

(5) N.g. down express ex Paddington 3.45 p.m., passed Ealing 3.53 p.m. Load, $12\frac{1}{2}$ coaches. Engine, 658 bc. goods. **G. W. R.**

RAILWAY SPEEDS AND MYTHS—TIMING OF TRAINS.

[26650.]—I may be asked with some acerbity what right I have to assume that the timings of trains at 80 and 90 miles an hour are all erroneous, what right I have to say that such speeds may not have been run on some particular occasion? It may be said, "Because you have no records of such speeds, it does not follow that somebody else may not have attained them. If a credible witness states that he has timed a train at 80 or 90 miles an hour, it is absurd for you to assert on mere theoretical grounds that it could not be done." And I may have quoted against me the old saying that "an ounce of practice is worth a ton of theory."

The answer is, however, very simple. I disbelieve the occurrence of such extreme speeds because I know that the same engines as those with which these apocryphal speeds are said to have been done—or others precisely similar—have been specially tried over and over again under the most favourable possible conditions, *and have invariably failed* to reach 80 miles an hour. I might remark that a year's constant travelling by all the fastest trains in Great Britain with the express object of testing extreme speeds, such as was my experience last year, could hardly fail to have brought out one or two instances if such extreme velocities are really run. But it was not so.

I had the opportunity of testing the swiftest and most powerful engine in the kingdom in highly propitious circumstances, and always found that 75 miles an hour (or a trifle over once or twice) was the *maximum possibile*, and that was only attained or approached, even with light trains, on sharply-falling gradients.

But I prefer to put my own experience—large though it be—on one side, and to take that of others. Mr. Clement Stretton has stated over and over again in these columns that no engine, excepting the Bristol, of Exeter (9ft. single), has ever been authentically proved to have reached 80 miles an hour. I have the best authority for saying that when Mr. Brunel and Sir D. Gooch tried the G. W. 8ft. engine down a track of 1 in 100, and with every preparation for getting the utmost possible out of the engine, the highest velocity attainable was 78 miles an hour, or slightly less with any load. Some of your correspondents talk about a "load being needed to keep the engine steady." No doubt; but that steadiness is obtained at the expense of velocity. The more weight you put behind an engine, the less speed, other things being equal, you will get out of her. Theory and practice both prove this conclusively. The experimenters with "Iron Duke," "Great Britain," and "Courier," down the Wootton Basset bank, found that back-pressure effectually prevented any excess of speed over 78 miles an hour, and hitherto that obstacle has not been removed. That higher speeds might be run I do not doubt; but it would only be by increasing the diameter of the cylinder and driving-wheel, while retaining relatively short piston stroke and sacrificing the pulling power of the engine. On the G.N. I know that a number of careful experiments by the authorities proved the highest speed of the 8ft. engines to be about 75 miles an hour. A statement, made originally under a misapprehension, that a G.N. 8ft. took 16 coaches at 75 miles an hour, has been often quoted, and it has been logically argued that if this were accurate, surely the engines would take five or six coaches at 80 or more. Probably they would; but it was subsequently shown that the *distance* was incorrectly estimated, owing to the removal of a mile post in some repairs, and that the *time* was only taken with an ordinary watch, without even a seconds hand. On a repetition of the feat being attempted, it proved impossible, and it was not until the load was reduced from 16 coaches to 6, that the engine was able to attain 75 miles an hour down 1 in 200.

I was struck, during my experiments, with the uniformity of the maximum which different classes of engines were able to realise. You could get the time for a mile down to a fraction over or under 48 seconds, but there you stuck, and it was exceptional to get much below 49 seconds. As for the extraordinary speeds alleged to have been run by the Americans with their small-wheeled coupled engines, their impracticability is self-evident to any one having a knowledge of the subject. To talk about an engine, with 5ft. or $5\frac{1}{2}$ft. four-coupled wheels, going 80 or 90 miles an hour is to talk flat nonsense, if I may be pardoned the expression. Be it observed, I do not exempt myself from the list of those who have believed themselves to have recorded a speed of 80 miles an hour. When I was a small boy, I used always to time the speed of trains by which I travelled, and I once distinctly believed myself to have timed a G.W. train of four coaches at the rate of a mile in 44 seconds (or 81·8 miles an hour) down 1 in 1,320. Although juvenile, I was very careful, and I cannot even now say how the error arose. But that there was an error I do not for a moment doubt, because I know now that it was not within the power of the engine to run four coaches at that speed on a nearly level line.

I believe I mentioned this run some years ago in these columns. I give up my own timing as completely as I discredit others of a like character, and it seems to me idle and mischievous—as tending to promulgate and perpetuate erroneous notions—to treat such impossible records as genuine. So my fellow correspondents cannot justly complain, seeing that I treat my own records as stringently as theirs. I confess I am not satisfied about that of the quoted run of "Great Britain" from Paddington to Didcot, 53 miles in $47\frac{1}{2}$ min. (By the bye, it is usually quoted now as "$53\frac{1}{4}$" or "$53\frac{1}{2}$" miles in "47 min.," once even "41 min.") I should like to see it tried nowadays. I strongly suspect that if it could be really tested, it would turn out to be from what is now Westbourne Park to the place where steam was shut off for stopping at Didcot (or, say, the distance signal), and that the time may have been only a second or two under 48 min. (or more likely just under 50 min.); if so, we should get a far more probable result. The number of different versions of that run that have been published seem to me to throw considerable doubt upon it. I question whether any engine in the present day could run 53 miles in $47\frac{1}{2}$min., including stopping and starting, and upon a slightly rising gradient all the way. At all events, none ever does so, even when extreme speed is most desired. Then there is that remarkable run of 15min. 10sec. from Slough to Paddington ($18\frac{1}{2}$ miles), said to have been done in 1841, long before the 8ft. engines were built. We shall never know the truth of that now; but there is no engine of the present day that could do it, or, at least, that does it.

I am sorry to damp the zeal of those who believe in "90 miles an hour," but no good end can be served by believing in what is at present a myth. **Charles Rous-Marten.**

Wellington, N.Z.

RECENT WORK OF OLD LOCOMOTIVES.

[26651.]—During my railway wanderings in 1884 and 1885, I had several opportunities of noticing the good work done by old "single" engines of various once-famous classes. In a recent letter, I mentioned some runs with L. and N.W. 173 Cornwall. I shall have occasion another time to refer to the 7ft. 6in. "singles" on the same line, and to that G. W. 8ft.; but these engines are being still kept up, and may be deemed practically modern. The classes I refer to are S. E. R. 7ft., G. E. 7ft., G. N. 7ft. (229—240 class, outside driving-bearing), L. and N. W. 7ft. (Bloomers), and Midland 6ft. 8in.

With each of these classes excellent work was done, but I have no record of the coal consumption, which may have been disproportionate, although I have no reason to suppose so. The S. E. 7ft. single (cyl. 16 × 22) No. 204, on the 7.40 a.m. down mail, took 15 coaches from Cannon-street, and slipped two at Ashford (55 miles) in 74 min. Now this may not seem at first sight a great feat; but when the ascent of the Halstead and Sevenoaks banks is borne in mind it will be seen that the work was not at all to be despised. The 12-mile ascent (1 in 120 to 1 in 140) from New Cross to Halstead summit, was surmounted in 21 minutes, or at the average rate of nearly 35 miles an hour. The 7ft. and 6ft. coupled bogie engines generally took a similar time to ascend the bank, notwithstanding their superior tractive force. Of the G. N. 7ft. singles (cyl. 17 × 24, formerly 17 × 22), on the fast Leeds express (down), starting at 1.30 p.m., and timed to reach Peterborough in 88 minutes, No. 229 kept time exactly, with 13 coaches, weighing in all over 159 tons, exclusive of engine and tender. The Potter's Bar bank was ascended in 19 minutes, the speed never going below 45 miles an hour after Hornsey, and rising to 70 down the Hatfield and Abbot's Ripton banks. The same engine on the up midday Cambridge express, with 6 coaches, did the 58 miles in 69min. travelling time, stopping at Royston and Hitchin, and attained a speed of 73 miles an hour downhill near Baldock, doing the $9\frac{1}{4}$ miles from Ashwell to Hitchin (stopping at the latter station) in $8\frac{3}{4}$min. No. 235, on the 3 p.m. down Cambridge express, ran, with 7 coaches, to Hitchin in 40min., including a stoppage of 1min. at Finsbury Park. The $29\frac{1}{2}$ miles from Finsbury to Hitchin, including starting and stopping and the ascent of the Potter's Bar and Welwyn bank, occupied only $34\frac{1}{2}$min. But perhaps the best performance of all was with No. 234 on the 8.21 p.m. up express from Peterborough, with a heavy train of 16 coaches. The time allowed for the $73\frac{3}{4}$ miles to Finsbury Park was 91min., and the distance was done exactly in that time, in spite of a special stop of nearly 2min. at Huntingdon. The run of $56\frac{1}{4}$ miles from Huntingdon took only 66min. This seems to me most admirable work, especially when it is recollected that a seven-mile bank of 1 in 200 has to be climbed past Hitchin, and a six-mile bank past Hatfield.

As an illustration of the fast travelling of the G.E. 7ft. singles with light trains, I may mention that on one occasion No. 290, with the "seaside train," which was allowed 47min. for the $38\frac{1}{2}$ miles from Spalding to Lincoln, made up *seven minutes* on that fast time, and maintained an even speed of 60 to 65 miles an hour for 35 miles continuously, doing the $38\frac{1}{2}$ miles in 40min., starting and stopping. The L. and N.W. "Bloomers" (7ft. single, cylinder 16 by 22) were little used on expresses while I was last in England, but occasionally ran as substitutes or on duplicate trains, and were usually put on the very fast 2.10 a.m. Birmingham up express when that was run in advance of the 12 noon from Liverpool, the times then allowed being only 41min. Rugby to Bletchley (36 miles), and 48min. Bletchley to Willesden ($41\frac{1}{4}$ miles), about the smartest timing on that line. The "Bloomers," Archimedes 989, Medusa 999, and Rowland Hill 1,008, ran it with seven coaches, and kept time excellently; indeed, Archimedes once gained a minute between Rugby and Bletchley, and attained over 72 miles an hour on part of the way. I was sorry to notice that at the beginning of last year the fast remaining "Bloomers" were deprived of their regular numbers, and placed in the condemned class (1800-1900) and that more recently their names have been transferred to new engines. They have been excellent servants in their day, although they lack power for modern loads and slip excessively at starting.

My experience with the Midland 6ft. 8in. singles was mostly in "short" expresses between Leicester, Derby, and Nottingham. In one instance, No. 31, with eight coaches, started from Trent, and covered the first nine miles in 11min. No. 4 (formerly No. 130, Stephenson's build, date 1852) took a heavy train of 15 coaches crowded with passengers from Derby to Trent ($9\frac{1}{4}$ miles) in 12min., starting and stopping, and attained a speed of 60 miles an hour near Draycott.

All these are highly respectable specimens of locomotive work; and as these fine old engines will soon be mere memories of the past, I feel sure that those correspondents who have at various times championed them even against their modern rivals will be glad that their more recent achievements should be placed on record.

Wellington, N.Z. **Charles Rous-Marten.**

DIETETIC FALLACIES.

[26652.]—There is a paragraph on p. 342 which, taken as a whole, seems generally accurate and common-sense, but in which I am surprised to find the extraordinary statement made that it is a fallacy to regard arrowroot as nutritious: "it is simply starch and water." Unless some occult meaning attaches to "nutritious," I should like to ask what proof there is that starch is not a food? If it is not, what about potatoes, rice, maize, sago, tapioca, and the cereals generally, which are mainly

starch? Perhaps it is meant that in the form of arrowroot the starch is not assimilated; but that can scarcely be, because it is acknowledged in the same sentence that it is "restorative," and if "restorative," why not nutritious in the sense that nutriment is food? In an adult, the actual amount of nitrogen required is small compared to the quantity of heat-giving or force-producing food that must be taken, and even much of that is thrown out by the system unutilised, so far as physiologists can possibly say. Can any of your readers tell me of experiments which would go to show that starch is not nutritious, or explain on what ground the statement is made? Many assertions of a similar kind are made nowadays, according to the hobby of the utterer or writer; but it seems to be considered unnecessary to offer an atom of proof. Some little time ago I saw it stated that tea is adulterated with salts of iron; but surely if that were so, the infusion would be so nauseous as to be undrinkable, for, according to my chemistry, it would be a sort of black ink. Perhaps your able chemical writer, Mr. Allen, can tell us whether he ever found a sample of tea adulterated with salts of iron.

A Grocer.

RANGE OF BAROMETER.

[26653.]—WITH reference to the low reading of barometer on December 8th mentioned by "R. S. T." (letter 26622, p. 369), it may be interesting to state that the extraordinary low reading of 27·39in. was recorded here at 1.30 p.m. on Wednesday, December 8th, when the centre of gale must have passed very near to us, but slightly north, as the wind veered from south-south-west round by west at 2 p.m. We only felt the violence of the wind here at from 3 to 4 o'clock on that morning, when heavy rain squalls were experienced; but we had very little wind—comparatively —from that time until after midnight of that day, with wind from W.N.W., when the centre had passed over to Scotland. The cyclone had evidently been retarded after it passed here, as it had been deflected to the north-east by a subsidiary depression which had slightly preceded it over the south of England on same morning, and the two depressions had apparently mixed up. On Tuesday evening, at 9.30 the mercury stood at 29·27in., and in twelve hours it had fallen to 27·87in., being 1·4in. in that time. The following are the readings taken by a local optician, as indicated by a Kew standard barometer, reduced to mean sea-level and 32° temperature:—

December 8,	9.30 a.m.,	27·87,	falling.
"	" 10. 0 "	27·83	"
"	" 10.30 "	27·76	"
"	" 11.15 "	27·70	"
"	" 11.30 "	27·67	"
"	" 12. 0 noon,	27·59	"
"	" 12.15 p.m.,	27·54	"
"	" 12.30 "	27·46	"
"	" 1. 0 "	27·44	"
"	" 1.15 "	27·41	"
"	" 1.30 "	27·38,	lowest.
"	" 2. 0 "	27·39,	rising.

I am informed by a friend who was in Carlow, in the south of Ireland on that day, that his pocket aneroid (a fine one, by Beck) indicated 27·40in. between 12 and 1 p.m., so that the depression must have been an extended shallow trough, and not a steep and deep centre of limited area, such as the centre which passed about 60 miles north of here on January 26, 1884, when the mercury fell to 27·5in., and the wind from 4 to 5 p.m. showed a velocity of 72 miles per hour. The highest reading of barometer here for some years was recorded on January 18, 1882, when the mercury stood at 30·91in., so that we had a range of 3·53in.—probably as great as shown anywhere on the globe.

I understand that a reading of 31·125in. has been recorded in Boston, U.S.A.; but I am not aware that the exceptionally low reading of 27·38in. has been known there.

Belfast, Dec. 27. **I. W. Ward.**

LONDON is at present supplied with water from the Rivers Thames and Lea, and from certain springs in the valleys of the Thames and Lea, supplemented by Chadwell springs, and from eleven wells in the north of London, and ten wells in the south of London, all down to the chalk. The proportions from each of these sources for the month of October, 1886, were nearly as follows:—From the River Thames and certain chalk springs in the Thames Valley, about 52 parts of the whole: from the River Lea and certain chalk springs in the Lea Valley, about 36 parts of the whole; from the eleven chalk wells in the north of London, about five parts of the whole; from the ten chalk wells on the south of London, about seven parts of the whole.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[60432.]—**Architecture.**— Undoubtedly architecture has suffered much from archæology, though I doubt whether university societies, if indeed such exist, have had much outside influence. My reference to Oxford architecture referred entirely to work of the 16th and 17th centuries, and not to modern revivals. But I go further, and condemn Classical archæology no less than Mediævalism, and contend that if the Americans, in designing a many-chambered, irregularly planned building for their Capitol, chose for model the Pantheon, which is a single circular apartment, they showed themselves as far from that union of common sense with artistic perception, which should be the architectural ideal, as some self-styled practical people nearer home. Mediæval Gothic was, as a style, admirably adapted to Mediæval requirements and resources. Much of it was, and still is, artistically admirable, and capable of giving the beholder the highest pleasure. Modern Gothic usually deserves all that is said against it. In Greece a score of centuries ago architecture had reached an astonishing perfection in certain directions; but to-day, in London or Manchester, the characteristic forms of Greek architecture—a portico or pediment—are at least as unsuitable as lancet windows. Architecture, like all things else, must develop—"evolution" is the fashionable word for the process, and architectural forms must adapt themselves to altered circumstances or become mere fossils for the archæologists. Now, for nine-tenths of those who have to do with building, Capitols and palaces are but of secondary importance, the vital question being the structure of our homes of humble brick and timber. Success in this art will be a better preparation for more grandiose architecture than the most scholarly study of Vitruvius or the Pantheon.—W. A. S. B.

[60530.] — **Lens Grinding.** — Amateurs are likely to attempt to polish the first lenses they grind before they are ready for polishing; the result is more than double the work and a very inferior lens. The last emery I use is the finest flour, obtained by putting a quantity of the emery I had used for grinding into a bowl and mix with plenty of water, and then filter it through two thicknesses of muslin. By this means I am sure no coarse or gritty particles are mixed to spoil my work. Before polishing, I wash and dry my lens, and carefully examine the surface with a good glass to see that there are no scratches or roughness, especially at the centre. To polish, I first heat the "tool" until it will melt yellow pitch. I rub the surface over with a lump of pitch, and thus obtain a nice even coating of it. Over this I put a piece of good thick silk, press it down evenly, and let it cool; on the silk I put the putty powder and water, and keep up the supply as required. By attending to these particulars, I find no more trouble in polishing a lens than in grinding one. I grind and polish in the lathe by attaching a horizontal table on which the "tool" is screwed; it is much quicker than the hand.—BRIAN BORU.

[60868.] — **Numbering Stamps.** — Do away with the ink, and substitute a ribbon of carbonic paper as follows:—Fix a roller a little distance behind, and on a level with the stamping cushion. On this roller, which has a long slit for the purpose, is wound the carbonic ribbon, and the end of the ribbon is passed through a very narrow slit, fixed somewhat below level of stamping cushion. In order to print a number you simply draw your carbonic ribbon forward on top of the paper, and then obtain an impression. By having different coloured manifold papers you can obtain different coloured numbers, and you can even take two or more impressions at the same time.—T. D.

[60920.]—**Mangel Wurzel.**— There are some good papers, by the late Dr. Voelcker, on the sugar-beet in the "Transactions of the Royal Agricultural Society"; but, unless your correspondent wishes to dive very deeply into the matter, the following may be sufficient for his purpose. Any given beet-root contains its maximum of sugar just at the time it reaches maturity —that is, when the early leaves begin to decay— say, in September. If warm, rainy weather prevails, the roots will begin to send out new leaves, and every one of those will be produced at the expense of the sugar. As a rule, the small and medium-sized roots are richer in sugar than the large ones, and loss of sugar goes on during the whole of the time the roots are kept. Therefore, feed them to the cattle as fast as the latter want them. If you want more particulars, write again. —SAML. RAY.

[60925.]—**Violin Query.**—No advantage, except with certain kinds of wood—e.g., beech.— E. W.

[60948.] — **Electrical Replacement Indicator.**—I am an admirer of Mr. Conry's answers to queries and general information, therefore I trust he will not think it rude or out of place my referring to his electrical replacement indicator (p. 327). Will he kindly look again at his diagram?—and I am sure he will then see his error. I presume the diagram was planned under pressure for time, or otherwise he must have noticed it. I have waited a week thinking he would have corrected same, and, seeing another query relative to it this week asking dimensions, &c., I thought it would not be out of place to draw Mr. C.'s attention.—JULIUS.

[60963.]—**Terracotta.**—If I wanted such a furnace as "Architect" indicates, I should write to Mr. Fletcher, of Warrington. I think he has them large enough in stock; but at any rate would tell the querist whether he had or not.—SAML. RAY.

[60977.] — **Ventilation of Sewers.** —"Surveyor" may possibly find what he wants in Latham's "Guide to Sanitary Engineering"; but there is nothing satisfactory about ventilating sewers anywhere. The only feasible plan seems to be to run up pipes at intervals above the house-tops, or to adopt the free ventilation by street grids. —NUN. DOR.

[60979.]—**Polishing in the Lathe.**—See a reply (60845) on p. 349, and the indices of back volumes. For ornamental work, you cannot do very much in the lathe, but must use wire brushes, and little rubbers and burnishers. What is known as "Sheffield lime" is the finishing powder, and that is used with dollies made up of discs of calico to a thickness suitable to the work.—NUN. DOR.

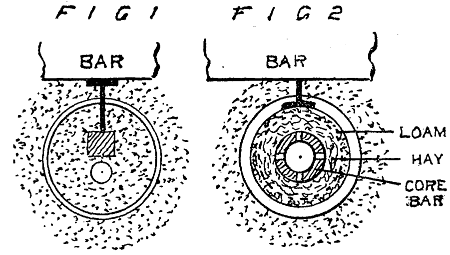
[60987.]—**Organ Query.**—The following would be a very nice specification, and would suit your room very well:—

Stopt. diap. bass...	C C to ten. F...	18 pipes
" " treble	ten. F to C ...	43 pipes
Dulciana............	ten. F to C ...	43 pipes
Principal............	C to C	61 pipes

The above specification is taken from an actual organ, the dimensions of which are as follows:— Height, 7ft. 3in.; width, 4ft.; depth, 1ft. 10in.— T. D.

[61000.] — **Pipe Moulding.** — I am not acquainted with the practice of the Glasgow shops, nor with the special apparatus employed in the manufacture of hot-water piping, which is quite a distinct occupation by itself. But I can tell you how to cast thin pipes. There are two ways of making the cores. One is to have an iron core box hinged and bored out, and to ram the green sand cores in this on a solid square iron bar; venting as is usual with green sand cores by means of a rod laid down the centre, which is afterwards withdrawn, leaving a vent hole throughout. The chaplets are rammed up in the core, resting against the iron bar, and projecting through certain holes in the core box, to a definite distance, or far enough out to touch certain bars in the moulding box, whose position corresponds therewith. Since the bars in the moulding box and the holes in the core box must correspond, this is suitable only for repetition work, which will pay for the special apparatus. There is thus no mass of metal in the body of the actual pipe, Fig. 1;

FIG 1 FIG 2



but the stop effectually prevents the rising of the core. When the pipes are cast the chaplet head is cut off. The core sand must be free and open to give readily to the shrinkage of the pipe when very thin, say, ⅛in. With $\frac{3}{16}$in. or ¼in. thickness loam cores can be, and are, used, the core bar being of the usual perforated form, wound with *loose* hay, spun on (i.e., not made into bands), and covered with loam. The chaplets are of *cast* iron, very small, and press against the core in the usual way, Fig. 2. They become partially fused and soldered before the metal sets. The metal is soft iron, and run as hot as possible. As soon as the pipe is cast, the core bar is pulled out endways to allow the shrinkage to take place freely. I do not know if plumbago is used in Scotland for thin pipes; but should think not—first, because the pipes are not so smooth and glossy as one expects to see when plumbago is used; second, because unless laid on very thin, it would be apt sometimes to wash up into the top, and produce inequality of

surface. Besides, pipe-making is a rough and cheap class of work, and plumbago, being expensive, is reserved for the better kinds of castings. —J. H.

[61006.]—**Length of Belting.**—To the correspondents who replied to the above. Please examine the formula inserted with it. I think the cosine should *not* be employed in finding the length of the straight parts. The belt being a tangent to the pullgys at the extremities of contact, the lines drawn to the centres of pulleys are parallel to each other, and consequently the sum of the straight parts is $= c =$ 24ft. 2in.—MILLER.

[61055.]—**Varnish for the Bright Parts of Bicycles.**—I have used an American lacquer called "lustrine" for the bright and nickel-plated parts of my bicycle, and it answers admirably well. It is transparent, and is removed at once by a little spirit of wine. It will preserve any steel-work from rust.—F. RICHARDS.

[61057.]—**Steam Launch.**—Thanks to "Engineering" for taking up this query. The dimensions given are correct, and I may mention that the yacht was built from a design in Dixon Kempe's "Handbook of Yacht-Sailing." Her speed under canvas with a moderate breeze is about 6 knots.—ITCHEN.

[61070.]—**Lathe.**—There is a stud tapped into the lathe-head a few inches below tail of spindle, and on this stud the quadrant plate pivots, and also on same stud runs a pinion having a sleeve, on which another pinion as required is placed. The quadrant plate carries a pinion on one side, and two pinions on the other side of the first pinion, and gearing with it. He will now understand, if quadrant-plate is moved up, one pinion gears with mandrel pinion and drives one way, and if down, the reverse. The quadrant has a slot and set screw tapped into head for fixing it, as desired in either gear, or out of gear entirely.—T. C., Bristol.

[61071.]—**Planing-Machine Tools.**—I think your difficulty with planer is, perhaps you have cranked your tools so as to throw point behind pivot of tool-box.—T. C., Bristol.

[61092.]—**Hot-Air Motor.**—TO MR. SEAL.—I have not the drawings by me small enough to be inserted in these columns, but I will get them out as soon as I can spare the time. I will send drawings of ½ man-power, then you can make allowance either way, if you wish to make one of ¼ or 1 man-power.—J. SEAL.

[61096.]—**Organ Building.**—I have seen an organ of the kind you inquire about. The stopt. diapason bass is permanently open, and consequently requires neither slide nor stop knob.—T. D.

[61099.]—**A Rule of Grammar.**—I have waited to see what further criticisms this query would produce, and find that my reply was not so "blindly copied" as "Doctor Medicinæ" would wish to be believed. Take the following example: —Query, Who is there? Would you reply I, or me, remembering that the reply is meant for I or me "am here"? Which is right? Custom may favour the expression "me" somewhat; but if it is correct, for what earthly reason is the opposite cited in modern grammars and taught in all schools worthy the name? Can any reader of the "E. M." give a reliable instance where an English scholar is taught that the verb "to be" does not take the same case after it as before it? "D. M." would do well to read the first period of the reply in the issue of December 17th of "What is sauce for the goose is sauce for the gander."—W. C. HALL, Newport, Mon.

[61099.]—**A Rule of Grammar.**—Much, perhaps too much, has already been said about the question of "Doctor Medicinæ." It is not at all a specially English question. The fact at which the question points is a very plain one: a grammatical error, admitted by common, tacit consent. Numerous instances are to be found in many languages, and the same discussion, started by the doctor to-day, may arise again after another error has crept in, which will not be accepted so readily by everyone. It may be admitted that the correct form, "It is I," or any other expression, will be upheld by those who have a more keen feeling for correct language; but, finally, they must submit to the majority, and, as happened in French, adopt the erroneous form "C'est moi." In English, it appears, the grammatical error is neither generally adopted nor rejected; everyone chooses according to his taste, without the least care for, or knowledge of, correct language or logic. The grammatical error of "It is me," has been pointed out by Mr. Hall and Mr. Bottone, and I fully agree with both of them.; but "Weald's" answer will leave the impression that "It is I" and "It is me" are both equally correct, and what is worse, he suggests that "It is I" may "possibly" be an erroneous way of expressing oneself. He will allow me to say that both his arguments to justify the English "It is me" are wrong. "Es ist mich" is not German: it ought to be "Ich bin es"; and "Moi" is not and never was a nominative; it is, and always has been, an accusative, only employed erroneously as a nominative since the 14th century. In the time of Froissard (1337-1410) and even in Marot's days (1495-1544) one still said "Je qui suis." The confusion of cases is of very general occurrence, not only with the verb "to be"; for instance, in English, "He told me himself." In Italian, though the subject is seldom the accusative, one very often says, lei for ella; lei sa, you know; che dice lei? what do you say. One ought to say: Sono io—it is I (litt., am I); but in the dialects one generally says, "Son mi," mi accusative; and here and all along the Riviera one always says: Mi non so, I do not know, instead of Io non so. The accusative for the subject is, however, an exception, and only used in common conversation; but when the personal pronoun is the predicate, then the erroneous form, the accusative, must be used: S'io fosse lui (and not egli), if I were him.—W. VAN EYS, San Remo, Dec. 1886.

[61101.]—**Stars Visible from Bottom of Well.**—I can transfer my question now to "B. A., Handsworth," and accordingly beg to ask him why he thinks that Gamma Draconis would be "about the only star likely to be seen in the latitude of London" in the daytime from the bottom of a well. I have not been able to find any mention of the subject in Ball's "Story of the Heavens," in Newcomb's "Popular Astronomy," or in Lardner's Astronomy; while all that Sir J. F. W. Herschel says (para. 101, "Outlines") is "Indeed, from the bottoms of deep narrow pits, such as a well, or the shaft of a mine, such bright stars as pass the zenith may even be discerned by the naked eye." It seems to me that the querist asked for a list of such stars visible in these latitudes, and if Gamma Draconis is the only one, I ask why that is so? Do not Phecda, Mizar, Merak, Chaph pass as near the zenith as Etanin?—E. D.

[61131.]—**Electric Cautery.**—I am obliged to "Ohm" and Edward Conry for their replies. I am sorry I cannot comply in this letter with "Ohm's" request for diam. of cautery wire, and whether resistance given was hot or cold; but I will obtain and forward it. I am a surgeon, and have to depend on others for my electrical appliances, and have, in consequence, suffered much. I may tell Mr. Conry that I had six bichromate cells ($K_2Cr_2O_7$ and H_2SO_4 in Aq) with 4in. by 4in. of immersed zinc—no porous cell—and they no more than made the platinum point so hot that it could not be retained in the grip of the fingers. The zincs certainly were not all of a size; there were four, as stated (zinc and two carbon plates), one with two zinc, and carbon between, perhaps 3 by 4, and one a large zinc rod. There was ample solution round them all. Of course, the making of any instrument for measuring current cannot be undertaken by me, as I have neither tools, nor appliances, nor skill to use them. But if "Ohm" or Mr. Conry will kindly give fuller details, I could get an instrument made. I have been told that not less than 14 ampères is necessary for surgical work. My own cautery is worked at present from a hired accumulator; but not satisfactorily.—A. DUNLOP STEWART, M.B., &c.

[61131.]—**Electric Cautery.**—TO MR. E. CONRY.—Excuse delay in replying. I have been laid up with a hurt hand, and could not write. I have found two formulæ for finding what you want; but they are both so intricate, and would require for their application so much trouble, that I really think they would not help you. However, I give them as they stand. For myself, I prefer in such small matters as the making of an electric cautery to rely rather on experience and experiment than on such nice calculations. Three good Leclanché jars will bring to a bright red about ½in. of platinum wire, No. 30, or thereabouts. If you will give the exact size and length of the wire you require heated, I could tell you better aud more practically than I could do by calculation. (1) Let c = current in ampères, R = resistance of wire in ohms, W = weight of wire in grammes, S = specific heat of metal (T, heat of platinum = ·0355), H = rise of temperature per second in °C., also ·24 calories = 1 ampère. Then $H = \frac{\cdot 24 \times c^2 \times R}{W \times S} = \frac{66\, c^2 R}{W}$ = copper °F. The melting point of platinum = 2,100° C. (2) The heat generated in time T (seconds) by a current C, through a wire of resistance R, is $\frac{C^2 R T}{J} = \frac{E C T}{J}$ gramme degrees, where $J = 4{\cdot}2 \times 10^7$, and $C_1 R_1$ and E are expressed either in absolute electromagnetic or electrostatic units. For practical use when C is ampères, R ohms, E volts, and T seconds, the heat generated in time $T = C^2 R T \times 0:24$ or $E C T \times 0{\cdot}24$ gramme degrees.—EDWARD CONRY.

[61139.]—**Chromic Acid v. Bichromate.**—The statement that chromic acid is twenty times as strong as bichromate is an expression devoid of meaning. The amount of work, or the depolarising power of the solution, depends upon the quantity of CrO_3 dissolved. Diluted acid saturated with bichromate contains about 8 per cent. CrO_3, and if you substitute chromic acid in equivalent quantity you gain no electrical advantage whatever. Chromic acid is, roughly speaking, about ten times as soluble as bichromate, and, therefore, at first sight it would appear possible to manufacture a solution having ten times the durability. Now, according to the equation—

$$\underset{65}{Zn} + \underset{392}{4H_2SO_4} + \underset{201}{2CrO_3} = Zn\,SO_4 + Cr_2 3SO_4 + 4H_2O + O_2.$$

For every 201 parts CrO_3 we require 392 H_2SO_4, 294 of which act on the CrO_3 and 98 on the Zn. 100cc. of solution containing 8gr. CrO_3 must contain at least 15·6gr. H_2SO_4, or, by volume, 8·5cc.; therefore, 100cc. of solution containing 80gr. CrO_3 must contain 85cc. of H_2SO_4. I have never tried working with such strongly acid solutions, so cannot say what would be the result. I should think the zinc would be dissolved with rather greater rapidity than would be agreeable. At the same time, it must be remembered that I have quoted the minimum amount of H_2SO_4; it is customary to use more than is required by theory. Another reason why one ought to avoid the use of a large quantity of H_2SO_4 is that the $ZnSO_4$ would separate in the solid form through want of water in which to dissolve. Zinc is not soluble in concentrated H_2SO_4, but it becomes superficially incrusted with a film of sulphate.—A. PERCY SMITH, F.I.C., Rugby.

[61145.]—**Does it Boil?**—Surely "Weald's" query can hardly be called quite bonâ fide when it concealed a "presumed belief." Would it not be wiser, before starting any hypothesis of his own, to read up what is to be found on the subject in any elementary treatise, such as "Deschanel's Physics," for instance, and then if difficulties still present themselves, he will be in a better position to frame an intelligible query, and one which could perhaps be answered without writing a complete treatise. However, I rejoice at his protest against being put off with the substitution of polysyllabic ebullition for simple boiling as an explanation.—W. A. S. B.

[61156.]—**Battery for Lamps.**—TO "ALBO-CARBON."—The factor for judging lasting power of bichromates, which I promised in 61156, 17th December, is as follows:—10oz. of saturated solution of bichromate of potash, in a double-fluid cell, outer containing sulphuric acid and water 1 to 10, will give a current of 16 watts for one hour, or a less amount of energy for a longer period, in proportion. Watts = volts × ampères. With cells of one pint and over, and well made, without unusual space between zinc and carbon, this standard holds good without much variation whatever may be the relative proportions of volts and amps. making up the watts. Cost would be for 10oz. about 3d.—EDWARD CONRY.

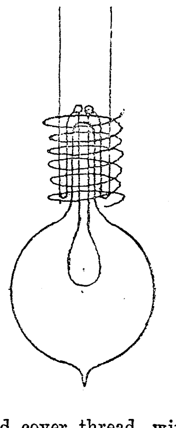
[61175.]—**Removing Scale from Boiler.**—I am pleased to note your query *re* sugar for this, but should like to ask if you have only recently taken charge of the boiler, and consequently have treated it somewhat different to former attendant. The reason I ask is: Some few years since I had an 8-horse vertical which used to throw off its scale, and which heaped up between vertical tubes and nearly choked the sides above mud-holes in a few weeks, and the water used was principally the heated water returned from some heating pipes, no composition used of any kind. Anyhow, you can safely remove all present scale, and then let a crust as thick as this paper grow to protect plates, and keep it at that.—T. C., Bristol.

[61175.]—**Sugar for Removing Boiler Scale.**—I do not consider that sugar, under the conditions of its use as a disincrustant, would materially corrode boiler plates, although, with free exposure to the air such a corrosion would be material enough. I question if there is in the market a boiler liquor of which it could be confidently asserted it was entirely innocent of solvent action on iron, and on iron particularly at the temperature and pressure of ordinary boiler work. At least, I assume so from the fact that most of them have caustic soda, and therefore more or less carbonate of soda, as their essential constituent. We find in Watts's "Dictionary of Solubilities" an assertion to the effect that iron dissolves in carbonate of soda with evolution of hydrogen. Doubtless the efficacy of boiler-liquors as anti-incrustants is in part due to their minute solvent action on the face of the plates.—NORMAN M'CULLOCH.

[61176.]—**Wimshurst Machine.**—Cement the broken plates by means of Kay's coaguline. I cemented in this manner two of my plates about a year ago, and they are still holding.—T. D.

[61178.]—**Electric Lamp.**—File glass away till imbedded platinum wire protrudes. Pierce a fine hole in a narrow strip of very thin copper (or flatten end of copper wire and then pierce it); place hole over projecting platinum; bend wire or strip of copper down the narrow part of lamp, and securely tie it there with thread. Put on the hole

a drop of soldering fluid; now a bead of solder, and hold bit on till it runs; bring up liberated end of copper wire or thin strip, and tie to some small



part of lamp, and cover thread, wire, solder, &c., with sealing-wax (or, preferably, thick gum), and you should succeed so well as—J. W.

[61183.]—**Engine Details.**—You can't cut off satisfactorily at $\frac{1}{2}$ stroke with a single valve; be contented with $\frac{3}{4}$. If $\frac{3}{4}$ will do, you will require $\frac{7}{16}$ lap on valve, and a consequent travel of $1\frac{1}{8}$in., and throw of eccentric will be $\frac{5}{8}$in. I have no lap on exhaust edge. The area of ports is usually $\frac{1}{20}$ to $\frac{1}{25}$ area of cylinder, and width and length are varied by different makers; but in all cases the travel of valve must equal twice the width of port, added to amount of lap. The above amount of lap rather cripples exhaust, so you had better have $\frac{1}{16}$ less, then travel need only be $1\frac{3}{8}$.—T. C., Bristol.

[61183.]—**Engine Details.**—The following are dimensions of slide-valve, &c., to cut steam off at half stroke:—Length of valve, $2\frac{11}{16}$in.; width $2\frac{1}{4}$in.; exhaust cavity, $1\frac{1}{8}$in. by $1\frac{3}{8}$in. by $\frac{3}{8}$in. deep. When the valve is in the middle of its stroke or travel it will have $\frac{13}{32}$in. outside lap, and $\frac{1}{16}$in. inside lap; the lead may be $\frac{1}{32}$in.; steam ports to open, $\frac{7}{32}$in.; throw of eccentric must equal travel of valve, which is $1\frac{1}{4}$in., being twice the amount of lap and port opening. It will be seen by the above figures that to cut steam off at half-stroke, the valve must have a lap equal to twice the amount of port-opening required, and the travel of valve will be about three times the lap. The ports in the cylinder under notice have not been proportioned for a high speed and a cut-off at half stroke with full port-opening ($\frac{5}{16}$in.), but are about right for a $\frac{3}{4}$ cut-off, which requires a lap equal to the port-opening and travel of valve four times the lap. Taking $1\frac{1}{4}$in. for the travel, we get a $\frac{5}{16}$in. lap, and $\frac{5}{16}$in. port-opening—viz., the full width. We now come to the question of area of steam ports. As a general rule, they should be for a moderate piston speed one-twentieth, and for high speeds one-tenth the area of piston. Your steam-ports are about one-sixteenth area of piston, and if the engine is to be run at a high speed I should advise you to lengthen them as much as possible. To find at what portion of stroke the steam is cut off when lap, lead, stroke of valve, and stroke of engine piston are given, the rule is, to twice the lap, add the lead, divide the sum by the stroke of valve, square the quotient, and multiply it by the length of stroke of piston. The product is the distance of piston from end of stroke when steam is cut off. —E. L. P.

[61188.]—**Storage Cell.**—To "A READER."—You would want four cells if your lamp is actually as low as 8 volts, and with most lamps sold as such you would require five cells. I should not advise you to try painting the plates with anything. You will do better if you "form" them from the plain lead, especially as you want a small cell. The acid for the cells is a mixture of sulphuric acid and water in proportions to give a specific gravity of 1·150, i.e., about 1 part acid to 10 water. If by your expression "I want to carry it about" you mean in the pocket, you certainly will not get any storage battery to give 10 ampère hours (that is about what you would require) of size small enough to be carried in any garment. You would want in each cell 200 square inches of peroxide plate, which you could obtain by plates 5in. by 10in. each—two + three—being in each cell, or any other adjustment of sizes convenient to your resources. You could make it a "dry" battery by filling the spaces between the plates with clean, fine sawdust, or coarse white felt or flannel, the last for preference, and keeping such material saturated with the battery acid; but in that case you would need several more cells, probably three more, as you would very much increase the internal resistance of the cells, and consequently the total resistance of the circuit, by making them in the dry form. If you start to make such a battery you will much increase the readiness of formation by soaking the plates in equal parts nitric acid and water for about 12 hours.—EDWARD CONRY.

[61190.]—**Differential Feed.**—With a right-hand screw the revs. of screw must usually be greater than that of the bar. I think "Goodeve's Mechanism," page 207, will supply all you require, with a little thought. Briefly, it is driving wheels divided by driven; this gives rate of screw as compared to bar. It is the difference of their motion that gives the feed, so that if screw makes 5 and bar 4 revs. the screw makes $\frac{1}{4}$ turn more for each turn of bar—that is, $\frac{1}{4}$ of $\frac{1}{3} = \frac{1}{12}$in. cut, and for same thread as screw it must travel twice the speed of bar, so that in your case $\frac{A \times G}{B \times D} = 2$ for 36 threads per inch—that is, 12 times No. of leading screw; value of train must equal $1 + \frac{3}{36} = \frac{13}{12}$. Use any wheels, as in screw-cutting, that will gear to this value, and each pair of wheels that gear must be of the same total number of teeth if of the same pitch. Thus number of teeth in A + B must equal number in D + G. It is here where the difficulty creeps in, and the simplest way is to get the ratio with A and B, and then put a pair of equal wheels any pitch that will gear on C and D. Of course, C D may always be the same if the sum of the teeth of wheels A and B is always the same. For 35·8 threads the nearest wheels are 129 and 119 on A and B.—T. C., Bristol.

[61194.]—**E.P.S. Secondary Batteries.**—Charging these in series with an arc lamp circuit is an unusual method, but I do not know of any reason why it should not answer; you should connect them, however, all in series, instead of in two lines as you have drawn—by the latter method you halve your charging current. You could not, however, expect a battery of that size to hold very much. Allowing $\frac{1}{2}$in. space for each plate, and that is under rather than over the best working allowance of room, you would be doing very fairly if you got 10 amp. hours out of the battery after one hour's charging in series with 15 amps. current. Are you sure that the cells do not run themselves out by internal short-circuiting. This is the constitutional plague of all small storage batteries; and are you careful to keep the acid always above the tops of the plates? Such small cells would need filling up with water several times in the course of an hour, charging with a current of 15 ampères, which is heavy charging for such small cells—much more than advisable at all. How are the plates separated from each other? I should suggest charging them for one exact hour at the above current (since, under the circumstances, you would not be able to diminish it), keeping them carefully filled up all the time, adding water only, and at the end of the hour run them out through 1 ohm resistance—i.e., about 25yds. No. 22 copper wire B.W.G., and a low current ammeter, or through a lamp of known resistance, and notice accurately the time, in hours or fractions of an hour, for which they keep up the light without its beginning to fail markedly. Then, by the formula $C = \frac{E}{R}$, you can reckon what current has been going through the lamp, and see if your cells give 10 amp. hours or what. If they do not give anything like that, as, for instance, not more than one or two amp. hours, take all the plates out and thoroughly wash and clean them and the cells and separators, and try again with fresh-made battery acid. Before you start a trial, however, at all, you should take a galvanometer and battery (one of the cells detached will do if it has any current in it) and test each cell to see if there is any contact between the + and − plates. If you get a distinct deflection of the galvo. needle, that cell is short-circuited internally, and that would account at once for your trouble. In that case, you must wash clean and remake, test again with galvo., and, if all is right, proceed to another trial. —EDWARD CONRY.

[61197.]—**Motor and Coil.**—I am afraid it would be difficult, if not impossible, to answer accurately your first question, as the average cost of working any electro-motor depends so much on the particular battery used, and the construction of the electro-motor itself. Perhaps, however, the following figures may be of use to you. They represent, as nearly as I can say without actual experiment, the cost of working various electro-motors from $\frac{1}{4}$ to 3H.P., as you specify, assuming the loss of power in the motor to be 20 per cent. The figures are deduced from what I have found to be the cost of working several electro-motors of different sizes—viz., 1l. per hour for a 1-watt current, the battery being a good form of cell which I always use for such work, and well kept (no wet boards to stand on, or external leakage of current from slopping, and no internal short-circuiting, and no added resistance from dirty connections). From my experience with this battery, with cells of 1 pint size and upwards, it does not make much difference in cost how the watt is made up, whether of high volts and low ampères, or vice versâ; but this must not be taken as applying to batteries generally. Theoretically the cost would be the same in proportion for a small motor as for a large; but practically the cost becomes relatively less, as the larger motors are more economical than the small ones.

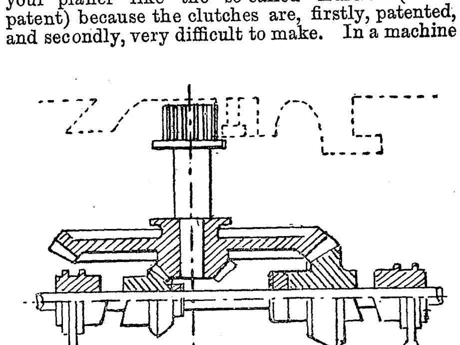
	For 1 hour's maintenance.
(1) $\frac{1}{4}$H.P. takes 223 watts, costing ...	2s. $0\frac{1}{2}$d.
(2) $\frac{1}{2}$H.P. " 447 " " ...	4s. 1d.
(3) $\frac{3}{4}$H.P. " 671 " " ...	6s. 2d.
(4) 1 H.P. " 896 " " ...	8s. $2\frac{1}{2}$d.
(5) $1\frac{1}{4}$H.P. " &c., &c., as above.	

From this cost may be deducted, as the sizes rise, a percentage as follows: (2) $2\frac{1}{2}$ per cent., (3) 5 per cent., (4) $7\frac{1}{2}$ per cent., (5) 10 per cent., &c. As to induction coil, No. 26 would do for a secondary coil, if none other were obtainable, but it would not be the proper gauge. For most coils, No. 36 would be nearer the mark. No. 26 is an unfortunate size; too small for a primary, and not large enough for a secondary. If you are obliged to use it, I should say, as a guess, that you would want about 4lb. to get a 1in. spark; but am not at all certain that you could readily get a 1in. spark with wire of that gauge for the secondary. Coils made in sections have the advantage of being less likely to short-circuit in the secondary than those of ordinary make, besides rendering it easier where the connections are arranged for this to localise and remedy such a fault. Working details would be rather too long and difficult to give here; but if you bear in mind that the principle of the affair is to avoid putting parts of the secondary between which there is a high difference of potential near each other or lying on each other, you may be able to work out an arrangement of section winding for yourself. If you can, look up subject in Mr. Sprague's "Electricity," where you will find full details. The platinum points for contact breakers for all ordinary coils may be as small as you can make them.—EDWARD CONRY.

[61205.]—**Mechanics.**—The lift of bar is 4in., and in 100 revs. this will be equal to $\frac{4}{12} \times 100$ft., and the resistance is 10lb., so that amount of work is $\frac{4}{12} \times 100 \times 10 = \frac{4000}{12} = 333{\cdot}3$foot-lb. The horse draws the cart at the rate of $\frac{2 \times 5280}{60}$ feet per minute, and in one minute performs $\frac{29216}{3}$ ft.-lb., so it must pull with a force of $\frac{29216}{3} \times \frac{60}{2 \times 5280} = \frac{29216}{528} = 55{\cdot}3$lb.—T. C., Bristol.

[61205.]—**Mechanics.**—Neglecting friction, the work done in 1 revolution of the plate $= \frac{10}{3}$, or $3\frac{1}{3}$ units or foot-pounds. Work done in 100 revolutions $= \frac{10}{3} \times \frac{100}{1} = \frac{1{,}000}{3}$, or $333\frac{1}{3}$ units or foot-pounds. (2) The horse, at the rate of 2 miles per hour, goes the distance of $29\frac{1}{3}$ft. in 1 minute. $\frac{88}{3} = 29\frac{1}{3}$ft. $\times 3 = 88$ft. distance drawn in 3 minutes. The work performed by the horse as given = 29·916 foot-pounds. The pull in pounds on the cart multiplied by the distance travelled = work performed = 29·916 foot-pounds. Let x = pull. $x \times 88 = 29{\cdot}916$. $x = \frac{29{\cdot}916}{88} = 340$lb. nearly.—DUD DUDLEY.

[61211.]—**Planing Machine.**—You can't make your planer like the so-called Eureka (Haas' patent) because the clutches are, firstly, patented, and secondly, very difficult to make. In a machine



I have in progress I shall use the appended arrangement, which will, I think, answer as well, if not better, than the Haas patent, as there is no spring. I have used Haas' No. 2 machine, and have found that it sometimes fails to reverse, from the cam sticking on the spring. In my machine I have no cam or spring to stick. A vertical lever

weighted at the upper end and connected with the striking gear in falling past the centre pushes the plate R right or left, according to the movements of the table. The rack on my machine stands with its teeth sideways. I prefer this way, as there is no tendency to spring the table either upwards or downwards. You will have to make your rack slip stiffly an inch or an inch and a half; otherwise you must expect broken teeth in the driving gear and many jolts. In Germany machines planing up to three-quarters of a mètre long are sometimes driven with a gear similar to that used in shaping machines. This arrangement is, however, very cumbersome. The teeth in sketch are as follows:—Forward motion, 24 and 77; return motion, 22 and 30. For power machines my arrangement could be as equally well outside instead of underneath; but then dirt is liable to get into it. I have drawn ordinary clutches, as the form of clutch is still an open question with me.—A. F. SHAKESPEAR, Lüttichaustr. 14 III. Dresden.

[61212.]—**Oilcloth.**—The bulk of the block is of deal in several thicknesses, and glued up with the grains crossing; the face of block should be of pear tree, but is frequently of holly or sycamore, and best of all of box. You will only find scattered reference to the subject in encyclopædias.—T. C., Bristol.

[61217.]—**Improved Pocket Barometer.**—Replying to your correspondent "Towers," he appears to have very happily grasped one of the many facilities with which the possession of the variety of markers endow the instrument, and the want of which has, as he describes, hitherto made the results obtained by carrying an ordinary pocket barometer far less satisfactory than the wearer could have wished. The several recording motions shown in the engraving which you so successfully transferred from the photograph of the inst. to page 304 of December 3, are quite independent of each other, and although the markers overrun both the English and French scales simultaneously, the latter might, no doubt, be omitted for a non-traveller, when economy is of more importance than the corresponding return from the additional outlay. But, in view of the increasing interest now taken in the barometrical readings now so frequently telegraphed from abroad to the daily papers, I would suggest to "Towers" that he might perhaps preferably retain the French scale—which serves for not only the French, but for the reports from almost all European countries—and rather exercise the desired economy by substituting silver cases instead of gold. Lastly, on the important question of size in point of thickness, which "Towers" inquires about. I feel with him the strongest repugnance to carrying anything in the shape of a tub in my waistcoat pocket, and I made it a *sine quâ non*, on giving the order to the maker, that the improved barometer, utterly unlike those which he describes, should be in every respect the facsimile in diameter, thickness, and make of the gold pocket chronometer which I carry in the fellow-waistcoat pocket. The instructions were faithfully followed, with entire success, and I can assure "Towers" that the result was a really handsome and shapely instrument of under 12 millimètres in thickness, whilst the diameter (which is the exact size of your engraving) gives ample space for reading the many tales it has to tell. I shall be happy to show it or give further details to "Towers" or other of our readers who may like to communicate at 23, Park-crescent, Portland-place, W., with—MONTMARTRE.

[61218.]—**Lighting Lantern.**—We have heard a good deal during the last few months about the Bernstein low-resistance lamps. You might get a 40c.p. among these, but any of the ordinary lamps of so high a c.p. would take an E.M.F. that nothing short of a little army of battery-cells in Indian file would produce. You might make a hand-dynamo to do, but I should strongly suggest your contenting yourself with several 10c.p. lamps of about 25 volts or less. You can run all these in parallel, and with only about 14 or 15 cells, according to the sort of battery you use. With chromic acid you would want 14. The number of nights the battery would run would depend on the size of it.—EDWARD CONRY.

[61222.] — **Electric Indicator.** — TO MR. CONRY.—Excuse delay in answering. I have been debarred from writing for a week by a hurt finger. Wind the bobbins with five layers No. 28, and make the cores a clear 1in. between the flat ends of the bobbins. The distance between the N. and S. points of the permanent magnets depends a good deal on the size of the electro-magnet bobbins. When one horn is touching one side of the bobbin, the other should be about $\frac{1}{8}$in. from the other side of it. The usual size is a semicircle inclosing 1in. or a trifle less between the extremities, and for the bobbins $\frac{5}{16}$in. for the core, between the points of a pair of calipers; the rest of $\frac{1}{2}$in. or $\frac{9}{16}$in. diameter being wire.—EDWARD CONRY.

[61232.]—**Bracelet Snaps.**—These must be either fastened with soft solder or, what is better secured by rivets or rings. A small plate is previously soldered to the bracelet, and the catch riveted on. The exact manner in which this is done depends altogether on the make of bracelet and the ingenuity of the workman.—OS.

[61234.]—**Bursting Pressure.**—As a 1in. shaft will bear 4cwt. acting on a lever 1ft. long, a $1\frac{1}{4}$in. shaft will just bear $4 \times (\frac{5}{4})^3 = 8$, nearly; but your lever being 4ft. long, you can only apply 2cwt. at the end without breaking off the screw. The power of the combined screw, lever, and wedge are, in proportion to distance moved by end of lever to that of the opening formed by movement of wedges —that is, in one revolution of handle $= 8 \times 3{\cdot}1416 = 25{\cdot}132$ft., the wedge advances $\frac{1}{4}$in., but the side movement $= \frac{1}{12}$ of $\frac{1}{4}$ of an inch; the power is, therefore, $25{\cdot}132 \times 12 \times 12 \times 4 = 14{,}476$ times power applied at end of lever, or $14476 \times 2 = 22952$cwt. This, however, is theoretical bursting power, and must be reduced to one-half or one-third, to allow for the great friction between surfaces of wedge and of screw, which is also a wedge.—T. C., Bristol.

[61235.]—**Telegraph.** — Probably one of the earth wires is broken beneath the ground, or has become detached from the plate. Nothing smaller than a No. 8 (B.W.G.) wire should be used for such a purpose; and the soldered joint should be several inches long, to insure a perfect connection. It may with advantage be painted over, or coated with some damp-resisting compound. — E. E. BAUGH.

[61235.]—**Telegraph.**—TO MR. BOTTONE.—I can only say that there must be a defect in connection somewhere. The following modes are adopted to insure good connection to earth:—(1) A ton of good, hard coke or retort scurf (graphite) is buried at a depth of about 6ft. in the ground; interspersed with the coke there being galvanised iron wires about $\frac{1}{8}$in. diameter, joined above into a cable, which connects to the earth-line; (2) In other places galvanised iron plate one yard and a quarter square is placed upright in running water or a spring well. If water is not available, then the plate is also connected to all the water pipes (leaden) in the vicinity. Gas-pipes must not be connected, as, in case of a thunderstorm, explosions might ensue.—S. BOTTONE.

[61235.]—**Telegraph.**—The fault *may* lie in the peculiar arrangement of the earth between the two plates, some particularly non-conducting substance as dry sand being interposed like a wall between the earth plates; but this is rare. I have only met with it in two instances, one at Aldershot, where the soil is notoriously gritty and poor, and once at Weybridge, where I learned on inquiry that a broad belt of dry gravel extended between the two earth-contacts from about 1ft. below the ground to a considerable depth, when the same fault as the one you remarked was present—a deflection of the galvanometer, but not sufficient current to ring a bell, and it had to be remedied by the same means —a second wire. I should think your difficulty was more probably caused by your having used galvanised iron for the earth-wires and plates. The zinc and iron being in contact in presence of acids in the damp earth, would set up a local action between them, which would probably make hay of your battery current. You have, in fact, made a sort of "Callan's battery" at both ends of your earth return. Dig up your plates and wires, and substitute plain iron wire and plates, or, better still, copper for both, and then see.—EDWARD CONRY.

[61237.]—**Lathe.**—You should be able to turn safely as great diameter as will clear saddle and bottom slide of rest, say 11in. for sliding; but for a pulley, for example, it is somewhat a question of speed, which must not be such as to heat the tool on a diameter of 20in., which is about as much as the lathe should have to do. Some lathes would do more if they had a greater variety of speeds. For example, I have used a 10in. lathe and turned 2ft. diam. on it, but had trouble with the speed being too great, and so spoiling the tools. If I had had a slower speed, the lathe was plenty stiff enough for the job.—T. C., Bristol.

[61241.]—**Climate for Chronic Catarrh.**—No need to leave England. Try Babbacombe, in Devon; it is mild and bracing. What with exercise, patience, and a course of Turkish baths to be had here, there is no reason why you should not gradually recover the health you have been losing. BABBACOMBE.

[61242.]—**Canvas for Diagrams.**—Here is one way of preparing what you require. Size the canvas well, and let it dry. Then paint over it with a mixture of glue and lampblack, and dust on very finely-pounded and sifted coke. If preferred, the canvas may be painted with oil and turps as the media for the black.—NUN. DOR.

[61243.] — **Failure of Amalgamation.** — I should say that the difficulty is most likely in the zinc. If cast, it is very difficult or impossible to protect, even if moderately pure; but it is very apt to contain tin and lead. Has the querist tried the addition of oil, as mentioned in my second edition, p. 126?—SIGMA.

[61247.]—**Hot-Air Motor.**—TO MR. J. SEAL. —You do not give the size of your cylinder; if it is the same size as my small models—viz., $\frac{7}{8}$in. by $1\frac{1}{4}$in., the air passage should $\frac{1}{4}$in. by $\frac{1}{8}$in., or larger if you can make it. The best proportions I have found the cylinders should have is, the heater should have about double the capacity of the working cylinder.—J. SEAL.

[61251.]—**Boiler.**—Height 3ft., diameter 2ft., firebox 1ft. 8in. high, and 1ft. 6in. diameter, and chimney 5in. diameter, made of $\frac{1}{4}$in. plate and worked to not more than 80lb. Heat with coke and small coal.—T. C., Bristol.

[61252.] — **Windmill.**—A windmill so constructed would work, but it is not a good shape. One modelled on the principle of the revolving shutter cowl for chimney pots would do better—i.e., with about six times as many "shutters" as you have drawn, each making an angle of about 45° with the outer circle of the frame holding them, and if they were curved to form each a quadrant of a circle, so much the better.—EDWARD CONRY.

[61252.]—**Windmill.**—If this be made as shown in diagram, it would certainly revolve in the opposite direction to that indicated by the arrow; the power would be increased by adding top and bottom ends to each of the sails. The best shape which I have tried is long cones like a candle extinguisher. I have a model working at this moment in which there are four sails similar in shape to the diagram, save that each measures, say 1ft. long by $2\frac{1}{2}$in. each side, with triangular end-pieces, and the edge marked E in diagram is parallel to each arm. There was the figure of a man attached, who apparently kept turning it by a crank handle, and my object was to make a mill which could not revolve at a violent speed with any pressure of wind. But the power to be obtained from this or any other possible arrangement of horizontal windmill, is very inferior to that given out by the usual vertical one, because in this latter the thrust is (assuming, of course, a steady wind) constantly kept up, and there is not the same resistance of sails coming up against the wind; and, finally, all the sails are always equally in action. I may say that I fully endorse R. Browne's opinions *re* P. Vallance's statements on page 369, and not feeling bound to believe in any horizontal mill, or the inventor or rather arranger of the same, intend to wait till I see.—A., Liverpool.

[61253.]—**Electrical.**—It is just possible that Deprez's galvanometer (illustrated in the same number as that in which the query appears) would suit this correspondent.—OS.

[61253.]—**Electrical.**—Certainly; a brass arm or pointer, pivoted near one end, kept in a normal position by a fine spring, or weights, and having attached to it at the short end a cylindrical armature sliding in a solenoid coil of wire thick enough to carry your current without heating, while carrying at the long end a small pencil just touching a moving slip of paper, will do what you want. You would have, of course, to calibrate your instrument for the first time in order to see how much stroke on the paper represented a difference of 1 ampère, or whatever fraction of an ampère you wished registered; and you would have to arrange some mechanism to keep the paper moving —either weights on the Dutch-clock principle, or a drum worked by a coiled flat-spring and train of wheels, like a clock. A "Watt-meter" was patented some year or so ago by Mr. Frederick Walker upon this principle, automatically registering as "watts" the electrical H.P. expended.—EDWARD CONRY.

[61254.] — **Combination Machines.** — Some time this year I saw, in the *Engineer*, I think, illustrations of a milling machine for roving machine frames. It appeared to be essentially a planing machine; but had several headstocks carrying milling cutters. These headstocks were on both upright frames and also on cross slides, four or six in all, and were driven by means of gearing—there being a spindle in each vertical slide and also in cross slide; these spindles being grooved to drive the gear by a sliding feather as in a driller. The headstocks could also be set to various angles.—T. C., Bristol.

[61257.]—**A New File.**—About seven years ago I read a paper before the Society of Arts, on J. and W. Kirkwood's patent file for soft metals and wood. I may also state that the two files exhibited then have been in daily use ever since, and that they have done an enormous amount of work, having filed up the top of several thousand zinc baths. The blades were originally $1\frac{3}{4}$in. by $\frac{3}{8}$in. by 14 wire gauge; they are now about $1\frac{3}{8}$in. by $\frac{1}{2}$in. We do not recommend this file for iron or brass; but for zinc, lead, or hard wood nothing can equal it. Its cutting qualities are far more than double that of an ordinary cut file. I may also state that this file was invented forty years before

us, and was described by Montufel as White's perpetual file. While writing allow me to state that zinc can be hardened or softened; but cast zinc is as soft as it can be made. Two curious things which we constantly observe is that zinc which has been exposed to quite a low heat for a few weeks becomes quite soft, and if it is immersed in water, and then pour a few drops of vitriol on it, allowing it to remain a few seconds, and wash off, it will be seen that it has become crystalline. Again, if unannealed zinc is for a number of years exposed to the action of hot water, as in an old bath, it becomes almost as hard as iron, and much harder than any zinc can be rolled.—JOHN KIRKWOOD.

[61259.]—**Induction Coils.**—TO MR. BOTTONE AND "BOBADIL."—My experience is that one may reasonably expect to obtain $\frac{1}{16}$ of an inch spark for every 424ft. coiled on the secondary up to about 6,740ft. Beyond this, unless the coil is specially built, it is difficult to increase the spark in proportion, owing to greater difficulty in insulating so high a tension, and also owing to the greater distance of the wire from the core. Hence, while 1lb. of No. 38 will easily give 1in. spark, 2lb. will not readily give 2in. A condenser must not be used with the secondary coil.—S. BOTTONE.

[61259.]—**Induction Coils.**—The length of spark obtainable from an induction coil depends on the length of the secondary, and the battery-power employed. It is usual to expect 1in. spark from every mile of secondary, in small coils. The length of a certain quantity of wire is stated in several tables. Thus 1lb. of 36 is about one mile long, and when we know how much is used the approximate length of spark is obtained. However, the real secret of maximum efficiency is insulation. Bad insulation of a secondary of any length whatever, means a very small spark in proportion to the length of wire. The sizes of the parts of a given coil are not strictly absolute; but between all the working parts there must be due proportion. The laws of electro-magnets, slightly modified, determine the size of the core. The size and number of layers of primary depend on the power of battery to be used so as to get the greatest current. The balance of experience, however, is in favour of the well-known rule, "two layers of primary." Regarding condensers in the secondary circuit, I may say that I have tried them in various ways, and the result has always been a very bushy spark; but never an increase in length.—BOBADIL.

[61260.]—**Dip for Brasswork.**—Put into half-gallon spirits of salts 6oz. arsenic, 4oz. iron scale (from a smith's anvil), 2oz. sulphate of copper, have the latter crushed before using. Either shake or stir occasionally; it will be ready for use in two days. Shall be glad to give you any practical information how to use above if you have not done bronzing before.—IGNORANT.

[61261.]—**Mirror Galvanometer.**—Brass will do, but you must be careful that it is well insulated from the coils. What do you mean by "capacity"? If you mean "farads," see my answer to 61253 in this number; but if you only refer to ampères, as seems probable, then the essential features of a galvanometer to measure this are in one form low resistance, and the movement of a needle either by the action of a solenoid on an armature, or its movement against the tension of a spring, as in the Siemens dynamometer.—EDWARD CONRY.

[61262.]—**An Electrolytic Estimation.**—This query, as it stands, is almost unanswerable. Unless the resistance of generator and electrolyte is given, the volts cannot be calculated. Again, without knowing what metal, and how much is deposited per hour, the ampères cannot be calculated from the data given. The following may assist "R. T." to solve his query. Each ampère of current working through the electrolyte will deposit (per hour) the following weights of different metals, viz.:—Copper 17·3gr., gold 37gr., silver 62gr., nickel 17·2 grains, zinc 18gr. (nearly). Of the mixed gases, about 5·1030gr. will be evolved per hour. To facilitate the reduction of the latter to cc. I may say that 5·1030 grains is equal to 0·3405 gramme, nearly.—S. BOTTONE.

[61262.]—**Electric Units.**—In reply to "R. T.," it is unfortunately true that a committee appointed at Paris have made certain alterations in the values of the electric units, to which they have tried to give validity by calling the new values "legal," and asking some of the Governments to recognise them as standard. The result is that they have utterly confounded all knowledge, and nowadays the terms "volt" and "ohm" convey no meaning to anyone. Some engineers adopt the proposed units, while the Post Office authorities repudiate them; and unless the value of the units is stated in each case, no one can tell what is meant by them. Notwithstanding the use of the word "legal," and the partial acceptance of these new values, it is impossible for them to be finally adopted. It may seem disrespectful to the distinguished committee to say so, but the basis of the new units is so childishly absurd that common sense must revolt. The absurdity can only be equalled by the fact that the same committee coolly adopted melting platinum as the standard measure for light. On p. 233 of my "Electricity," I have shown the wide range of values experimentally found for the original B A unit or "ohm." The latest generally-accepted value is represented, I think, by a square millimètre of mercury 106·2 centimètres long; so this committee agreed, in order to avoid fractions, to make the ohm value 106 centimètres of such a column. Now, no human being ever made, or ever will make, a true tube of one square millimètre section. It is a pure matter of calculation and of adjustment of a column as near the size as can be got; so the committee have in pure pedantry wilfully adopted a known wrong value as a standard, and that wrong standard is to be used in working out calculations of course to half a dozen places of decimals. Then they have been pleased to define the volt as that E.M.F. which will send an ampère current through this erroneous ohm. When we reflect that there is no means of measuring an ampère with exactness, and that its chemical value is varied about every three months, one is struck with admiration when one reads elaborate calculations about exact measurements of E.M.F. My standard puzzle to my electrical friends is the question, "What is a volt?"—SIGMA.

[61264.]—**Safety Valves.**—Area of valve $= (1\frac{7}{8})^2 \times \cdot7854 \; 2\cdot761$ sq. inches. Blowing off pressure $= \dfrac{28 \times 13\cdot5}{2\cdot76 \times 2\cdot5} = 55$lb. nearly. This would probably be increased by weight of lever to, say, 57lb. It would begin to blow earlier than that, say 50lb. to 52lb.—T. C., Bristol.

[61265.]—**Loss of Magnetism.**—Probably there is a loose connection somewhere in the shunt circuit, through which by vibration of the machine the electrical contact is maintained sometimes and not others. Examine carefully all connections on this, especially the coupling where the wire of one F.M. is joined by that of the other.—EDWARD CONRY.

[61268.]—**Soldering Lamp.**—I think I should prefer a soldering bit, to be heated by a small portable furnace made of sheet iron, as this is often used for similar purposes.—OS.

[61268.]—**Soldering Lamp.**—I do not know of any better one than the single or double-jet lamp where the flame of a lamp in the bottom is blown outwards by the heated vapour from a little boiler on top, with a curved pipe leading down from the top to just above the flame of the bottom lamp, and terminating in a fine hole. This, though it lights instantly, requires to burn for a few minutes before it begins to "blow," unless it is hot already, but it is the best I know of.—EDWARD CONRY.

[61271.]—**Electric Bell Circuit.**—This circuit is entirely wrong. The zinc in every case goes to earth, which is the return wire. Connect zinc to earth, carbon to one terminal of push, other terminal of push to one of bell, other terminal of bell to earth. With an earth circuit, the connections must be particularly good.—BOBADIL.

[61271.]—**Electric Bell Circuit.**—The carbon pole should be attached to the wire or overground part of the circuit, and the earth or underground part made the "return" to the zinc. I should not trouble about what the treatise says on the other matter. The consideration of such a question is not of any practical use, and is only likely to lead to mental confusion.—EDWARD CONRY.

[61273.]—**Saddle Boiler.**—You can do no possible harm by letting off any air; but your best plan is to connect a small-bore pipe at the highest point in pipes, and carry it up to same height as feed tank; then the pipes will get rid of their air as it tends to accumulate.—T. C., Bristol.

[61274.]—**Cell.**—I can give you the recipe of a very good and cheap dry cell for testing if you like to advertise your address and apprise me of having done so; but it is really too good a thing to be given away by general publication, being a private and patented matter.—EDWARD CONRY.

[61274.]—**Cell.**—The most suitable thing for this querist's purpose will be a chloride of silver cell (E.M.F. 1·45 volt). These cells can be obtained in sealed ebonite cases, measuring about 3in. by 1in.—E. E. BAUGH.

[61275.]—**Coppering Carbons.**—A muddy deposit is often the result of too strong a bath of sulphate of copper. Try diluting yours with two or three times its bulk of water.—BOBADIL.

[61275.]—**Coppering Carbons.**—Don't attempt to put a thick coating of copper on carbons, as a very thin coating is best and sufficient. I find that a thick deposit is more likely to peel off after it is tinned and soldered. This (the coppering) does not require a length of time at all approaching a few hours, and I prefer to use a separate battery. Coppered carbons are not used as a rule for Leclanché cells, they will not keep in order so long as the ordinary lead-capped carbons. Ammonia in any form acts very strongly on copper. It is, of course, the cheapest and most easy method. If it were better than the lead it would have been long since generally adopted.—OS.

[61277.]—**Multiplex Copying Ink.**—As you suggest, the proper mode of cleaning the preparation is by rubbing with a wetted sponge; but with tepid water if cold fails. As this rubs it away to a certain extent, a good plan is to heat it till liquid, and allow to set again. I have heard that if the ink remains on the graph for some time it is harder to remove; but how far this is true I cannot say.—W. C. HALL, Newport, Mon.

USEFUL AND SCIENTIFIC NOTES.

Almanacs, &c.—Amongst the useful works published annually we have to acknowledge the receipt of *Transit Tables* for 1887, by Latimer Clark (London: E. and F. N. Spon), which give the G.M.T. of transit of the sun and of certain clock stars for every day in the year, and enable any one with a transit instrument (Mr. Clark's patent in particular) to obtain accurate time in any part of the world without calculation. These tables have been found very useful, and are looked for, as a new year approaches, by a gradually-increasing circle. *Whitaker's Almanack* (London: 12, Warwick-lane, E.C.) is increased to no fewer than 632 closely-printed pages, and although the price has been raised to 2s. 6d., it is a wonderful compilation for the money. The Colonial section has been thoroughly revised and greatly extended, and there are several special articles to which frequent reference will be made in the course of a year. *Whitaker's Almanack* is, in fact, an indispensable occupant of the library table and the office desk. *Calvert's Mechanics' Almanack* is, as usual, practical and interesting, and this issue contains special articles on "Lever and Spring Safety-Valves," and the "Proportions of Crane-Hooks, Pulley Blocks, and Shackles." The sheet almanack, also issued by Mr. Calvert, is a useful addition to the workshop.

Purification of Coal-Gas.—At a recent meeting of the Birmingham and Midland Section of the Society of Chemical Industry, Mr. C. W. Watts read a paper on the "Claus Process for the Purification of Coal-Gas." Mr. Watts first pointed out that the process had for its object the complete purification of coal-gas in closed vessels. It was founded on the processes invented by Mr. F. C. Hills some years ago, which had the same object in view, but did not completely succeed. The material used to combine with the impurities of the gas was ammonia, employed in the form of gas. As all the impurities of coal-gas were, with the exception of ammonia itself, of an acid character, they were removed in combination with ammonia dissolved in water. The first treatment was to pass the cold spent liquor through the series of five scrubbers, gradually dissolving the impurities of the gas. The second part of the process consisted of the decomposition by heat of the carbonate and sulphide of ammonium contained in the liquor—a process invented by Mr. Hills. The essential point of the system was that it effected a complete purification of coal-gas by a perfectly continuous operation carried out in closed vessels, so there was no possibility of nuisance arising from the opening of purifiers and the exposure of purifying material to the air, nor any loss of gas or admixture of air from the former cause. The illuminating power of the gas was not reduced by the process; indeed, the average of a large number of tests showed a slight excess of illuminating power over that of the same gas purified by the ordinary process. The by-products — sulphur and ammonia—were obtained in a more valuable form. The ground covered by the plant was considerably less than that required for dry purification, being about 10·12ft. per ton, as against 20·30ft. He was hardly prepared to give a statement as to cost of working, as the cost of a small experimental plant would be proportionately greater than that for regular work. The cost of the fuel for raising steam had been about $2\frac{1}{2}$ per ton of coal, but with a larger plant it would undoubtedly be much less. A vote of thanks was passed to Mr. Watts for his paper, and the proceedings terminated.

Welding Steel.—In the *Genie Civil* Mr. Paul Herzog, of Peterswalda, has given the following as a special composition discovered by him for use in welding steel to steel or to iron: 500 grammes borax, 70 grammes sal-ammonia, 70 grammes prussiate of potash, 35 grammes unrusted iron filings. "This compound is to be pulverised in a mortar, and then turned into a sheet-iron pot or crucible; water is added until a thick paste results, and then the crucible is put over a wood fire and the contents constantly stirred. The resulting mass resembles pumice-stone with green and grey streaks; this is cooled, pulverised, and is at once ready for use."

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

60709. Electro-Metallurgy, p. 182.
60712 M.R. Engines, 182.
60719. Balance.—To "Fellow Workman," 183.
60712. Push.—To Mr. E. Thornton, 183.
60739. Continued Fractions, 183.
60749. Chamber Organs.—To "G. S.," 183.
60755. Prof. Trusses' Valves.—To P. J. Davies, 183.
60760. Boehm Flute Making, 183.

60931. Bicycle Making, 269.
60946. Locomotives, 270.
60974. Steering Apparatus, 270.
60976. Arithmetical Question, 271.
60980. To Mr. Striffler, 271.

QUERIES.

[61280.]—**Link Motion.**—Will any of your kind readers inform me to what extent the lap and lead of the slide-valve are affected by the various portions of the slide-valve rod with regard to the link in (1) Stephenson's link motion, (2) the stationary link, (3) Alban's link motion? I cannot find the complicated motion resulting from an intermediate position at the slide-valve rod in the link explained in any work to which I have access.—LINKUM DODDIE.

[61281.]—**Worm-holes in Violin.**—I shall feel thankful if someone will suggest a method of stopping the ravages of the small woodworm. I have a violoncello, also a violin, each of good quality; but the worms are boring in all directions, and little will be left of either instrument in a year or two. I have tried corrosive sublimate and benzoline; but to no purpose. Anything containing fixed oil would injure the wood.—ONE WHO IS BORED.

[61282.]—**Length of Belting.**—Two pulleys 10ft. and 6ft. in diam., respectively, and with their centres 15ft. 6in. apart; find the length of open belt for the same.—MILLER.

[61283.]—**Hot-air Engine.**—Would someone kindly give me particulars of the displacers generally used in hot-air engines, and what they are made of? Is the displacer more area than the working cylinder?—HOT AIR.

[61284.]—**Electro-Magnet.**—With two medium-size Leclanché batteries, I wish to make as powerful electro-magnet as possible. What size core do I want, and how much wire, and what size? If it would lift a piece of iron of a certain weight by being in contact with it, what would be its power if the armature was 1in. away? Is there any rule which will give me the power of electro-magnets on the armature at different distances from it?—G. S.

[61285.]—**Screw Tool.**—I have some brass castings. I want to put threads on with screw tool. I put on slow speed and cut a clean thread, but cannot get them to fit. Will any reader kindly inform me on the subject?—ELBON.

[61286.]—**Heating by Means of Paraffin.**—I shall be extremely obliged by any information in regard to heating steam and hot-water boilers by means of paraffin. I am aware that this substance has been used both on locomotives and some steamboats; but cannot ascertain what kind of furnace is employed. My principal object is to arrive at some simple means of heating by means of paraffin the hot-water boilers of small greenhouses, and so obviate the need for constant attention, and also the uncertainty attaching to all small furnaces in which coal or coke is burnt.—AN OLD SUBSCRIBER.

[61287.]—**Tempering Gun-lock Springs.**—Would you kindly kindly inform me through your valuable paper how to temper main springs of gun-locks? I have made several attempts, but always a failure. They were either too hard or too soft. Any information on the subject will be received with thanks. Also the process of tempering ordinary lock springs?—JOHN FAULKNER.

[61288.]—**Carmine.**—Among the numerous recipes for the preparation of this pigment which have appeared in encyclopædias, technical journals, and receipt books, I have not yet met with one which gives satisfactory results, some of them having been copied haphazard from earlier publications. Moreover, every ingredient prescribed as essential in some of these recipes has been omitted from others. Equal confusion prevails in the details of the manipulation. Should any of my fellow-subscribers be able to give or refer me to a reliable formula, I am sure an obligation would be conferred on others as well as myself.—P. O. V.

[61289.]—**Object Glass.**—To "PRISMATIQUE."—In your articles on "Object-glass Working," in relation to correction for colour, do the terms "red" and "blue" indicate that these are the true colours seen when the correction is complete, or will it be the mixed light inclining towards these tints—that is, in test on bulb in sun? When the rays are brought to parallelism, will the cone of rays within and without the focus show blue rings with a narrow corona of red, and red disc with equal margin of blue respectively, the colours being prismatic "red" and "blue"? Will you kindly add this information to your already generous contribution on the subject?—HARD CROWN.

[61290.]—**Mediæval Outlines.**—I am interested in the progress of modern art ornament of a Mediæval character, distinct from the ancient art of illuminating. Can any of your correspondents refer me to any exceptionally intricate modern outlines of borders, capital letters, and even title-pages (like the title-page to the *Graphic* newspaper)? I am informed that excellent specimens of such Mediæval design and ornament can be found in the circulars and trade catalogues of many manufacturers.—DRAUGHTSMAN.

[61291.]—**To Impart the Appearance of Age to Delicate Wood Carvings.**—I have lately repaired some delicate wood carvings of Swiss and Russian origin; but have been unable to impart to my work the appearance of age, although I have tried many stains. Whilst I was in Switzerland, I learnt that the appearance of age could be imparted to delicate carved wood by chemical fumes; but what chemicals were used I was unable to ascertain. Can any of your correspondents kindly oblige me with this information?—NAWS.

[61292.]—**The Serious Accident at Carlisle.**—Wanted, the cause of the failure of the vacuum brake on the North-Western train. What was the number of the Midland engine that was knocked off the road?—ANTI-VAC.

[61293.]—**Compound Loco. on Cal. Ry.**—Will any reader oblige by giving the result of the grand trial trip on the Caledonian Railway with engine 124 last week? It is Mr. Drummond's new compound that was at the Edinburgh Exhibition.—LOCO.

[61294.]—**Octave Coupler.**—I should feel much much obliged if any of our organ correspondents would give me particulars how to make an octave coupler for a chamber-organ—one that will take up little space being preferred?—T. D.

[61295.]—**Turning Slate.**—Can any of our readers tell me the best way to turn slate in the lathe? The pieces I require to turn are about ½in. thick and from 1in. to 5in. in diam. I find that in turning across the grain the tools wear out very fast.—SLATE.

[61296.]—**Gas-burners.**—TO MR. FLETCHER.—Having occasion to extemporise a gas fire, I used a star burner to ignite a loose heap of asbestos, &c., piled over it. The burner soon became heated to a cherry red, and then the flames, which were at first of the well-known almost invisible blue tint, became luminous and yellow while remaining clear and smokeless. The burner had not lighted back, for when it did it gave off dense smoke. What is the explanation of this change in the character of the flame?—W. A. S. B.

[61297.]—**Pepper Mill.**—Would any brother-reader of "ours" kindly give illustration of mill? Also say the best stones for grinding pepper?—A. W. G.

[61298.]—**Armature.**—Can any electrician describe a "Cabella" armature?—KENT.

[61299.]—**A Capricious Dynamo.**—Can any reader give some plausible reason and remedy for the following freak which my dynamo (Mather-Platt) has twice played me? The machine is compound wound, and is used for plating. It ran six weeks right off without a hitch, when all of a sudden it ceased to give current, and on examination it was found that both pole-pieces had become north. The most powerful current I could send through the coils from a 6-cell bichromate would not permently effect any alteration in this extraordinary polarity. Temporarily, the polarity became as it ought to be—viz., N. and S.; but directly the battery current ceased the two poles flew back to the N. condition. The poles are remarkably soft iron. Any assistance will oblige.—SELIM.

[61300.]—**Saccharine.**—(See p. 367.) If this new and wonderful substance passes through the "organism" (by which is meant, I suppose, the human system, stomach, and all) "unchanged," what is it that causes (1) its high antifermentive property, (2) its antiseptic property? What authority is there for these statements?—R. S. T.

[61301.]—**Amateur Workshop—Brass Foundry.**—(See page 362, second column.) "Advantage being taken of the fact that the melting points of alloys are lower than those of their constituents." In asking the question, I am not doubting; but may this be taken as an axiom without an exception? It is true of iron and aluminium (see Mitis Castings). Is it true of all alloys? It is notably of the alloy called "fusible metal."—R. S. T.

[61302.]—**Billiard Table.**—Will any correspondent kindly give me the exact measurements from inside to inside of cushions, both length and breadth, of a champion billiard table, and also the width of the pocket openings, and say in what respect the champion table differs from those in ordinary use?—FINEM RESPICE.

[61303.]—**Chemical.**—The scullery in my house is supplied with rain water made hot by the usual process of back-boiler heating, and is conveyed through wrought-iron piping from a supply tank of galvanised iron (6ft. by 3ft. by 3ft.) to the sink. This tank is replenished from a cistern underneath the scullery through leaden piping 1½in. diam. by 30ft. long by a force pump in the usual way. The lead suction of a common pump also dips into the cistern, which, by test, is quite impervious. Silver spoons washed in this water take a frosty appearance afterwards, and glasses look very cloudy indeed. What is the probable cause of this?—EARNEST ENQUIRER.

[61304.]—**Emery Wheel.**—Will any fellow-reader kindly inform me what quantity of emery and what quantity of glue I should require to make an emery wheel 5in. in diam. and 2in. thick, and the best way to make the wheel?—EMERY WHEEL.

[61305.]—**Dental Composition and Aluminium Solder.**—TO MR. FLETCHER AND DENTISTS.—Wanted, formula for preparing the dental composition, for impressions of the mouth, known as "Stent," "Godiva," or "A 1 modelling composition," &c. Has a really satisfactory solder been found for aluminium, and, if so, how used and made? If it can be soldered as easy as gold or dental alloy, it will be very useful, not being subject to oxidation.—STORY.

[61306.]—**Question in Mechanics.**—The following question is given in Twisden's "Theoretical Mechanics": "A rod of beech wood (A B) 12ft. long, with a small uniform cross section, floats on the surface of still water. By means of a thread tied to it, the end (A) is lifted to a moderate height out of the water, so that the rod floats obliquely; find how much the rod will be immersed. Why must the thread take a vertical position?" The answer given in the book is 5·43ft., and the specific gravity of beech is taken as ·7. Is not the answer given wrong? I have been quite unable to get it to come to this amount, and should therefore be obliged if some of your readers will work it out for me.—J. C. E.

[61307.]—**Occultation of Aldebaran.**—Will any of your astronomical readers kindly say whether the occultation of Aldebaran on Jan. 7th next can be observed with an ordinary telescope, such as is used by the Coastguard, with sufficient exactness to give the correct time? Also whether any, and what, allowance for longitude should be made between the time stated in *Whitaker's Almanack* for an observation at Greenwich and one at Bridlington Quay?—A. W.

[61308.]—**Amateur Workshop.**—In No. 1135, under this heading, is a chapter on Brass-founding. I have all the requisites for moulding; but find great difficulty in getting the moulding sand—that is, in a small quantity, say 6lb. or 7lb. If you could give a hint to me, and, no doubt, to others also, you will greatly oblige—HAYWARD.

[61309.]—**Photographic.**—Will one of your readers kindly answer the following? (1) What is the best way to remove the varnish from old negatives? I have tried strong alcohol, but it seems to have but little effect. (2) Which brand of Isochromatic plates is the most sensitive to yellow?—J. G.

[61310.]—**Electricity.**—Would one of the electricians be kind enough to tell me whether an electric machine exists powerful enough to kill a dog, and not too expensive for the generally limited means of the societies for protection of animals?—W. VAN EYS.

[61311.]—**Water Resisting Cement.**—I am in want of a cement which will resist water, and at the same time dry thoroughly hard. Can any reader tell me of a recipe?—SELIM.

[61312.]—**Steel Furnaces.**—Can any of our numerous correspondents give me a description of the most improved steel furnaces? If the description is accompanied with illustrations or drawings, so much the better.—GLASGOW.

[61313.]—**Making Cotton Fabric Fireproof.**—Can anyone kindly inform me how cotton or woollen fabrics can be rendered fireproof?—W. R.

[61314.]—**Footpaths.**—Is a farmer allowed to plough up a footpath which traverses his field?—G. F. O.

[61315.]—**Joints in Water-pipes.**—Will some of our able and experienced readers kindly answer the following? I have to replace some 5in. water-pipes from reservoir to mill with 8in. ones. What is best material to make joints with for permanance, as they will be covered with very great depth of earth? They are ordinary faced flange joints. Vulcanised indiarubber rings objected to.—A POOR MECHANIC.

[61316.]—**Turning Bowls for Calenders.**—I shall have paper and cotton bowls for calenders to turn shortly. What is best shape and form of tool to use? Also speed of surface of bowl at cut. I have heard of, but never seen, metal bowls being turned off their own journals. Please give description, with sketch, if possible, of stays required and mode of driving bowl (I understand that they are not held in the centres of lathe at all). I shall also have wooden bowls, 10ft. long, 26in. dia., to turn and bore through for centre hole about 4in. dia. Give description of auger or other tool required. Should bowl or tool revolve, and at what speed? What speed per sec. is best for wood turning, and what is the best form of slide-rest tool required? Send sketch, if possible.—A POOR MECHANIC.

[61317.]—**Gilding on Glass.**—Will any reader give a description of the process worked by several London firms (patent process silverers) of gilding on glass with a liquid?—J. FORREST, JUN.

[61318.]—**Tricycle.**—Would any reader kindly give me a little information as to making a small tricycle suitable for a boy twelve years old? I want to know how to make the bearings of the wheels and the framing of the machine.—AMATEUR.

[61319.]—**Photographic.**—TO "BOBADIL" AND G. EDWINSON.—Thanks for your previous answers. Mr. A. Watt states in his last publication: "If cyanide of potassium has accidentally been added in excess, a little more chloride of gold must be added to neutralise it." I wish to know if it is necessary to leave enough acid in the chloride of gold to cause a chemical action to take place, still keeping the red mass apparently dry?—IGNORANT.

[61320.]—**Static and Potential Energy.**—What are the correct terms for describing the following conditions? Suppose I take an indiarubber door-spring, connect one end to a hook in the ceiling, and, pulling with a force of 10lb., attach the other end to a weight resting on the table. As the force of 10lb. is still there, I imagine that will be a case of potential energy. Suppose, then, I attach a string to a similar weight, strain it with a force of 10lb., and then twist it round a hook in the ceiling, will that represent static energy, or what? I can see that in the case of an elastic spring the force used to stretch it remains; but what becomes of the strain put on the string?—JEHU.

[61321.]—**Brake Failure.**—Why did the Midland express on the 16th inst. run right past Appleby? What brake was in use, and what engine?—ANTI-VAC.

NOTICE TO SUBSCRIBERS.

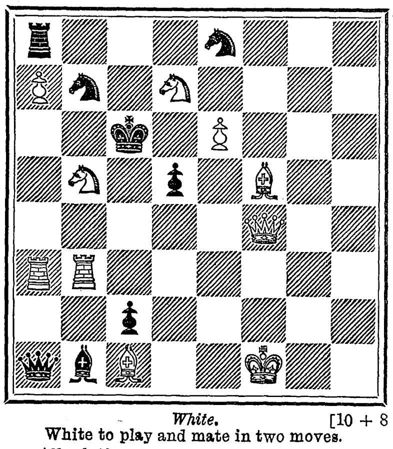
Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a PINK Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

CHESS.

ALL Communications for this department must be addressed to J. PIERCE, Langley House, Dorking.

PROBLEM MXXIV.—By G. J. SLATER
(First Tourney Problem.)

Black.



White. [10 + 8

White to play and mate in two moves.

All solutions must be *received* by Jan. 12.

SOLUTION TO 1,022.

White.	*Black.*
1. Q-Q R 6.	1. Anything.
2. Q or Kt mates.	

(Four variations.)

This problem requires a Black Kt at Q 8 to prevent 1. P-Q B 4 (ch), &c.

NOTICES TO CORRESPONDENTS.

CORRECT solutions to 1,022, by A. Bolus, G. T. Stringfellow, F. Krasser, W. Duff, J. Mackenzie.

J. P. AND A. R. B.—If 1. P-Q B 4, P takes P *en passant*, but 2. Kt-Q B 3 is mate (see solution above).

A. BOLUS.—Many thanks for the problem, and for the compliment.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 332, *Strand, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, Dec. 29, and unacknowledged elsewhere :—

W. GRUGGEN.—W. McCartan.—S. M. Hopkins.—J. H.—J. Williams.—S. Bottone.—Clement E. Stretton.—Unsuccessful.—A. Bedford.—Wm. Young.—Urtica.—Brass Finisher.—Pneumatic.—A Novice.—Three Dimensions.—T. Griffiths. — Anxious.—W. F. D.—William.—Improver.—Chemical.—Dr. Ussher.—Puzzled.—Lanternist.—Box 4, Northallerton.—Drofsidde.—R. Bennett.—A Country Miller.—Electric Light.—C. H. F. C.—Holland.—Brian Boru.

P. HOLLAND. (The Act prescribes that a trade mark must consist of the name of an individual or firm printed or impressed or woven in some particular and distinctive manner, or of a written signature of the individual or firm applying for registration thereof as a trade mark, or a distinctive device, mark, brand, heading, label, ticket, or fancy word or words not in common use. Hence, it would seem that "Jones's sensible boots" could only be a trade mark so far as the word "Jones" is concerned, and anyone could use "sensible boots.")—TINTO. (Tinman's solder, 2 parts tin 1 part lead; plumber's solder, equal parts of tin and lead. If for blowpipe, use 3 tin to 2 lead.)—GALVANO. (By its colour and weight, and by its infusibility. See indices. You merely want a spark to pass over the gas-jet when the circuit is closed, or a little spiral of platinum wire made red-hot by the passage of the current from a battery.) — B. LOCKHART. (Bed the pipe in ashes, the finer the better, and use plenty of them. Failing ashes, sand will do.) — AMPERE. (You should procure Munro and Jamieson's "Pocket-book of Electrical Tables," published by C. Griffin and Co., 12, Exeter-street, Strand. Messrs. W. T. Glover and Co. publish a useful table of wires. Their address is Booth-street, Manchester. Macmillan and Co. publish Prof. S. P. Thompson's book on "Electricity and Magnetism.")—SLANEY. (It cannot really be called "tanning" when the hair is left on: "curing" is the term. Rub in the flesh side a mixture of powdered alum 2½lb., salt and coarse wheat meal 1lb. each, and sufficient sour milk to form a paste. Having rubbed the compound thoroughly into the hide, spread a layer of it on the skin, and fold up the hide with the flesh side touching, and put away into a cool place for a day. Repeat the process several times, washing well at each. Finally wash thoroughly, and dress the flesh side with a strong solution of alum, and hang up to dry. When nearly dry, roll and pound the hide in every direction, and generally do anything that will tend to render it soft. 2. For dyeing sheepskins, see No. 992, p. 74.)—A POOR MECHANIC. (Thanks, but we think we have given enough electrical alarms, at all events, for the present.)—B. ROLSTON. (If the numbers are in print, they will be forwarded to you; but they will almost of necessity contain general directions only, as we have not given dials for all sorts of localities. 2. Mix ivory black with best copal and draw the lines with a fine camel-hair brush. Probably the best paint of the kind is, however, fine lampblack ground up with oil of spike lavender and mixed with a little good spirit varnish.)—T. WALKER. (We do not understand your query as written; but if you mean gilding by the battery process, see the indices of back volumes, or Nos. 1013, 1014, pp. 569, 591, Vol. XXXIX.) — J. FORREST, JR. (Merely a varnished colour print attached to sheet zinc with paste or glue containing an acid. 2. As you say that none of the answers which have appeared in reference to liquid gilding are satisfactory, we will insert the query.)—DECORATOR. (Presumably you mean a liquid glue or a "mouth glue," the latter being simply glue which has been soaked well, the water poured away, the glue melted, and about half its weight of sugar stirred in.)—ELLIOTT. (For painting the slides, procure Sable's "Manual" from Mr. Hughes, Brewster House, Mortimer-road, Kingsland, London, E., or refer to No. 946, p. 226. There is no book on the construction; but Chadwick's "Lantern Manual" will be useful. It is published by Warne and Co., Bedford-street, Covent-garden, W.C. Unless you have had some experience, you had better purchase a lantern.) — A NEW READER, Dover. (It would be almost impossible to find all the necessary details in any one number, although they have often been given. You should read the papers by Mr. Wassell, which have been given in recent volumes. Grinding a glass specula requires a high degree of mechanical skill, and there is no "simple method.")—INQUISITIVE. (Most likely they took a negative from it, and printed in the usual manner.)—G. M. S. (Do you not think it would be more reasonable for you to procure some textbook of astronomy, than for us to occupy space with such queries, and replies to them?)—JUST OUT. (Use the ordinary bichromate solution, or any of those recommended in recent numbers for use with zinc and carbon couples.)—B. (The information has been given several times, and you can obtain it on application to the Registrar, University of London, Burlington-gardens, W. There is a matriculation examination to pass.)

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

6s. 6d. for Six Months and 11s. for Twelve Months, Post Free to any part of the United Kingdom. For the United States, 13s., or 3 dol. 25c. gold; to France or Belgium, 13s., or 16f. 50c.; to India (via Brindisi), 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office Order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 4d. each to cover extra postage.

Messrs. JAMES W. QUEEN and Co., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes, they must be paid for at the rate of 4d. each copy, to cover extra postage.

Vols. IV., VII., XXVI., XXVIII., XXX., XXXII., XXXIII. XXXIV., XXXV., XXXVI., XXXVII., XXXVIII., XXXIX., XL., XLI., XLII., and XLIII., bound in cloth, 7s. each. Post free, 7s. 9d.

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in February and August, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d. each, through any bookseller or newsagent, or 2½d. each, post free from the office (except index numbers, which are 3d. each, or post free, 3½d.).

Indexes for Vols. I., VI., VII., VIII., and IX., 2d. each. Post free 2½d. each. Indexes to Vol. XI., and to subsequent vols., 3d. each, or post free, 3½d. Cases for binding, 1s. 6d. each.

CHARGES FOR ADVERTISING.

For every succeeding Eight Words..	0	3

ADVERTISEMENTS in the SIXPENNY SALE COLUMN.

	s.	d.
Sixteen words	0	6
For every succeeding Eight words	0	6

*** It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions and in cases where the amount sent exceeds One Shilling, the Publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement, and charged for.

Advertisements *must* reach the office by 1 p.m. on Wednesday, to insure insertion in the following Friday's number.

OUR EXCHANGE COLUMN.

The charge for Exchange Notices is 3d. for the first 24 words, and 3d. for every succeeding 8 words.

What offers for 52in. **Bicycle**, in good condition, with lamp, bell, spanner, &c., strong, and suitable for a beginner. Can be seen by appointment. Wanted good air-gun, and part cash. For value see Sale Col. advt.—C. E. K., Lady Cross, Gayton-road, Harrow.

Materials for **Induction Coil**, new, well proportioned, and complete; cost £3. Offered for Dynamo. A little cash added if necessary.—Box 5, P.O. Stirling.

Wanted, ½-plate Sliding Body **Camera**, with one double dark slide. No lens or stand. Will give Marion's Miniature Camera in exchange.—J. GUARDIA, Helston House, Rozel-road Clapham.

Wanted, Rose's "**Pattern-Maker's Assistant**," Rose's "Practical Machinist" in exchange.—J. DUNBAR, Melton Constable, Norfolk.

What offers for **Vertical Engine**, 3¼ by 5½ stroke, 20in. fly, turned, bright. No rubbish.—CHAS. MINTO, Byers-green, Spennymoor.

"**Amateur Work**," wanted back Vols., or Vols. XIV. to XVII. given in exchange.—Offers to ELLIOT, Gennaro Serra, Naples.

Good **Magic Lantern**, exchange for horizontal Engine, ⅜ bore, reverse motion, or pair cylinders with eccentrics for loco.—FRASER-COTTOURN, Glencarse, N.B.

One of Fletcher's **Furnaces** for melting brass, &c., with two 12lb. pots, crucible tongs, bow tongs, and burners, complete, value £2. What offers? Used twice only.—A. HANESWORTH, 34, Lyndhurst-street, Bolton.

Bicycle **Perambulator Wheels** (set of four), with axles and caps, complete; also set of three. Exchange anything useful.—LOWE, 12, Tealby-terrace, Glebe-street, Nottingham.

Wanted volumes I. to IX. "**Journal of Society of** TELEGRAPH ENGINEERS," bound or unbound, for Electrical Books.—JAMES, 72, Cambridge-street, Birmingham.

Churchill's Walking Beam **Fretwork Machine** with driller and blower, nearly new, cost 50s. What offers?—GEO. HEYS JONES, 12, Addison-gardens, Kensington.

Brass **Grandfather's Clock Works**, 6s., or exchange 7s. 6d. Verge Watch, exchange 3s. New Engraving Tools, cost 5s. Exchange lot.—41, Breck-road, Liverpool.

Perpetual Motion.—Marvellous discovery; large working drawings by practical draughtsman. Exchange for 7d. value.—P. PITMAN, Mellor, Marple Bridge, near Stockport.

Cinderless Coal.—Wonderful production; exchange for sample value 7d.—Above.

Metal Polish.—An everlasting protector from rust; exchange receipt 7d. value.—Above.

Wanted 2 or 3 **Collections of Stamps**, from 300 to 800 varieties, or more if reasonable. Exchange.—J., 12, Park Village East, Regent's Park, London.

Microscopic.—Offered twelve packets of unmounted objects for two good slides, or other unmounted material.—W SIM, Gourdas, Fyvie, N.B.

The English Mechanic
AND WORLD OF SCIENCE AND ART.

FRIDAY, JANUARY 7, 1887.

NOTES ON THE CHURCH ORGAN.
III.

By GEORGE ASHDOWN AUDSLEY, F.R.I.B.A.

BEFORE proceeding to pass a few remarks on the speaking stops most desirable and suitable for the Church Organ, it is, perhaps, expedient that I should first allude to the question of wind pressure—a question of not a little importance in the present epoch of organ building. It must be freely admitted, I venture to think, by all true admirers of the organ, outside a certain class of interested builders, that there has been of late years, in this country at least, a decided tendency to over-blow the organ—to produce as much sound (I cannot say tone) as possible from the pipes, without much regard to its quality, by a system of heavy-pressure blowing and, of necessity, strained voicing. That all organs built on this system have lost immensely in the elements of refinement and true beauty, cannot be questioned by anyone endowed with musical taste and possessed of some knowledge in matters connected with the organ. It is simply painful to listen to many of the instruments which have been placed in churches during the last twenty years, and one yearns for a return to the true and good old style of voicing, in which the early masters of the art displayed both their skill and musical taste. Let any doubting individual compare an unspoiled Diapason by Father Smith, Renatus Harris, or Snetzler, with one of the modern screaming affairs, and judge for himself. It is much to be regretted, this modern practice of over-blowing organ pipes; but it is a necessary outcome of cheap organ building and the desire to get as much sound as is practicable out of pipes of insufficient scales. Pipes of small scales weigh less, and accordingly cost less, than those of large and adequate scales, and the temptation to use the former, and cover their weakness by the means which cost nothing, is too great to be resisted by builders who desire large profits or work at any price.

There can be no question that the tones produced from large-scaled and substantial metal pipes blown by a copious supply of wind at a moderate pressure are in every way vastly superior to those produced from small-scaled pipes blown with high-pressure wind. For Church Organs, there can be no comparison between the two; for the tones yielded by the former are characterised by richness, volume, and great travelling power—just the qualities required for choral accompaniment, while the harsh, thin, and unimpressive tones of the latter utterly fail to satisfy the conditions of a true and sympathetic accompaniment. I could enlarge on this important subject, and bring forward proofs innumerable in support of the above simple statement; but here I must rest content with making the statement: those who question its accuracy may statisfy themselves by a careful study of organs built on the different systems, and a slight acquaintance with the science of acoustics.

There is some diversity of opinion with reference to the lowest wind pressure suitable for the manual departments of a church organ, that is to say, when only one pressure is adopted throughout them. In large instruments it is usual and generally desirable to adopt different pressures. An extreme example of the latter method is presented by the fine organ in the parish church of Leeds, which has no fewer than five distinct pressures, as in the following list:—

Pedal organ	3¾	inches
Great organ (generally) ...	3¾	„
„ „ Tuba only ...	7	„
Swell organ	3	„
Choir organ	2½	„
Echo organ	1½	„

While it is, as a rule, advisable to adopt a medium pressure, say 3in., for organs of small or ordinary size, I am strongly in favour of the more frequent use of a lower pressure, say 2½in. or 2¾in. If such a pressure is adopted, in combination with large-scaled pipes and copious windage, the richest and roundest qualities of tone can be obtained—the tone which best blends with and supports the human voice in the dignified music of the Church. In the preceding article I mentioned the remarkable *Diapason* in the Leeds Parish Church organ; this is probably the finest stop of its class in England. It is of very large scale and very copiously winded at 3¾in. pressure. The tone is dignified and round beyond description; indeed, as I have already said, the stop is a Great organ in itself. Stops of this class are, however, hardly suitable for Church Organs of the ordinary size, although there can be no question as to their impressiveness and sustaining powers. What is really required in the average Church Organ, so far at least as the chief *Open Diapason* is concerned, is a stop of similar scale and windage, but voiced on a much lower pressure.

It may interest some readers to have an idea of the scale and windage of the Leeds Diapason, above alluded to:—

	CC-8ft.	C-4ft.	C-2ft.
Inside diameter	6¼in.	3⅝in.	2½in.
Width of mouth	5¼ „	3 3/16 „	1⅞ „
Height of mouth	1½ „	15/16 „	½ „
Diameter of wind hole in foot	1¼ „	1 „	9/16 „

In instruments of medium size, which can be supplied with wind of two pressures, I should advise the Great organ to be voiced on 2½in. and the Pedal and Swell organs on 3in. wind. Large scales being used for the Great and medium scales for the Pedal and Swell departments. A quiet grandeur should characterise the general tone of the Great, and brilliancy that of the Swell. This is a fact sometimes disputed and almost invariably ignored at the present time. It is now extremely difficult to get low pressures of wind properly tested by professional organ-builders; and one experiences a hopeless feeling when one has a 3in. wind pressure advocated for such an instrument as a *chamber organ* on the sole ground that such a pressure is necessary for the *pneumatic action* employed. For my part, I would sacrifice everything in the shape of pneumatic appliances to obtain that grand and refined volume of tone which places the organ on the throne, and gains for it the title of "the king of instruments." It is unnecessary to pursue this subject farther in this place; but I may recommend those who doubt the efficiency of low pressure winds for the Church Organ, to go and listen to the Choir and Echo departments of the Leeds organ, which are respectively on winds of 2½in. and 1½in.

Speaking Stops.

The selection of the speaking stops is, for all classes of organs, a matter of the greatest importance; and one which in all cases should be governed by the purposes for which the instruments are designed, and the demands which are to be made, in the proper order of things, on their musical resources. It is either from a total misconception of the matter, or an equally serious neglect of the problem it involves, that so many modern Church Organs have been spoiled or rendered insufficient instruments.

The most important stops, and, indeed, those upon which the whole tonal structure of the organ is based, are commonly classed under the general appellation of *foundation-work.* The name is appropriate, and expressive of the dignified office fulfilled by the registers in question. In the manual departments such stops are of open metal pipes, yielding tones, peculiar to organ pipes, of great volume and richness. Chief among them are those of unison (8ft.) pitch, called *Open Diapasons;* and subordinate are those, derived from the unisons, yielding octave and super-octave sounds. There can be no question that upon the scaling and voicing of the *Diapasons* the Church Organ stands or falls as a worthy instrument. First of all, therefore, it is imperative that they should receive the greatest consideration in every stage of their manufacture. The best quality of "spotted metal" should alone be used, and of sufficient thickness to stand the most copious windage, and to produce a perfectly firm tone. It is impossible to obtain the tone required in a true *Diapason* from pipes made of inferior metal, or from those of insufficient thickness in any metal.

The following table of suitable scales for the *Open Diapason*, according to the system of Prof. Töpfer, may not be out of place or uninteresting here. The figures give the diameters in inches.

	CC-8ft.	C-4ft.	C-2ft.	C-1ft.	C-6in.	C-3in.
SCALE I.	7·51	4·50	2·67	1·59	0·95	0·57
„ II.	6·94	4·12	2·45	1·45	0·87	0·52
„ III.	6·36	3·78	2·25	1·33	0·80	0·48
„ IV.	5·83	3·47	2·06	1·23	0·73	0·43
„ V.	5·35	3·18	1·88	1·13	0·67	0·40

Under no circumstances should a smaller scale than No. V. be adopted for the *Open Diapason* of a Church Organ; while scales Nos. III. and IV. may be accepted as those most generally useful. The larger scales are only required for the instruments placed in cathedrals and very large churches; or for those to be heard under very unfavourable acoustical conditions.

When two or more *Open Diapasons* are planted in one organ, it is imperative that their scales should be as widely different as practicable, and that their voicing should be dissimilar. Attention to these matters prevents loss of sound through sympathy, and secures desirable variety of tone in these all-important registers.

To retain the requisite domination of the unison sounds of the foundation-work, it is necessary to select scales for the octave and super-octave *derived* stops considerably smaller than those of the *parent* unisons. Instead, therefore, of the *Octave* CC-4ft. being similar in diameter to the octave or thirteenth pipe of the *Open Diapason,* it should not exceed the diameter of the nineteenth (F sharp) pipe. Thus, if the parent unison is of scale No. I., its CC-8ft. pipe will be 7·51 inches in diameter; while the corresponding CC-4ft. pipe of the derived Octave should be 3·17 inches in diameter. The following table gives the scales for the *Octave*, in relation to those already given for the *Open Diapason.*

	CC-4ft.	C-2ft.	C-1ft.	C-6in.	C-3in.	C-1½in.
SCALE I.	3·47	2·06	1·23	0·73	0·43	0·26
„ II.	3·18	1·88	1·13	0·67	0·40	0·24
„ III.	2·91	1·73	1·03	0·62	0·37	0·22
„ IV.	2·67	1·59	0·95	0·57	0·34	0·20
„ V.	2·45	1·45	0·87	0·52	0·31	0·18

The *Super-octave* should be slightly smaller in scale than the *Octave;* the CC-2ft. of the Super-octave being equal in diameter to the thirty-third pipe of the parent unison. The relative scales of this acute stop are given in the following table.

	CC-2ft.	C-1ft.	C-6in.	C-3in.	C-1½in.	C ¾in.
SCALE I.	1·88	1·13	0·67	0·40	0·24	0·14
„ II.	1·73	1·03	0·62	0·37	0·22	0·13
„ III.	1·59	0·95	0·57	0·34	0·20	0·12
„ IV.	1·45	0·87	0·52	0·31	0·18	0·11
„ V.	1·33	0·80	0·48	0·28	0·17	0·10

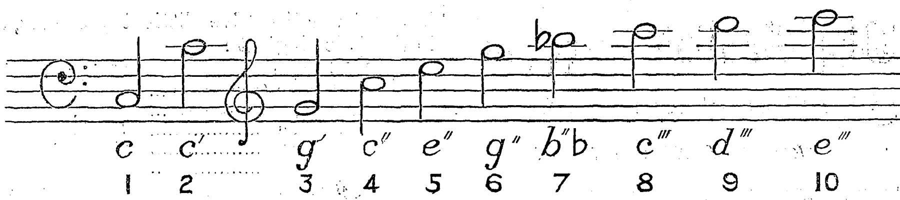
Of the mutation and "harmonic corroborating" stops I do not propose to speak at any length here. It is sufficient to remark that, although mutation registers are useful, and even desirable in large organs, they are by no

means indispensable in Church Organs of small size, or in those containing less than twenty speaking stops. When introduced, they should be of much smaller scale than the foundation work, and be voiced to yield full, quiet tones, which, instead of asserting themselves in the tonal structure of the instrument, simply enrich the natural harmonics of the unison tone. The most important mutation stop is, of course, the *Twelfth* (2⅔ft.), producing sounds which reinforce the second upper partial tones of the unison registers.

Although I do not lay much stress on the introduction of the simple harmonic or mutation stops, I strongly advocate the introduction, in all Church Organs, of the *Mixture* or compound harmonic stops. As I have already said in my "Notes on the Chamber Organ," without a *Mixture* of some kind it is impossible to secure that quality of tone which contributes so largely to the glory of the organ. I feel quite satisfied in my own mind that the early organ builders and their followers erred in making their *Mixtures* far too assertive, by adopting inordinate scales and loud voicing; and, sometimes by introducing too many of them in their organs. For instance, Father Smith inserted in his Temple Church organ, which contained in all only twenty-three speaking stops, no fewer than five *Mixtures*. These comprised 713 pipes out of the total number of 1,715 pipes in the instrument. Again, in the Great department of the organ built by Renatus Harris for the church of St. Sepulchre, Snow-hill, London, three *Mixtures* were included in the list of fifteen stops. As I have said elsewhere, loud *Mixtures* introduced in such numbers are more than "*harmonic-corroborating*" stops; they are, in truth, *harmonic-creating* registers, and accordingly go entirely beyond their province in the tonal structure of the organ, and upset the acoustical conditions which guarantee their introduction in proper form and proportion.

Erring on the other extreme, organ builders of to-day are introducing too few, or altogether omitting *Mixtures* from their organs. Such a practice can only have originated in the desire for cheap organ building. A *Mixture* of four or five ranks, with, respectively, 232 and 290 pipes, is both a costly and a troublesome affair; yet it makes but one stop, and is represented by a single draw-knob. When an organ is competed for, and its contents are left to be suggested by the competing builders, there is a very strong temptation to omit stops requiring so much skilled labour in their construction. Their argument is, if they are questioned, that such compound stops are neither necessary nor desirable in a Church Organ. But, again, I say it is impossible to obtain that rich and ringing quality of tone which is characteristic of the perfect organ without a proper proportion of harmonic-corroborating tone supplied by well-balanced *Mixtures*.

In scheming the compound stops for the Church Organ, the proper office which they have to fulfil in the general tonal structure of the instrument must be steadily held in view. On this subject Helmholtz remarks: "It is well known that the union of several simple tones into one compound tone, which is naturally effected in the tones produced by most musical instruments, is artificially imitated on the organ by peculiar mechanical contrivances. The tones of organ pipes are comparatively poor in upper partials. When it is desirable to use a stop of incisive penetrating quality of tone and great power, the wide pipes (*principal register* and *weitgedackt*) are not sufficient. Their tone is too soft, too defective in upper partials; and the narrow pipes (*geigen register* and *quintaten*) are also unsuitable, because, although more incisive, their tone is weak. For such occasions, then, as in accompanying congre-



gational singing, recourse is had to the *compound stops*. In these stops every key is connected with a larger or smaller series of pipes, which it opens simultaneously, and which give the prime tone and a certain number of the first upper partials of the compound tone of the note in question. It is very usual to connect the upper Octave with the prime tone, and after that the Twelfth. The more complex compounds (*cornet*) give the first six partial tones, that is, in addition to the two Octaves of the prime Tone and its Twelfth, the higher major Third, and the Octave of the Twelfth. This is as much of the series of upper partials as belongs to the tones of a major chord. But to prevent these compound stops from being insupportably noisy, it is necessary to reinforce the deeper tones of each note by other rows of pipes, for in all natural tones which are suited for musical purposes the higher partials decrease in force as they rise in pitch. *This has to be regarded in their imitation by compound stops.* These compound stops were a monster in the path of the old musical theory, which was acquainted only with the prime tones of compounds; but the practice of organ builders and organists necessitated their retention, and when they are *suitably arranged and properly applied, they form a very effective musical apparatus*. The nature of the case at the same time fully justifies their use. The musician is bound to regard the tones of all musical instruments as compounded in the same way as the compound stops of organs."

To make this matter still clearer to the reader—and it is desirable he should clearly understand it—I give a further quotation from the learned writings of Helmholtz: "On exactly and carefully examining the effect produced on the ear by different forms of vibration, we meet with a strange and unexpected phenomenon, long known indeed to individual musicians and physicists, but commonly regarded as a mere curiosity, its generality and its great significance for all matters relating to musical tones not having been recognised. The ear, when its attention has been properly directed to the effect of the vibrations which strike it, does not hear merely that one musical tone whose pitch is determined by the period of the vibrations in the manner already explained, but in addition to this it becomes aware of a whole series of higher musical tones, which we will call the *harmonic upper partial tones*, and sometimes simply the *upper partials* of that musical tone, in contra-distinction to that first tone, the *fundamental* or *prime partial tone* or simply the *prime*, which is the lowest and generally the loudest of all, and by whose pitch we judge of the pitch of the whole *compound musical tone*, or simply the *compound*. The series of these upper partial tones is precisely the same for all compound musical tones which correspond to a uniformly periodical motion of the air. It is as follows:—

"The first upper partial tone is the upper Octave of the prime tone, and makes double the number of vibrations in the same time. If we call the prime *c*, this upper octave will be *c'*.

"The second upper partial tone is the Fifth of this Octave, or *g'*, making three times as many vibrations in the same time as the prime.

"The third upper partial tone is the second higher Octave, or *c''*, making four times as many vibrations as the prime in the same time.

"The fourth upper partial tone is the major Third of this second higher Octave, or *e''*, with five times as many vibrations as the prime in the same time.

"The fifth upper partial tone is the Fifth of the second higher Octave, or *g''*, making six times as many vibrations as the prime in the same time.

"And thus they go on, becoming continually fainter, to tones making 7, 8, 9, &c., times as many vibrations in the same time as the prime tone. Or in musical notation where the figures beneath show how many times the corresponding vibrational number is greater than that of the prime."

From the above particulars the true office of the *Mixtures* in the organ can be clearly realised, as well as the necessity for their introduction. I consider the advisability of keeping them soft in tone, so that they may simply corroborate the natural harmonics of unison sounds, is also satisfactorily proved by Helmholtz. Much more might be said in favour of the introduction of one or more *Mixtures* in every Church Organ; but space prevents a longer treatment of the subject here.

(*To be continued.*)

REVIEWS.

The Gas Engine. By DUGALD CLERK. London: Longmans.

NO one has done more than Mr. Dugald Clerk to explain in theory and practice the gas-engine, and no one has written a better book on the motive-power engine which is steadily coming to the front as the best of motors where only a moderate amount of power is required. The work opens with an historical sketch of the gas-engine from 1690 to 1885, the earlier date referring to the experiments of Huyghens and Papin; but, as Mr. Clerk says, the gun-powder-engine cannot really be classed as a gas-engine, which dates its invention from Robert Street's patent, No. 1,983, 1794. In that we have a motor-cylinder with a piston connected to a lever, which drives a pump. The bottom of the motor-cylinder is heated by a fire, and a few drops of turpentine are vaporised, when air is admitted to the cylinder, and a flame applied—the result being an explosion. The idea is correct, and was not improved upon until lately; but the inventions of Samuel Brown in 1823 and 1826 are of more importance, for his vacuum gas-engine was the first which is certainly known to have done actual work, and in some important points it has attained a measure of success not yet equalled. The first practicable engine was that of Lenoir, in 1860, since which date great advances have been made. In his first chapter Mr. Clerk discusses the gas-engine method, in his second he classifies the gas-engines, and in the third he considers the laws of thermo-dynamics as applied to the gas-engine, quoting Rankine, Schöttler, and Witz. This last-named chapter will be skipped by many readers; but the reader who wishes to thoroughly comprehend the subject will endeavour to understand the formulæ, and will be well repaid for his trouble. Chapters IV., V., and VI. deal with the causes of loss in gas-engines, with combustion and explosion, and with explosion in a closed vessel, and if the reader has followed the author with care and attention, he is prepared to comprehend the illustrated descriptions of the different types of engines which occupy nearly 90 pages, and include,

amongst others, the Otto, the Clerk, the Atkinson differential, and the Brayton petroleum engine. These are described as fully as need be; but the chapter which will most interest those conversant with the general construction of the gas-engine is that in which the igniting arrangements are described. As Mr. Clerk pithily says, "quite a number of witnesses, in the shape of unworkable gas-engines, in many engineers' workshops throughout Britain attest silently but emphatically the difficulties of the igniting valve." Mr. Clerk has done his best to remove these difficulties by means of illustrated explanations of the successful methods adopted, and while expressing the opinion that the flame methods are best suited for small gas-engines, he suggests that probably a combination of the flame and incandescence methods will remove the risk of extinction from draught. As regards the electrical methods, he is clear that they give too much trouble and are at best uncertain. Next to the igniting arrangements, the governor and starting gear are the most important details in connection with gas-engines; and Mr. Clerk devotes considerable attention to the devices already in existence, and does that in such a manner as to render his remarks useful to future inventors. Chapter X. deals with the theories of the action of the gases in the modern gas-engine, by which it will be understood that the subject is not clearly comprehended at present; while the concluding chapter refers to the future of the gas-engine, and in that Mr. Clerk takes the opportunity to say that the position of the gas-engine, as we know it, is mainly due to the patience, energy, and commanding ability of one man—Mr. Otto. We have not attempted to do more in this brief notice than give an idea of the contents of this book, and we can conclude with the statement that it is the best work on the gas-engine that has been published.

The Age of Electricity from Amber-Soul to Telephone. By PARK BENJAMIN, Ph.D. London, Paris, New York, and Melbourne: Cassell and Co., Limited.

THE author of this work, Dr. Park Benjamin, a well-known American writer, tells us that it is not a technical treatise, nor is it addressed in any wise to the professional electrician: it is, in fact, a popular account of the rise and progress of electrical science, into which only such technical terms as are in daily use have been introduced. In dealing with historical data, Dr. Benjamin has, when possible, gone to contemporary publications, and in many cases to the original writings of the discoverers themselves, while in his search after facts he has ranged through all the available literature, from Boyle's little pamphlet published in 1675 to the latest numbers of the electrical serials. Electrical like many other great inventions are, as a rule, the outcome of the labours of many men, and it is not easy to define the exact status of each. Dr. Benjamin says, "It is a singular fact that probably not an electrical invention of major importance has ever been made, but that the honour of its origin has been claimed by more than one person." The title of "father of the telegraph" is, he says, given to Wheatstone in England (not generally, it should be observed), and to Morse in the United States, "although to neither of these inventors, but to Joseph Henry, the lasting gratitude of the world belongs." Even Dr. Benjamin does not seem to be aware of the part played by Dr. Edward Davy, an Englishman who emigrated to Australia and died there not long ago; but it is unprofitable to inquire into the matter, for as we know in connection with the telephone, it is the man who succeeds in making an invention a practical success that is regarded as the discoverer. As its title implies, Dr. Benjamin's work deals with the electrical appliances which have been adapted to the service of man, and it gives all readers a good idea of the wonders that have already been accomplished, while in not a few it will inspire at least an inclination to pursue some branches of the subject further into detail. In future editions certain slips of the pen will no doubt be corrected; for instance, in the description of the Bunsen cell on p. 52, where it is stated that the carbon is immersed in bichromate solution; but errors in detail are of small moment in a work of this kind, the object of which is to present to the general reader a broad view of the "age of electricity." The book will be found to be an appreciated gift by the youths of both sexes.

Lives of the Electricians: Professors Tyndall, Wheatstone and Morse. By WILLIAM T. JEANS. London: Whittaker and Co.

THIS is the first volume of a series of the "Lives of the Electricians," and its object is to tell incidentally the story of the progress of the electric telegraph from its origin in 1837 to the present time. The present is the jubilee year of the telegraph, and the choice of "electricians" for the first series is thus accounted for—though it is customary to regard Prof. Tyndall as a physicist rather than as an electrician, albeit he has extended, and let us hope will still extend, our knowledge of magnetism. The lives of Wheatstone and Morse are written in a readable style by Mr. Jeans, who embodies in his narratives many facts of historical interest, and a good deal of controversial matter which must almost of necessity form part of a work which is intended to be also a sort of history of the electric telegraph. In speaking of Morse, Mr. Jeans says that his "ingenuity and perseverance gave to the world one of the most original and useful methods of conveying intelligence by electricity," a sentence which does not claim too much for Morse; while for Wheatstone may fairly be claimed the title of "father of the telegraph." The fame of Wheatstone, however, does not rest on one or two achievements, and the story of his life, as it concerns his inventions, is well told in this work, wherein some erroneous traditions are relegated to their proper positions.

Hours with a Three-inch Telescope. By CAPT. W. NOBLE, F.R.A.S. London: Longmans.

THIS little work is, as its author says, a "primer of the Three-inch Telescope," an instrument which in the shape of the popular "five-pounders" has found a large number of purchasers of late years, for whom such a work was much needed. It is, in fact, designed to instruct the beginner with a telescope which is devoid of elaborate accessories, and is mounted on a common table-stand. To a large extent it is a reprint of papers which originally appeared in *Knowledge*, and an observer with moderate eyesight and a telescope of 3in. aperture of fairly good quality, should be able to see and do everything described by the author, who will be pleased if his endeavours to teach should lead the amateur to pursue his studies with superior instrumental means, and Webb's "Celestial Objects," to which work the present is in several senses a stepping-stone. If the young astronomer will carefully read the directions given by Capt. Noble, and carefully work through the observations as occasions and the seasons offer and the weather permits, he will acquire a very respectable knowledge of the solar system and the starry heavens, and will be anxious to obtain a more powerful instrument as soon as possible. Not that a 3in. telescope is so very small, for this work will show the reader that a great deal can be seen with it. The book is freely illustrated, and a neat map of the moon forms an appropriate frontispiece. It is just the book to give the beginner with the telescope.

Gas-Fitting. By JOHN BLACK. London: Crosby Lockwood and Co.

THIS work is an addition to Weale's Rudimentary Series, and gives practical details of a handicraft which is rarely described in manuals of technology. The author tells us that the gas-fitter is in as great request to-day as at any time, and he evidently thinks that he will be wanted for some time longer. Mr. Black treats his subject in a workman-like manner—that is, he puts before his readers something to be done, and then tells them not only how it should be done, but also how to do it, illustrating his remarks with useful diagrams where they will help to elucidate the matter. The directions are full, and separate chapters are devoted to special branches, such as fitting up workshops, theatres, churches, shops, and cooking-stoves. A "Word to Consumers," as the last chapter is entitled, will be useful to many, especially if those who take a light to look for an escape of gas will remember what they can here read.

Safe Railway Working. By CLEMENT E. STRETTON, C. E. London: Crosby Lockwood and Co.

MUCH of the matter which this work contains has already appeared in substance in our pages; but Mr. Stretton has rendered his book complete by supplying diagrams of continuous brake arrangements and of systems of signalling. There is also a good deal of historical information put in a concise form, and much that concerns railway servants in relation to the law. The book should be studied by all members of Parliament, and if those whose business it is to comment on railway accidents in the daily press would read it their articles might be read with more attention than they now are by those conversant with railway working.

We have also received *A History of the University of Oxford*, by the Hon. G. C. BRODRICK, D.C.L. (London: Longmans), an attempt to present in a succinct form the history of a University which is among the oldest institutions in Europe. The work is of interest to all Englishmen, and will be valued by all Oxonians.——*Trusses of Wood and Iron*, by WILLIAM GRIFFITHS (London: Crosby Lockwood and Co.), will be found useful by students in Building Construction, and by architects and builders, the drawings being practical and clear.——*Expansion of Structures by Heat*, by JOHN KEILY, C.E. (London: Crosby Lockwood and Co.), is a volume which deals in a practical way with a matter that is too often neglected, and which is not often referred to in detail in works on construction. The book will be useful to architects, engineers, and builders. ——*Outlines of Quantitative Analysis*, by A. HUMBOLDT SEXTON (London: Charles Griffin and Co.), is intended for students who have but a limited time to devote to the study of practical chemistry.——*Historic Towns, London*, by W. J. LOFTIE, B.A., F.S.A. (London: Longmans), is one of a series of volumes edited by E. A. Freeman, D.C.L., and Rev. W. Hunt, M.A., and will be read with interest by all who regard London as the centre of the world. The work refers to many matters which are comparatively unknown or have been forgotten, and is illustrated by maps of parts of ancient London.

We have also to acknowledge *The Mechanics of Machinery*, by ALEX. B. W. KENNEDY (Macmillan); *The Portable Engine*, by WILLIAM DYSON WANSBROUGH (Crosby Lockwood and Co.); *The Conversion of Heat into Work*, by WILLIAM ANDERSON, M.Inst.C.E. (Whittaker and Co.); and *Practical Handbook of Pump Construction*, by PHILIP J. BJORLING (E. and F.N.Spon—) all works deserving of lengthy notice.

BUDENBURG'S RECORDING GAUGES.

A NOVEL improvement for use with pressure and vacuum gauges has been recently patented by Mr. A. Budenburg, of Southgate, Manchester. It has for its object the securing of a permanent record of the maximum pressure or vacuum indicated by the gauge to which it is attached. Hitherto it has been sought to secure such a record or indication by the use of an independent index finger or "maximum pointer," but in the case of a sudden increase in the amount of pressure or vacuum the maximum pointer is liable to be jerked or thrown beyond the actual point on the graduated scale reached by the true index finger, and an excessive indication is thus given. The improvements consist in attaching to the index finger of the gauge a light pen, pencil, or scribing point, and in securing to the dial, or in a plane parallel with the dial and concentric therewith, a disc of paper, card, or other suitable material upon which the pen may trace a legible curve. The disc of paper or other material may be, and by preference is, graduated to correspond with the scale on the dial of the gauge. If the disc is placed below the index finger, a part of the disc may be cut away so as to allow it to pass the index spindle, and it may be secured in position by a spring cap, by needle points, by catches, or other suitable means. By this arrangement the curve

FIG. 1.

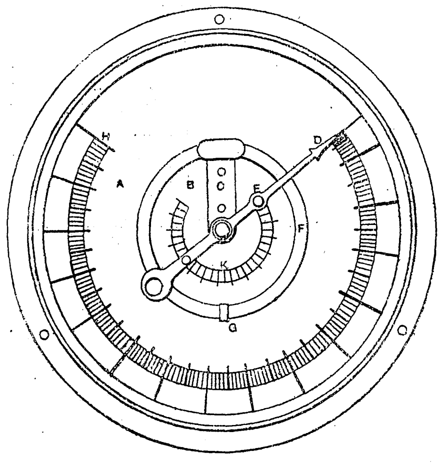


FIG. 2.

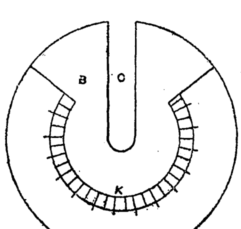

traced by the pen, pencil, or scribing point will correspond exactly with the amount of angular motion of the index finger and the maximum pressure or vacuum will be correctly indicated by the end of the curve.

Fig. 1 represents in front view a pressure gauge having these improvements applied thereto, and Fig. 2 gives in plan a representation of the disc of paper or card upon which the record of maximum pressure is taken. A is the dial of the gauge; B is the disc of card or paper upon which the record or trace is taken; C is a strap connecting the spindle with the ring F, and keeping it concentric therewith; D is the index finger, carrying at E a pencil or tracing point which bears upon B and traces thereon a curve the length of which is determined by the motion of D; F is a ring which serves to hold B in position; G is a lock or catch; H the graduation of the gauge, and K the corresponding graduation of B. The disc B is firmly held in position by the slot C, Fig. 2, and the strap C, Fig. 1, in combination with the ring F, which may be in halves, connected or disconnected at G, for the insertion or removal of the disc, or which may be hinged or pivoted at the outer end of C and be held or released by G. Alternatively the ring F and strap C may be fixed to the dial, and the disc be held in position by contact therewith. The pencil carried on the index finger traces a curve the extremity of which indicates the extreme pressure reached. The disc may be changed daily or at other convenient intervals, and to prevent tampering therewith the cover or front of the dial should be locked.

THE AMATEUR WORKSHOP.—XXXII.

Brass Foundry.—(*Continued.*)

THE particular sands used in brass moulding differ according to locality, and the best method for an amateur to adopt is to purchase such small quantities as he may require of a neighbouring founder. For the body of a mould the old floor sand which has been cast in over and over again is used; but the mould faces—that is, those portions next the pattern—are made with new sand, the latter extending to a depth of $\frac{5}{8}$in. or $\frac{1}{2}$in. only. The mould itself is faced with plumbago, or with oak charcoal, called blacking, or blackening, dusted on and sleeked over with trowel or sleekers. Flour, or pea-flour, are also used. The purpose of this is to prevent the burning of the sand into the casting; but if the blacking is of an excessive thickness—that is, beyond a mere film—scabbing will occur. Coal dust, ground up fine in a mill, is mixed with new sand previous to use, to render it porous. Sand once cast in becomes mixed with that on the floor, which is prepared for using over again by moistening with water from a watering-pot, and mixing with a shovel until it is uniformly damp—not wet, nor anything approaching to it, but just sufficiently damp to cohere; so that when a portion of sand is picked up and squeezed between the hand it does not fall apart on releasing the pressure, but retains the shape received. This watering and remixing is necessary after every casting, because the sand becomes dried and pulverised in contact with the hot metal.

The partings or joints between moulds are prevented from adhering by a sprinkling of parting sand, which is either the burnt sand scraped from the surfaces of castings, being of a red colour, and very loose and free, and, of course, perfectly dry; or brickdust simply.

The floor of the foundry is constituted wholly of the old or black moulding sand, while the facing sands are kept in suitable smaller bins or boxes. In a small workshop the black sand may be kept in the moulding trough, and the others in boxes at hand. Blackening is kept in a muslin bag in readiness for dusting over the moulds. Plumbago is kept in an open box, and taken up with the trowel or with lifters, and brushed over with a broad camel-hair brush before finally sleeking. Whiting or lime is kept in a bag, and dusted over the tops of cores when in place, or on the joints of moulds which have been uncovered, so that when the top part is replaced the transference or non-transference of the lime or whiting indicates whether or not there is contact between the joint faces of the bottom and top parts, or the drag and cope, as they are respectively termed. An iron pot, called a swab-pot, and a soft brush are kept at hand for watering the edges of moulds previous to the withdrawal of a pattern, and for mending up broken edges. A common pair of kitchen bellows are used for blowing out particles of sand which have fallen into the moulds, and for clearing the faces of patterns from parting sand. There should be a couple or three sieves, say 8, 16, and 24 mesh, a shovel, a couple of wooden rapping mallets, and a stove lined with brick, and closed with a sheet-iron door, for the drying of small cores. For an amateur's use, it may measure 2ft. by 1ft. by 1ft. inside, and be placed in any convenient situation over a common firegrate, constructed specially to supply the requisite warmth.

I cannot pretend to enter into a description of the art of moulding itself in these articles; but in the compass of a few paragraphs I will jot down some essential facts, of the nature of first principles, which, if understood and regarded, will go a long way towards helping an amateur in the requirements of this kind of work.

Perhaps the best plan will be to give two or three practical examples, and make these the medium for conveying the general instructions, and I shall select, therefore, only such articles as are likely to come within the range of the tasks undertaken by home workers. First, then, as a case of simple moulding, take a common brass bearing. This requires a two-parted box, and the journal face will be cast downwards. Hence, get a flask A (Fig. 370), of nearest size suitable, fill it with sand just roughly rammed in; bed in the pattern, sloping and smoothing the sand upwards from the hollow of the brass to the joint face of the box, as shown in the figure, first using the fingers, afterwards the trowel. Strew some parting sand all over the joint face, place on the drag B, Fig. 371 (empty, of course, and not as it appears in the figure), or that which is to be the bottom part of the flask in the mould; cover over with facing sand to a thickness of $\frac{1}{4}$in. or $\frac{3}{8}$in., the sand being worked by the hand through a fine sieve held over the mould. Throw in a shovelful of floor sand, and ram the pattern up, first with the pegging and then with the flat rammer. The knowledge of the precise amount of force required for ramming must be gained by practice. It should be only moderately hard; but as "hard" as a relative term, first watch a moulder at work, imitate him, and profit by failures. Hard ramming produces scabbing; soft ramming, lumpy castings. The sense of touch is relied on mainly for proper ramming, and the sand is levelled roughly by the left hand, or by the rammer as the process proceeds, and fresh sand filled in as required. Lastly, scrape off the superfluous sand level with the top edge of the box. Pierce it with some scores of vent holes with an $\frac{1}{8}$in. wire, allowing the wire to touch, or all but touch, the pattern each time.

Now turn over the two boxes, bringing box A, in which the pattern was embedded, uppermost; lift it off, leaving the pattern as shown at B, Fig. 371; knock out the sand from A, sprinkle the joint of the half mould in B with parting sand; replace box A, stick up a runner pin as shown dotted, Fig. 371, *a*, and ram up box A over the pattern similarly to B, that is with facing and with black sand; vent and level off. Scrape out a hollow cone with the trowel around the head of the runner pin, tap and loosen the pin, and draw it out. Lift off the cope A, stick a spike in the pattern and withdraw by gentle rapping and lifting combined. If the edges are slightly broken away in the process, moisten and make up the sand good. If they are broken badly, put in the pattern and make good to the pattern outline. If very bad, knock out the mould and run over again. Dust blacking over from the bag, or use plumbago, smooth with the sleeker of the nearest shape, and close ready for casting. Weight down, or clamp, as most convenient. If weighted, a patch of sand is levelled on the floor, the box laid down upon it, a slight slewing motion imparted to insure true bedding, and if of any considerable size, the vent wire is thrust several times between the bed and the bottom of the box to establish a communication between the vents in the lower portion of the mould and the outer air.

As one illustration of a pattern made in halves, and of a three-parted mould, I take the body of a common plunger pump (shown in Vol. XLI., page 205). In this the pattern joint of the half A is laid either on a truly strickled sand bed in the box part, as shown in Fig. 372, or on a bottom board, that is, a flat piece of board which fulfils the same purpose to the moulding box and pattern laid upon it that the sand bed in Fig. 372 does. The box B, Fig. 373, is then rammed over it, and vented precisely as described already. This box is then turned over into the position shown in the end view Fig. 373, and parting sand sprinkled; the half pattern C is laid upon half-pattern A, the middle part D put over and partly rammed up. But before completely filling the box the dowelled flanges *b*, are put on in place, and the sand tucked around and under them, and the whole rammed level with their top faces, if those faces happen to coincide with the top joint of the box part. If not level, the body of sand is rammed level with the box joint, and a sloping sand joint sleeked down to the faces of the feet. This frequently happens, and I have shown such an illustration (Fig. 375). After venting, the joint is sprinkled with parting sand, and the top E put on and rammed level and

vented. The boxes are then separated: the top E lifted first, then the two feet b withdrawn upwards; the middle D taken off, lifting with it the top half C of the pattern. This box being turned over and laid on supports, the top half of the pattern C is lifted from the joint, then the bottom half A is taken from the mould B. If the edges become broken—as, for instance, between the feet and the body, where the sand is thin and weak—ordinary cut brads or sprigs must be thrust in to bind it together and assist the mending up. Lastly comes the coring up. Cores are made with a free and "strong" sand, having mixed with it coaldust and horse-dung. Being dried in the oven, the burning out of the coal and dung leaves a remarkably hard yet porous mass. Cores are further vented by ramming up a wire or two within the sand of which they are composed, and withdrawing it before drying. The shapes of core boxes are familiar to those who have seen these articles; for this one in particular see the p. 205 just now referred to. Our mould being finished, therefore, the core is dropped into the impression made by the points c, c, c. The pump being properly cast on end, a hole is shown in the end of the box through which the runner is taken, the sand being cut away with the trowel for that purpose. Being cast on end, the box would be held together with clamps of wood or iron, and either stood leaning against a support or more properly sunk a little distance into a hole dug in the sand floor. Fig. 374 shows the mould arranged for casting. Remark also that though the runners are in the figure brought into the top of the mould as being suitable for shallow castings, if this pump were long I should put the runner in as shown in Fig. 381, and in connection with that figure I shall state the reason for doing so.

I have shown the box (Fig. 373) with flat bars in the drag, vertical bars in the cope, and no bars in the middle, which is the usual type. This is to be taken merely as illustrative of that type, since most small boxes for brass founding are without bars at all (see Fig. 356, p. 362). In cases where it is desirable to give support to the sand beyond that due to its own coherence, square rods of iron, or bars of wood are driven in between the box sides, bridging them across.

Fig. 375 shows the method of moulding an ordinary throttle-valve. The sand joint is cut down to correspond with the bevel of the edges of the valve, so that it and the chucking pieces a a shall lift vertically from the mould. This forms an example of jointing other than that in a horizontal plane. Though the joint of the box remains horizontal, the sand joints vary with circumstances, being in this and many such cases made to assume a slope approximating to the vertical. Such joints, with parting sand or brown paper intervening lift without becoming broken or damaged to any serious extent.

Fig. 376 shows the jointing of a pump bucket. The body piece A is laid bottom upwards, and box B laid over it, and the sand rammed while in that position, Fig. 376; then turned over, and the arch C, Fig. 377, is put on with dowels, rammed up in box D, and the sand joint made as shown in the two views; lastly, the top box E is rammed from this joint upwards. These joints indicate also the way in which the taper should be given: all from a upwards being slightly tapered upwards; from a to b being slightly tapered downwards; and all below b being also tapered in the same direction. In Fig. 376, C represents the core print, while Fig. 378 shows the mould cored up and closed, ready for running through the ingate.

So many make small model cylinders in brass and iron, that perhaps I cannot do better than conclude the subject of brass founding with an illustration of this kind, the description being suitable for any small cylinder of not more than a few inches in bore, and having the parts and feet arranged not very differently from Fig. 379. First, the half A is laid by its face joint on the face of a sand bed, or on a bottom board, as noted previously, and rammed up in box B. Over it is laid box C, in which the face of the flange D, with its port prints a are rammed, having regard to the partings and venting. The whole is then turned over, the half E laid on A by means of dowels; a round runner laid in the joint in the position shown in Fig. 381, and the top box F put on and rammed. If a two-parted box alone is available, the face of D and a can be made in a dry sand core, or piece of loam cake embedded in the sand of the box, the jointing edges being sloped, and replaced in the same position after the withdrawal of the pattern. The moulds being taken apart, F is drawn from joint face b, D from joint face c, A from joint face b, and the moulds mended up and cleaned. They are either dried, if made in core or dry sand, or only skin-dried for a few minutes; the latter being sometimes done in small work, though always risky in cylinder work, where the cores are numerous, and several faces have to be machined.

Cores are vented as before mentioned, by ramming wires in their body and withdrawing them previous to drying, the wires being proportional to the air-space required. They need not be large, since the core sand itself is, as already stated, in itself very porous, and the wire or vent-hole or holes simply carry off the gas which is driven from the exterior of the core to the central portions, and so convey it as by a main channel to the outside of the mould. With an inch core, for example, a $\frac{1}{4}$in. or $\frac{5}{16}$in. central hole is large enough. If the cylinder in our example were of 3in. or 4in. bore, a $\frac{1}{2}$in. or $\frac{3}{4}$in. rod would be big enough, and the core would be made from an ordinary box. With core bars and hay bands, of course, we have nothing to do in small work. When we come to the port and exhaust cores, these are weak and fragile, and hence, wires must be rammed up and left in them until after casting, to afford them the necessary support. They are withdrawn from the passages after casting by means of pincers, the flexibility of the wires (soft iron) allowing them to straighten themselves in the act of pulling out. Thus, for example, if the port cores were only $\frac{1}{4}$in. thick, the wires could not be more than a

full ½in. diameter, if the ports were ⅜in. or ½in. the wires could be ⅛in. They are first bent to the shape of the interior curves of the box and bedded in the sand during the ramming up, being kept as nearly central as possible. The central wire of all should be formed into a loop at the front end. These are different from the venting wires, since the latter have to be withdrawn, and in the case of slight curved cores, string is used for venting instead of wire, which would break the cores on withdrawal. The string is laid in the cores similarly to the wires, and withdrawn while the core is green. The cores are blacked with blackwash—that is, plumbago and water, or coal-dust and water, and dried.

Now the moulding-box being open at b (Fig. 379), and the valve face downwards, put in the two port and the exhaust cores into the prints on the valve face. These will each rest in one, or on a couple of studs or chaplets of the shape of Fig. 380, being simple moulding nails made of malleable iron, tinned if for cast iron, or brass nails if for brass. Before, however, these are put in, the thickness of metal between the core and the mould is checked by means of a clay thickness piece—that is, a piece of clay made pyramidal in form, rather higher than the required thickness of metal, and laid in the mould. When the main core is laid into its prints it presses the passage cores gently downwards, and with them the yielding clay beneath, until the main core finds its bearing in the prints. Then the clay is taken out, and its thickness checked, and if necessary to bring the thickness right, the cores are fudged by filing or rubbing. The thickness of metal in the body of the cylinder is also checked in the same way, to see if it be equal in top and bottom. When the cores are such as to give correct thicknesses the stops are driven into the sand, resting against the bars of the box, if possible, or, if not, in cubical wooden blocks embedded in the sand beneath, and the cores put in finally. Sometimes stops are put in to support the sides of the passage cores as well as at the back. If the curve of the core matches that of the cylinder core, and the two are kept close together by the hinder chaplet, there is little risk of their being washed aside. Chaplets may also be put between the passage and exhaust cores, but should never come against machined faces, as the cylinder bore and the valve face.

Cores being vented, there should be no chance of the vent-holes becoming choked up by the liquid metal. This is liable to happen if the cores do not abut closely; hence it is the practice, after the cores are put finally in place, to cement the ends closely with sand and black wash, moistening the bad or broken edges with water previously, and drying the mended part in place with a charcoal fire, or a mass of hot metal suspended over it for a few minutes. An important point also is that the coring up should be done not long previous to casting, so that if a mould is made a few days previous to casting, the cores will not be put in until, at most, a few hours before casting; the reason being that the cores absorb moisture rapidly from the atmosphere, and damp cores cause blow-holes.

Fig. 381 shows the cylinder ready for casting, with the cores anchored and chapleted securely. The ingate goes to the bottom of the mould, so that the metal shall not dash violently down, but rise slowly, carrying the sullage upwards into the head metal. The same method is pursued in Fig. 375. In Fig. 378 the runner answers the purpose of head metal to the boss of the bucket, which has to be bored. In Fig. 374 the position of the runner is not the best for casting on end, but as an alternative mode for castings not very deep. In Fig. 371 the runner could be indifferently placed in any position.

PROGRESS OF ELECTRIC MOTORS.

THE following paper by Mr. T. C. Robbins, of Baltimore, who has been intimately connected with the most successful electrically-worked tramway in America, was read recently before the American Street Railway Association. There is little reference to what has been done in this country: but as an historical *résumé* of the subject with some valuable notes of the present position of electric haulage it is an interesting document. Although termed a "paper," it is really a report of a committee.

In searching for the first experimenter in the field of electric locomotion, it very soon becomes apparent that extreme difficulty will be experienced, due to the great number of visionary experimenters which seem to be attracted to this branch of physics. Though the experiment of Jacobi on the river Neva in 1834 certainly demonstrated the possibility of producing a not inconsiderable force by electrical means, a casual inquiry as to the cost of the experiment conclusively proves that very little hope remained of its application assuming a commercial form so long as chemical decomposition was the only recognised means of exciting electricity.

It remained, however, for later scientific investigators to point out that this was not due so much to the inefficiency of the producer as the exceeding crudity of the receiving apparatus and the necessary high cost of the electric fuel, so to speak, which in this case, as in many subsequent cases, was zinc. In view of the really discouraging character of this experiment regarded as even a possible commercial achievement, it is surprising that many inventors could have been found sufficiently bold to make any other attempts until radical changes had been made in the producing force; but history records that a number of other daring experimenters attempted to supplant the steam locomotive within the next decade. It is not, however, recorded that a sufficiently hopeful result was obtained at this period to be regarded as anything more than an interesting scientific display.

The intervening experiments were hardly worthy of record until the year 1860, when Prof. Page made the first recorded experiment of any note, with batteries having carbon plates in place of the inferior copper ones formerly employed. It is recorded that by means of his improved apparatus, Prof. Page was enabled to drive a car-load of passengers through the streets of Washington with an electric locomotive, travelling at the rate of 20 miles an hour. Though it is quite possible the speed is here exaggerated, and that the car-load of passengers was propelled only on the level, which would not necessarily call for a powerful effort, it is still noticeable that such an achievement was possible simply by the use of batteries and the imperfect apparatus of that time, in a manner sufficiently satisfactory to have attracted a number of business men, who for some time anticipated great results. It is now evident that nothing of a commercial nature could possibly have followed with the means at command; and though a number of more or less successful experiments of a similar kind were made, nothing of sufficient importance to even promise a commercial result occurred until the year 1879, when Messrs. Siemens and Halske, of Berlin, operated a small electric railroad of about one-third of a mile in length at the Berlin Exhibition, employing an auxiliary conductor between the rails, from which the current was taken up by means of a metal brush and transferred to the motor in the now well-known manner. Several more of these small locomotives, being rated at one or two horse-power, were made during the years 1879 and 1880, and it is recorded that with this apparatus the current was sufficiently powerful to throw horses when accidentally placed in contact with the third rail. These latter experiments partook of a much closer approximation to the commercial character, for the simple reason that during the interval between Prof. Page's test and that of Messrs. Siemens and Halske the greatest advance yet recorded in electric locomotives had taken place—namely, the introduction of the mechanical producer or dynamo machine, which, apart from the details involved, rendered possible the substitution of coal for zinc as a fuel. That the energy of the former had now to be passed through a steam-engine was a comparatively important detail, considering the enormous disproportion between the energy produced from coal and zinc, from a financial standpoint; and though the inefficiency of the engine as a thermo-dynamic motor militated strongly against the complete triumph of this new order of things, the extraordinary efficiency of the infant dynamo operated in great measure to place the new power on a commercial basis. Indeed, so wonderfully efficient were even the earlier dynamos manufactured by Messrs. Siemens, that the first recorded results proved indisputably that under such favourable conditions as those which Messrs. Siemens were able to avail themselves of, competition with horseflesh seemed possible even from the first, though it was a daring man who in these times would even hint at competition with steam and other well-known converters.

The little machines above noted were so satisfactory in their operation that they were quickly followed by an electric railway for actual business traffic, which was constructed by Messrs. Siemens and Halske, between Lichterfelde and Military College, Berlin. The electric motor or car on this road was built so as to closely resemble the ordinary European tramcar, and the motor was attached under the floor. It is recorded that the performance of this car was eminently satisfactory in dry weather, but considerable difficulty was experienced in operating in wet weather, until several changes had been made in the manner of conducting the current, it being subsequently found necessary to use an overhead conductor, which is the first recorded example of this kind, and appeared to be so successful that the road has continued running without any radical changes up to this time. It must, however, be remembered that the power required was very small, since the road is entirely level from end to end, and the car was limited in size, being only able to carry about 25 persons when fully loaded.

Passing over a number of minor experiments which followed this achievement of Siemens on the other side, the first notable example after that of Prof. Page's in this country appears to be the electric locomotive of Thomas A. Edison in the summer of 1882, which is said to have attained a speed of nearly 40 miles per hour on a level track at Menlo Park, New Jersey. The experiments were conducted for a considerable time, but do not appear to have been of a character sufficiently encouraging to warrant any attempt in a commercial way, and no machines of this type were ever placed on a commercial road. The manner of taking up the current was similar to what had before been tested by Siemens in Berlin, and afterwards abandoned as not affording sufficient insulation in wet weather.

Later in the year 1882, Leo Daft constructed a number of small electric locomotives, which were tested and run for a considerable time on a track provided at the works of the Daft Electric Light Company at Greenville, New Jersey, which were the first recorded example of a number of locomotives (there were four employed at one time) running on the same track at the same time, from the same generating apparatus; and a number of experiments were conducted from time to time for the satisfaction of a large number of visitors, among whom were many electrical and engineering experts, to prove what was then a matter of considerable doubt, that locomotives could be run in parallel from a producer of sufficient capacity. This was so completely demonstrated at that time that in this direction no further doubts existed, though it seemed to be for a long time the standing objection to the progress of this new enterprise from those who were less familiar with the true inwardness of this problem. On these occasions the four cars were purposely manipulated in the most difficult manner, being all started at the same time as nearly as possible, and all the evolutions which a most exacting audience demanded were made without at any time showing the least reason to doubt that the system was capable of indefinite extension on the same lines. Not the least extraordinary of the effects which constant experiments developed was the remarkable tractive capacity of the motors when operated with insulated wheels and using both rails as the conducting system. It was clearly shown that a small locomotive weighing but 450lb. was capable of developing the extraordinary tractive force of 300lb. on a dry rail. This was repeatedly demonstrated, and the subsequent experiments with the same apparatus developed the astonishing fact that it was capable of ascending a gradient of 2,900ft. per mile without any extra tractive appliances whatever, with a driver weighing upwards of 150lb. to add on the car. It will thus be seen that an effect was arrived at contrary to anything which may be evolved from the coefficients of Molesworth. There have been many opinions as to the cause of this; but the fact remains that the above achievement was repeated day after day before a large number of technical persons, and can, of course, be repeated at any time, though it is not possible to reproduce this effect on the large scale required by commercial practice, for reasons which cannot form a part of this paper. The increased traction under favourable conditions is not by any means an unimportant feature in considering the relative weight and energy of a given motor. In the fall of 1882, an experiment was made at Chicago national exhibition of railway appliances with a motor consisting of a Weston machine placed upon a platform car and driven by a second Weston machine, by means of two copper conductors placed near the track. This car travelled on a circular track under cover without any gradients, and, as might have been expected, created a favourable impression among the spectators, though it would not be classed with commercial performances, since the energy required was comparatively insignificant; it served, however, to keep up the public interest in matters of that kind, and was so far successful.

In February of the following year, it is recorded that a motor weighing 300lb., constructed by Chas. J. Van Depoele, was put in operation at the works of their company, and operated a car which is stated to have been capable of carrying 25 people, and the trials were conducted for several days, and

are said to have met with perfect success. In the following year a number of experiments were carried out at the Daft Company's factory at Greenville, New Jersey, with a view to demonstrate the possibility of electric locomotion on a much larger scale; and in May, 1883, an electric locomotive, afterwards called "Ampère," was begun for an experiment on the Saratoga and Mt. McGregor Railroad, a narrow-gauge road running from Saratoga about ten miles to Mt. McGregor. Some time was occupied in experiment prior to the construction of this machine; but in the fall of the same year (1883), the locomotive was finally finished and forwarded to Saratoga, where a number of experiments were made on a part of the track which had been furnished with a third rail to the distance of about a mile and a quarter from the depot, the dynamo machines being situated about midway, and a few hundred feet from the track. In this case a third rail was used, supported on blocks of wood saturated with resin, and experiments revealed the fact that with the low potential employed, the insulation was sufficient for a practical experiment, even when a considerable portion of the tracks was covered with snow. The main achievement of this was that it towed a car weighing over 10 tons, loaded with 68 passengers, over the road, including a gradient of 93ft. per mile. Though several difficulties were experienced, due to the comparative crudeness and temporary character of the local arrangements, sufficient was accomplished to prove the possibility of commercial electric traction; and since it was the first example of electric locomotion on an ordinary steam railroad, it attracted attention, and encouraged others to proceed in the same direction. It is noticeable that about this time a number of experiments were recorded with what are now known as accumulators on the other side of the water, and a number of more or less successful experiments were made, which only served to develop the fact that accumulators were then, as they are probably now, susceptible of great improvement.

The extraordinary impetus which had been given by the introduction of the dynamo machine was re-enforced by the comparative success of the experiment just noticed, so that within the next few months a large number of electricians and others found themselves sufficiently encouraged to construct a great variety of electric apparatus for the complete extinction of horses and steam. As you are doubtless aware, the greater part of these have been entirely unproductive; but the most notable cases have not only survived, but are now being prosecuted with a vigour and success which naturally results from their having assumed a thoroughly commercial character; and in the year 1884 a combination of important capitalists was effected under the title of the American Electric Railway Company, with a view to placing everything of this kind on a sufficiently strong commercial basis to insure its adoption; but as some difficulty was experienced in securing concerted action, nothing of importance has yet resulted from this combination, the inventors, as before, pursuing their different ways alone. Here, perhaps, it may be as well to state that electric locomotion alone had not by any means absorbed the attention of inventors, the question of transmission of power for stationary purposes having appeared to present an even more attractive field. Much had been accomplished in this direction, and practical results attained by such distinguished inventors as M. Marcel Deprez, Messrs. Siemens and Halske, of Germany, and Sir William Siemens, of England, together with Messrs. Ayrton and Perry, and others of lesser note. Notable among the achievements of the French inventor was the transfer of nearly 40 horse-power for a distance of several miles by an ordinary telegraph wire.

In this country, though workers in this direction have apparently been less numerous, the results have generally assumed a more important character regarded as a commercial achievement. The first recorded example of the establishment of a central station exclusively for the distribution of power was that of the Massachusetts Electric Power Company, which was placed in May, 1884, and has since grown to considerable proportions. This company uses the Daft system. Several others similarly equipped have since been put in operation with entirely satisfactory results, which my paper will not allow me to describe. There are, however, a large number of satisfactory motors in operation in different parts of the country, though not, so far as I know, worked from stations exclusively for power; among the motors so employed may be mentioned the Sprague, Van Depoele, Edgerton, Baxter, D'hul, and a host of others, which may fairly be said to be too numerous to be mentioned, though with one or two exceptions these inventors have devoted themselves to matters of very small power, especially for use in operating sewing machines, dental instruments, &c.

In August, 1885, Messrs. Knight and Bentley operated a small road in the city of Cleveland, O., with a subterranean conductor, which may be said to be the first serious attempt with that form of conduit yet made in this country. The experiment extended over a considerable period, and is described as being quite successful, though for some reason of which I am not informed the plan was not adopted, and the experiments have been discontinued, though these gentlemen are still doing good work in Providence, R. I., and are, I trust, preparing themselves for a brilliant future. It will be unnecessary for me to remind you that a plan of this kind must ultimately be adopted in many of our large cities, particularly since the beginning of the overhead-wire crusade.

In the year 1885, C. J. Van Depoele constructed and operated a locomotive which is said to have done excellent work at the Toronto exhibition, in the fall of last year, and this has been followed up from time to time by notable works and experiments in different parts of the country, chiefly among which may be mentioned Montgomery, Ala., South Bend, Ind. This inventor, after the manner of the early German road, has adopted an overhead conductor, which sems specially suited for use in cities where the necessary permits can be obtained, and appears to have met with such success as to promise greater things in the future.

Passing over some minor achievements, I am led to speak of the installation of the Baltimore and Hampden Electric Railroad as the one commercial plant which has been operated for a sufficient time to allow of a proper statistical comparison, not only with horses, but with other mechanical tractors, and in so doing I append figures showing results of operating this road for twelve months by the Daft system, including a winter of extraordinary severity for that region, and under such conditions as I am sure you will conceive are sufficiently commercial in their character. A profile of the gradients and curves on this road will be a sufficient assurance that the experimental element has not been allowed to predominate in selecting the ground for such purpose, except in a manner sufficiently prejudicial to afford unusually severe means for satisfying ourselves as to its enduring character. The statistics here appended will afford so clear an insight to the results of this experience that I will not further dwell upon it, except to remark that, though I must confess myself strongly in favour of so convenient and sufficient a substitute for horses, or other mechanical tractor so far tested, I have not allowed myself to be led astray by the scientific allurements of the case, and feel satisfied that a careful analysis of the case will lead others to conclude, as I do, that electricity employed as the means of transferring the energy of mechanical tractors is not only coming, but is here, and in all essential particulars has been here for some time past. It is not too much to add that the Baltimore and Hampden-road stands alone in this particular, that it was started on a purely commercial basis as a purely commercial transaction, and has continued, and is now being extended, simply because it has proved its right to stay by the performance, which leaves little to be desired in that direction.

About the time that the Baltimore road was started, the Daft Company was engaged upon the manufacture of a large electric motor, Ben Franklin, intended for use for experiment on the Ninth Avenue Elevated Railroad in New York. This was subsequently put in operation and experimentally used for a considerable time on a short track at Fourteenth-street, and towed four cars over two miles of that road. It was ascertained during these experiments that a more powerful motor would be required to fully meet the requirements of the case, and the experiments will shortly be resumed on a larger basis.

Lieut. F. J. Sprague has since built and put in operation a motive car on a short branch of the Third Avenue Elevated Railroad at Thirty-fourth-street. The experiments with this motor have not yet been concluded, but I understand that they have been quite successful, and will probably result in an extended application of this motor.

In concluding this brief review of this comprehensive subject, I feel that I should not be doing it full justice if I were not to attempt a refutation of many charges which have been brought against electricity by persons unfamiliar with its peculiarity.

It is said to be unsafe; and though with high potential this is undoubtedly the case, I am prepared to say that with the potential now in use on the Baltimore and Hampden Railway, the experience by a year's constant running 18 hours per diem leads me to state that so far as human life is concerned it is absolutely harmless.

Secondly: It has been said to be uncertain. Again, quoting the experiences of a year, I am able to state that after the little difficulties incident to a primary installation had been removed during the first month or two, it is as certain as any other form of mechanical tractor in all weather.

Third: It has been stated that specially skilled help would be required to operate a line so equipped. I am again able to say that the experience before referred to has enabled me to place upon the road men who were entirely unfamiliar with electricity in any of its applications, and that these men are now our sole reliance for all the operations required, and interruptions are as much the exception with us now as with any ordinary road.

For the year ending September 1, 1885, the road carried with three cars, with horses, 227,155 passengers at 5 cents each, making 11,357.75 dol.

For the year ending September 1, 1886, the road carried with two cars, propelled by the Daft electric motor, 311,141 passengers at 5 cents each, making 15,557·05dol.

This shows an increase of 83,986 passengers with two cars propelled by electricity as against three cars propelled by horse-power for the same corresponding time, and an increase of 4,199·30dol.

The average number of passengers carried per car per annum propelled by electric power was 155,570.

The average carried per car per annum for corresponding time by horse-power was 75,718 passengers, an excess of passengers per annum in favour of electric power of 79,852.

The average gross earnings per car per annum, with cars propelled by electric power, was 7,778·52dol.; the average gross earnings per car per annum by horse-power was 3,785·91dol.; showing an excess of gross earnings per car per annum in favour of electric power of 3,892·61dol.

The average cost of horse-power per car per day is estimated at 6·50dol.; the average cost of electric power per day on this road is $1\frac{1}{2}$ tons of coal at 1·50dol., equals 2·25dol.; engineer, 2·00dol.; fireman 1·50dol.; oil and waste, 50 cents; interest on plant and repairs, 2·75dol.; making 9dol. per day. The power furnished at this cost is ample to run three motors and cars on this road, making electric power per day 4·00dol. Under more favourable conditions, such as cheaper fuel or water, power to drive the dynamos, and more favourable gradients and curves, the cost of electric power per car per day would be proportionately reduced.

BEE-FLOWERS.*

It is interesting to me to have confirmation of my experience of the value of Erica carnea as a bee-flower. Growing this beautiful vernal heath extensively for decorative purposes, I have observed for many years past that bees frequent it as soon as its blossoms open; but this does not take place in the North Midlands until March or April, unless, indeed, the season be abnormally early. It is somewhat presumptuous to dispute the accuracy of an observer of such eminence as Müller, whose observations in Switzerland led him to the conclusion that bees would not reach the malodorous secretions of Erica carnea, knowing the quick perception of the honey-bee in regard to honey-yielding flowers. I have concluded that either Müller must be mistaken, or that there exist varieties of E. carnea functionally different to the kind we cultivate, or bees that labour under a like disadvantage. I have gathered Erica carnea, or herbacea, in the mountains near the Lake of Thun, and comparing specimens of our cultivated kinds, I cannot distinguish any difference. Your correspondent, "Contingensis," writing from the South of Ireland, enjoys climatic advantages that do not reach England, and his teaching has rather a local than a general significance and application. Except in nursery gardens, Erica carnea is not to be found anywhere about Matlock. It is not native there. Bees are not invariably attracted by sweet-scented flowers. Daphne mezereum has both colour and fragrance, but it is not the most tempting flower to bees, and it is shy of removal and of difficult culture, and would be too expensive to an amateur bee-keeper whose indulgence in an apiary happened to be directed by considerations of ultimate profit. Too great a variety of bee flowers is not desirable, but a regular succession is eminently so, from spring until autumn.

Winter aconite (Eranthis hyemalis) is mainly visited by bees in early spring, as are crocuses, Scilla sibirica, Arabis albida, Aubrietia græca, and wallflowers, all easily grown and hardy plants. Then a great breadth of Limnanthes douglasii should be provided. The blossom of gooseberries, currants, and raspberries, though unattractive as regards colour, divert the attention of bees from all the brighter flowers about. Oddly enough, two apparently tempting flowers—sweet alyssum and seakale—are passed over unvisited by bees.

Nearly all the Borageworts are useful bee-flowers. Marjoram, thyme, and horehound are invaluable in their season, and I can indorse the recommendation of your correspondent in regard to Melilotus officinalis and alba—it is the blossom and not the seed that has the fragrance he describes. It is a late summer blooming plant, and a biennial,

* By W. INGRAM, Belvoir, in *Gardeners' Chronicle*.

and growing very tall, requires ample space. It is a great honey plant.

While on the subject of bee-flowers let me remark, in reference to the recommendation of R. Veitch and Son of Impatiens glandulifera, that my experience as to the value of this plant as a bee-flower is totally at variance with theirs. It is a handsome, free-growing, and blooming plant; but honey-bees, when they have any other flower to pasture on, never approach it. It abounds in pollen, but even that does not tempt them. The larger humble-bees find something in it congenial to their tastes, and casual observers may have been led astray by the frequency of their visits to it. I have for several years past advocated that the cultivation of bee-flowers should be pursued coincidently with the extension of the bee-keeping industry. I practically and successfully proved it last season, both as to the quantity and quality of the honey.

ELECTRICAL WELDING.

AT a meeting of the Boston Society of Arts last month, Professor Elihu Thomson gave a practical demonstration of his method of electrical welding. We extract the following account of the experiments from the New York *Electrical Review*:—By the processes in common use it is difficult, if not impossible, in many cases to weld together different metals. Two pieces of the same kind of cast iron, zinc, tin, brass, and especially copper have not been easily welded. By means of electricity they may be easily united. Iron, steel, and platinum, which have been the metals hitherto most easily welded, are by the new process still more readily united. To attempt by the new process to weld unlike metals may fail on account of a great difference of their temperatures of softening, or of their specific electrical and heat-conducting capacities. The method is to forcibly press together the two pieces to be united while passing a large current. Uses: The joining into one continuous length of short pieces of copper and iron wire. In the factory of the Thomson-Houston Company wires are joined by this method for making joints in all copper and iron wire used. The largest copper rod yet welded is a little less than ½in. diameter, requiring about 20,000 ampères. The same current will weld iron 1in. diameter, the difference in the size of the two metals being due to the greater resistance and lesser conductivity of iron. Specimens of various sizes, shapes, and materials were here shown; cast iron, steel and cast iron in one piece; steel, brass, copper also in one piece; copper rod bent at joint after welding. Brazing can be done successfully by putting brass on a hot joint while current is passing. The smallest wires yet united by welding by this process have been $\frac{1}{30}$in. diameter. Less fuel is required by the electric method of welding on account of the small time required for the operation and the application of the heat locally, and the small losses from radiation and conduction. The time required being so short, more joints may be made in the same time by comparatively unskilled labour. In arc-light circuits a current of 10 ampères, with an electrical pressure of 2,500 volts, is not infrequently employed. In incandescent lighting a current of 250 ampères, at an electrical pressure or electromotive force of 100 volts, would represent the same amount of electrical energy. In welding wire enormous currents are employed. Fifty thousand ampères, at an electrical pressure of ½ volt, would represent exactly the same amount of electrical energy. This amount of current would probably weld steel 1½in. in diameter in less than two minutes. Electric lights demand a continuous application of power, while the welding, for instance, of a 1½in. piece of steel would require 35 H.P. for only one minute, the same power being required continuously to operate 40 to 45 arc lights. The means for obtaining sufficiently large currents are two—storage batteries and alternate current machines connected with transformers.

A secondary or storage battery of very large surface, and consequently of low resistance, is put in an arc-light circuit and charged from the terminals of the cells; large-sized conductors connected with such binding posts as are shown in Figs. 1 and 2. The battery gives out its heat so fast that most of the energy is developed in the external circuit or at the point to be welded. The battery, however, is not portable; the liquids are easily spilled, a long time is required for charging, and it is not so manageable as the induction coil or transformer. The coil, Fig. 1, is composed of a bundle of fine iron wires L L, around which are wound a number of layers of comparatively fine wire connected by the terminals A A to a source of alternating currents, a dynamo in this case giving 50 to 100 alternations per second. The length of the iron core is 12in., the diameter about 1½in. The secondary coil S S represented in the diagrams as composed of 5 turns of large copper was in the smaller instrument shown composed of 64 No. 10 Brown and Sharpe's gauge copper wires wound in parallel eight times around the primary. The ends were bolted to copper plates upon which the clamps are placed, one of which slides by an adjustable spring shown at the bottom of the diagram. By means of a cam the clamps may be separated to any extent. It takes only a few seconds to place the pieces of metal to be welded in the clamps. The iron core on which the primary circuit is wound direct may be pulled in and out. The power of the currents induced in the secondary coil is thus varied and adapted to any sized piece of forging. The resistance of the secondary coil is ·00015 ohms.

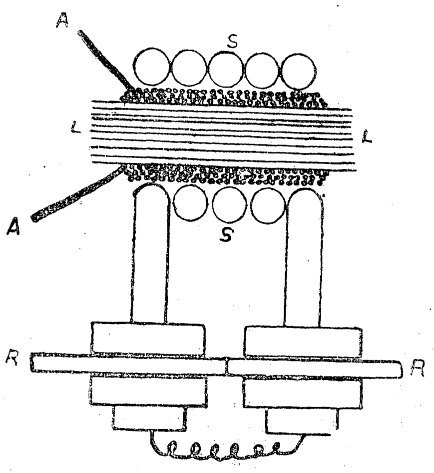

Fig I

In the transformer or induction coil, illustrated in Fig. 2, the primary coil P P is a ring 12in. in diameter, 2½in. wide, and ¾in. thick of many turns of insulated copper wire. The ends A A of this coil are connected with the alternating dynamo, and alternating currents thus pass through the wire of the primary coil. The secondary coil is a single heavy bar of copper bent to make one turn outside of the primary coil. The secondary is represented by the heavy black ring, the terminals of which S S are bent out to a parallel position and connected to massive screw clamps, M M. The secondary coil is shaped like a Jew's-harp. The parallel portions of this midway between S and M are made so that the clamp terminal M at the right may be moved. The screw C is used to force the terminals apart, the bars to be welded R R are clamped in position, the clamp C is unscrewed, and

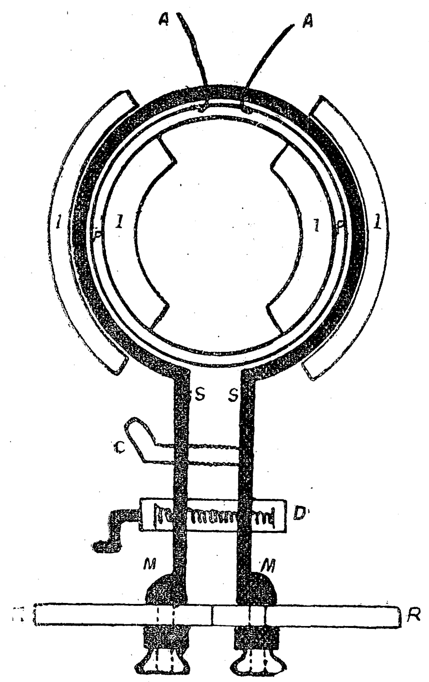

Fig II

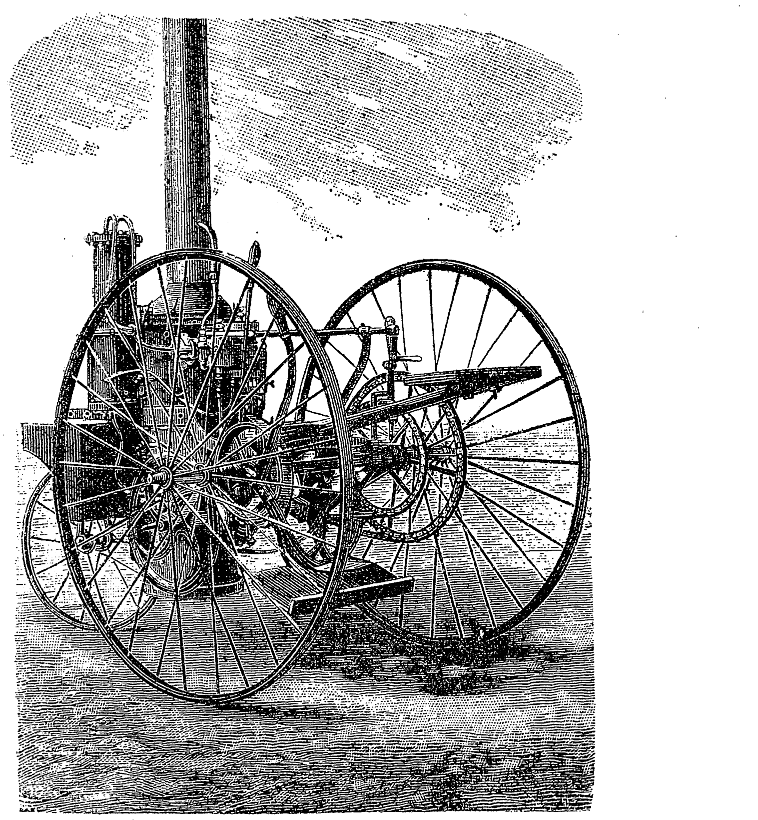
the tension of the spring D is adjusted by the screw attached to it. The pressure of the spring gives good contact of the bars R R. The primary and secondary coils are now wound around with an endless coil of iron wire I I I I. The iron wire does not touch the primary or secondary coils, but is wound on a sheet-iron casing, the secondary coil thereby being free. The resistance of the secondary coil is ·00003, and under the influence of a good primary current gives an electromotive force of two volts; less, however, is used in most cases. There is a small percentage of loss in the transformation, a current of 20 ampères and 600 volts in the primary circuit gives in the secondary circuit nearly 1 volt and 12,000 ampères. To generate the alternating current an inexpensive dynamo is used weighing 500lb., absorbing 25 H.P. at 1,800 revolutions per minute. There are 10lb. of copper wire on the armature, and 40lb. on the field magnets. The large output from so small a machine without destruction comes from the fact that the machine gives current only for short intervals. There are suitable switches to stop the flow of current when the weld is complete. The primary circuit may be cut or the resistance in the circuit of the field magnets of the dynamo may be varied, a method employed in the present case. To prevent overheating the primary coil of the machine illustrated in Fig. 1 may be pulled out to any extent, or resistance may be added to the primary circuit or the strength of the field magnets of the dynamo varied as described above.

The ends of the pieces to be welded are brightened, and are allowed to project a little beyond the clamps, when in position. A flux of some kind is then put on the joint—powdered borax for metals that have a high melting point; chloride of zinc, resin, or tallow for lead, zinc, and metals which have a low melting point. The current is now turned on, the ends of the rod become red, then white hot, and at the point of fusion soften; the tension of the spring causes the joint to become upset or thickened. The current is shut off, the clamps unloosened, and the bar, with the weld still red hot, may be removed. Of course, many metals do not require even a red heat for fusion. In uniting a large to a small piece, the end of the large piece is first turned down to the size of the smaller. Sometimes the joints are hammered while in the clamps. It is probable that the result is caused by heat alone, though some electrical action may play a part. One circumstance tends to produce uniform heating of the abutting bars. Suppose one part of the surfaces is in much better contact than the rest. The larger part of the current will therefore flow in the path of least resistance. This part becomes hot, its resistance increases in consequence, and the current is to a large degree diverted to the colder portions of the joint, until the whole of the abutting surfaces are equally heated. Two pieces of iron wire about $\frac{1}{16}$in. diameter were welded with the smaller induction coil. The pieces in position, Professor Thomson stood watching the machine one hand on the rheostat. The audience sat breathless. A movement of the switch, and in less than three seconds the junction of the pieces of wire was white hot, and the weld complete. There is more difficulty with the manipulation of brass on account of the oxidation of the zinc contained in it. Twice from a too sudden increase of the current there was a snap, and liquid metal was thrown out from the joint. Connections were then made with the larger apparatus, of which Fig. 2 is a horizontal section. Mild steel rods ½in. diameter were united, borax being used as flux and placed on the rods after they were placed in position. The joint during the passage of the current was very bright. In operating on some brass, the belt transmitting the power slipped. While the metals were cold, the resistance of the junction of the two pieces was low; when, however, the temperature rose the resistance increased, less current flowed, and the dynamo speeded, as the belt did not then slip, and an excess of current was caused. Notwithstanding this difficulty, the union of the brass was successfully accomplished. Copper ⅜in. diameter was next united. A copper rod $\frac{5}{16}$in. diameter and about 10in. long was bent into a circular form and clamped. To show the power of the apparatus, the current was turned on, and the copper maintained at a red heat. It could have been easily melted, as the limit of power of the apparatus was not approached.

STEAM TRICYCLE WITH PETROLEUM FURNACE.

A BRIEF description of a steam tricycle is given in *La Nature*, and may be of interest to some of our readers, though the use of motive power other than that obtained from human muscles seems to rob the tricycle of its raison-d'être.

M. Louis Lallemand, a skilful mechanic of Vassy, has just constructed a steam tricycle, to be heated by petroleum, and as the question of terrestrial mechanical locomotion is one that interests a large number of readers, we shall describe the apparatus. The length of the tricycle, as well as its extreme width, is 3½ft. The boiler is of welded iron plate. Its height is 2ft., its external diameter is 12in., and its total capacity is about four gallons. It is provided with 30 brass tubes, and serves as a frame for the engine, the cylinder of which is 2⅜in. in diameter, with a stroke of 4¼in. In the centre of the boiler there is a copper cylinder, forming a



steam-dome. The pressure gauge is placed to the left of the cylinder, under the eye of the driver, and the feed pump is to the right. The escape pipe enters the smoke stack and quickens the draught. The throttle valve is within reach of the left hand, as is also the lever of a Prony brake fixed upon the axle. Another hand lever, fixed to the foot-rest, is designed to serve as a bearing-point. The driver's right hand rests upon the steering winch, and has within its reach a lever for changing the velocity, that permits of throwing either of the two driving pulleys into gear. These latter are are driven by the shaft of the engine through the intermedium of pitch chains. The two large wheels are 3½ft. in diameter, and the small one 1¾ft. They are provided with a rubber tire, in order to prevent noise. The water-tank, which has a capacity of about 7½gals., is situated in front of the generator, and partially covers the front wheel. The petroleum reservoir, which holds 2¼gals., is situated over the tank. The firebox, which is of peculiar and very simple structure, is suspended from the generator, and always keeps a horizal position, whatever be the slope of the road. The petroleum enters the firebox through a flexible tube, and the fire is regulated at will through the intermedium of a distributing cock within reach of the driver. The total weight of the apparatus, empty, is 500 pounds. The consumption is about three and a quarter gallons of water and three and a half pints of petroleum per hour. It takes about ten or twelve minntes to get up a pressure. Upon a good road a speed of from seven to nine miles per hour may be obtained. M. Lallemand has already made four trials of this tricycle, each of which lasted twelve minutes. The distance run over in each of these was about two miles, and the gradients ascended never exceeded 3in. to the foot. On a level road, a pressure of two atmospheres suffices to run the apparatus at a speed of from 3½ to 4½ miles per hour. The constructor has not as yet been able to perform more prolonged experiments, as up to the present he has not obtained permission to run his apparatus in the streets. According to him, the use of petroleum is very advantageous as regards the regulation of the production of steam and as regards the quickness with which a pressure may be obtained; but in France this product is still too dear to prove economical.

NEW USE FOR THE RADIOMETER.

AT a recent meeting of the Société Technique de l'Industrie du Gaz en France, M. Frère, Manager of the St. Quentin Gasworks, brought forward a proposition for employing the radiometer in gasworks to indicate the time for putting on the night pressure. He said he had himself used the instrument in this way for some months, and had found it act satisfactorily. It was constructed in the usual way—viz., a glass globe in which four vanes, black on one side and white on the other, revolved almost *in vacuo;* the motive power being furnished by the increased pressure imparted to the air on coming in contact with the hottest part of the apparatus—that is to say, the blackened sides of the vanes. It is well known that as long as there is sufficient light the vanes will turn; but when the luminous rays become feeble, the rotary movement ceases. If the radiometer is exposed to the setting sun, the vanes stop, in very clear weather, about 20 minutes after sunset; and in very dull weather sometimes 30 minutes before sunset. In applying the peculiar property of this instrument to the practical purposes of a gasworks, M. Frère recommended that the workman in charge of the governors should begin to put on the pressure five minutes after the stoppage of the vanes; and if this were done, the consumers would, he said, have a proper supply of gas at the moment they require it. By taking note each day of the exact time at which the radiometer ceased turning, the average time for lighting up could be determined at the close of the month. M. Frère thought that, without putting forward the indications of the radiometer as absolutely reliable, it would be possible to make good use of the monthly averages. These, compared one year with another, and with corresponding months, would enable gas managers, in certain cases, to give the consumers a reasonable explanation of any excess of consumption which might be the subject of complaint.

AN official compilation shows that the average age of the members of the Society of Friends who have died during the denominational year just completed was 58½ years, an average age much in excess of that amongst the general population.

FRENCH official statistics relative to sugar show that during the eleven months of 1886 which ended on November 30 last there was a diminution of 46,146 tons in the importation into France of foreign Colonial sugar. As to foreign beetroot sugar only 288 tons were imported, as against 48,450 tons in 1885. On the other hand, the exportation from France of home-made sugar increased from 2,672 tons in 1885 to 18,687 tons in the eleven months of 1886. The exportation of refined sugar also rose from 65,487 tons in 1885, to 100,087 tons.

THE *American Inventor*, of Cincinnati, a monthly journal, says:—"We print this month's issue for the first time by means of electricity. We are running four presses with a single motor, and it is quite a novelty in action. The motor is built in a very substantial manner, and there are no parts that wear rapidly even with ordinary care. The expense for repairs cannot amount to 10 per cent. of that required for either steam, gas, or hot-air engines, and we now see no reason why it will not give, for many years to come, as good results as at present."

SCIENTIFIC NEWS.

DURING the present year there will be an annular and a total eclipse of the sun, and a partial eclipse of the moon. The total eclipse will take place on August 19, the line of centrality passing over the southern part of Russia, part of Chinese Tartary, and the principal island of Japan. The sun will rise partly eclipsed at Greenwich at 4.53. The annular eclipse on Feb. 22 will be visible only in the Southern Pacific. A partial eclipse of the moon on Feb. 8 will be invisible at Greenwich; but the similar phenomenon of Aug. 3 will take place from 7.36 to 10 o'clock p.m., and the eclipse will amount to 0·42 of the moon's diameter at 8.49.

It appears from the calculations of Dr. H Oppenheim of Berlin, and Dr. J. Holetschek, of Vienna, that Finlay's Comet (*e* 1886) is identical with De Vico's periodical comet, probably with the elements altered by perturbation. It is still twice as bright as at time of discovery, and will probably be visible with a telescope until the end of February. It is in the constellation Pisces, and its position for Jan. 8, Berlin midnight, is, according to Dr. Holetschek, R.A. 0h. 28m. 10s., N. Dec. 3° 45′.

Barnard's comet is still visible to the naked eye; but is becoming rapidly fainter, and on Jan. 10 will probably require a telescope for most observers. Its position on that date is at Berlin midnight R.A. 20h. 11m. 46s., S. Dec. 1° 20·1′.

Another minor planet (No. 264) was discovered on the 22nd ult. by Prof. Peters, of Clinton, New York State. It is the eleventh discovered in 1886. No. 261, discovered by Prof. Peters on Oct. 31, has been named Prymno.

By a strange error of the telegraph, the death of Prof. Theodor von Oppolzer, of Vienna, in his 46th year, was announced as that of Prof. T. von Bamberger.

The death is announced of Mr. H. M. Jenkins, secretary of the Royal Agricultural Society, and formerly editor of the *Journal* of the Geological Society. Mr. Jenkins was a member of the Technical Instruction Commission, and prepared an elaborate report on agricultural education in the United Kingdom and the Continent.

Mr. Thomas Moore, F.L.S., who for 38 years had been curator of the botanic garden belonging to the Society of Apothecaries, which adjoins Chelsea Hospital, died suddenly on New Year's Day at the age of 65. Mr. Moore was co-editor with Lindley of the "Treasury of Botany," and author of "Index Filicum."

The death is also announced of Mr. John B. Root, inventor of the water-tube boiler which bears his name, and of spiral riveted piping and machinery for making it. Mr. Root, who was fifty-seven years of age, had taken out more than seventy patents.

The Association for the Improvement of Geometrical Teaching have arranged, by permission of the authorities of University College, Gower-street, to hold their annual meeting in the College on Friday, Jan. 14th, at 11.30 a m. The afternoon sitting, the President, Mr. R. B. Hayward, in the chair, will commence at 2 p.m., when the following papers are to be read:—"The Teaching of Modern Geometry," by the Rev. G. Richardson; "The Modern Treatment of Maxima and Minima," by the Rev. J. J. Milne; and "Geometry from an Artist's Point of View," by Mr. G. A. Storey, A.R.A. All persons interested in the objects of the association are invited to be present at both meetings. The association have issued during the year "The Elements of Plane Geometry," Part II. (corresponding to Euclid, Books III.-VI.), and a "Syllabus of Elemetary Geometrical Conics" (both published by Messrs. Swan Sonnenschein), and have sent out to members an abstract draft of a syllabus of elementary solid geometry. Syllabuses of arithmetic and of elementary mechanics are in a forward state of preparation.

The snowstorms have produced the usual number of suggestions for the rapid removal of the snow from the streets, the most feasible of which is the use of salt, followed by prompt

washing down the sewers, as is done in Paris. The mixture of salt with snow produces a freezing mixture which has a temperature of about zero, or below, according to the proportions, and if allowed to remain on the surface it does injury to the public health, and also to the roads and the pipes beneath, when allowed to soak in. One writer, a "surveyor," proposes to melt the snow by means of batteries and coils placed in gully holes. When the batteries are not required to make the snow melt "rapidly" they may be kept in subways beneath pavements, and there provide a "substitute for gas" for adjacent dwellings!

The number of applications for patents during 1886 was 17,162, slightly more than in any preceding year. In 1884 the number was 17,110, and in 1885, 16,101. The departmental committee appointed to inquire into the working of the Act, and to suggest reforms, should hurry on their report.

The town council of Bombay has unanimously resolved that the municipality must bear its share, with the Government and other public bodies, in the expenses of the establishment of a technical school, and a sum of 5,000 rupees was voted for the purpose at a late meeting. The scheme is one drawn up by Dr. Cooke, Principal of the Poona College of Science, and explained by him to the Council. The skilled artisans, he said, turned out by the school would be a benefit to the country and to the municipality alike.

The wires of an electric arc lamp outside a shop in Holborn fired the other day, and being covered with some inflammable material, flames of about a foot long were produced and maintained for some minutes. Probably the use of inflammable material was considered permissible as the wires were in the open air.

The Consett Iron Company are extending their steel works, and three of the new and large boilers are to be heated by gas.

At a recent meeting of the French Académie des Inscriptions, M. Berthelot read a paper on "Certain Metals and Minerals used in Ancient Assyria and Chaldea." By the help of chemical analysis he had investigated the substance of several objects from Assyria and Chaldæa with interesting results. A sacred tablet from Khorsabad was found to be entirely composed of pure carbonate of soda—a rare substance even at the present day. Among the objects brought back by Mr. Sarzec from his excavations at Tello are two remarkable examples of the employment of metals without alloy. One is a vase of pure antimony; the other is a statuette of copper without any trace of tin.

A correspondent writes from Venice to the *Frankfurter Zeitung*, that one or two days before Christmas a singular phenomenon was seen at Savile, near Udine, which recalls accounts of the mirage sometimes presented near Messina. The sky was partially covered by clouds, in which the surface of a calm sea was discerned, with boats passing over it, and even a steamer cutting its way. Presently houses came in view, then large beautiful buildings, palaces, and churches, and, as the features became more defined, the cathedral of St. Mark, with the Piazza and tower were plainly presented, and the neighbouring canals. The spectacle faded gradually away, having made a great impression on all who saw it.

The New German Rifle.—The new rifle, which bears the title "M." (*i.e.*, Mauser), "71, 84," in token that the old model 71 has been adhered to in principle, with some modifications of it made in 1884, is described as being 1·3 mètre long without, or 1·8 mètre with, the bayonet, and weighs 4·6 kilogrammes with empty magazine or 5 kilogrammes when the magazine contains its full store of eight cartridges. These are cased with brass, each being 78 millimètres long, and weighing 43 grammes. The powder charge consists of 5 grammes of new rifle powder—"M. 71." The weapon, of which the barrel is of rifled steel, coloured brown outside, to protect it against rust, can be sighted for a distance of from 200 to 1,000 mètres. It has a calibre of 11 millimètres. The rifle can be used either as a single shooter or repeater, and is fired in the usual way. It is also announced that velocipedes—both bicycles and tricycles—will soon be introduced into the German Army, chiefly for the use of orderlies in fortresses, and in the region of detached forts.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, *332, Strand, W.C.*

All Cheques and Post-office Orders to be made payable to J. PASSMORE EDWARDS.

**** In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects; For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks, a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

6 SERPENTIS AND OTHER PAIRS.

[26654.]—IN the ENGLISH MECHANIC for May 29th, 1885 (letter 24270, Vol. XLI.), I called attention to some twenty double stars, chiefly discoveries of Mr. Burnham's, and remarked that a careful examination of them at the present time would at once show whether they were physically related or only optically double. In the *Journal* of the Liverpool Astronomical Society for December last Mr. K. J. Tarrant gives the results of three nights' measures in 1885 of one of the pairs alluded to in my letter—viz., 6 Serpentis (β 32). The following are the principal measures of this beautiful object:—

De.	13·2°	2·28″	1875·41	(4 nights)
β.	13·6	2·37	1879·40	(2 nights)
Tarrant	14·0	2·27	1885·49	(3 nights)

The annual proper motion according to Auwers's Bradley (this I take from the recently published Pulkowa Catalogue of 3,542 stars, for a copy of which I am indebted to the great kindness of Director O. Von Struve) is − 0·0053sec. − 0·098″. If the small star was unconnected with 6 Serpentis, the angle at the date of Mr. Tarrant's measures should have been about 21·5°, and the distance 3·51″. Hence these two stars are animated by a common proper motion, and probably form a physical pair.

I trust that American observers will not neglect the fine pair Ceti 82 (β 395) mentioned in letter 24270. The place for 1885 is in 0h. 31m. 26s. − 25° 24·0′, and therefore it is almost too low for observers in this country. The star is visible to the naked eye, and has an annual proper motion of 1·355″ in the direction of 91·3°. In addition to the stars already mentioned in letter 24270, an examination of the pairs B.A.C. 920 (β 525), B.A.C. 1101 (β 533, cf. *Memoirs* R.A.S. XLVII. p. 231), 15 Hydræ (β 587), 52 Herculis (β 627), B.A.C. 6762 (β 658), and B.A.C. 708 (β 668), at the present time would tend to throw light on the physical relationship of their component stars. The beautiful, but rather unequalled and difficult, pair β 163 is evidently another physical object. The principal star is Lalande 41386, which according to Argelander, has a motion of + 0·0006sec. − 0·105″. The only measures of this pair I can lay my hands on at this moment are Dembowski's; but they are sufficient, though only extending over three years, to prove that this pair also is animated by a common proper motion. He gives—

252·2° : 1·18″ : 1874·549 (one night)
Mags. 7·5, 9·0 : aria velata.
250·6° : 1·18″ : 1875·548 (one night)
Mags. 7·0, 9·0 : meglio in distanza.
252·6° : 1·16″ : 1876·463 (one night)
Mags. 7·0, 9·0 : sufficiente.
253·7° : 1·10″ : 1877·819 (one night)
Mags. 7·0, 9·0 : la definizione varia.

If this pair was an optical one the angle would have increased to 267° at De's last epoch. The place of this pair for 1887·0 is 20h. 13m. 7·3s. + 11° 7′ 24″. It is about 15sec. preceding, and 22′ north of a small 6 mag. star.

Jan. 4. **H. Sadler.**

ASTRONOMY BY PHOTOGRAPHY.

[26655.]—BECAUSE the Brothers Henry and some other observers have succeeded in taking wonderful photographs of the starry vault, we are threatened with a revolution in our methods of studying astronomy, and the following, which appears in a Liverpool paper under the rather strange heading of "Science Notes," may be taken as a sample of the stuff that is to come:—"At the recent soirée of the learned societies of Liverpool, held in St. George's Hall, there were exhibited a number of stellar photographs which attracted the attention of nearly all present. This was due very largely, no doubt, to the remarks of the mayor and of Sir Robert Ball on their vast importance to the astronomical world. The photographs were not particularly interesting in themselves except to those who understood their deep significance, yet they were surrounded by a great crowd all the evening. They consisted of photographs about ten inches by ten, of stellar spaces, of little white dots, varied by misty dashes, on a brownish ground. These uninteresting-looking pictures relate to one of the most fascinating phases of scientific research. Over 2,000 years ago Ptolemy made a catalogue of the stars, marking them by numbers from one to six, according to their brilliancy. Number six was the smallest star visible to the naked eye, and that quaint old star chart is full of interest to the modern astronomer. From the days of Ptolemy to the times of Tycho Brahe, in the 16th century, astronomy was lost in the mists of the dark ages; but the patient labours of the poor Dane, and the invention of the telescope by Galileo, brought it once more to the front. Every year some new discovery has been made, or some larger or more perfect instrument added to the countless ones already turned skyward; but the application of photography to astronomy has revolutionised the science (!) The work of the Brothers Henry, of Paris, in photographing the stars, has been told all over the world, and the French savants are moving energetically to have photographic apparatus sent to Algiers and every favourable spot on earth. The idea of photographing the stars has a very definite purpose. We know that our world circles round the sun, and that the sun and its family of planets are moving round somewhere else; but what the solar motion really is is not so well known. If the star map of Ptolemy had been photographed, we could now have measured the solar movement which has taken place since that time; but, unfortunately, it was taken by hand in a crude way, and for exact measurement is of no value. The maps made by Herschel a century ago, and by Argelander, in Bonn, fifty years later, are of great use to modern workers, but are not of such an exact nature as science demands. The Brothers Henry took photographs of the sky with a view to determine, in a scientific and reliable way, where we are all going to. They have exhibited enlarged copies of their work, which have gone round the world. But they never show their negatives—that is, we only see their improved and corrected work; we never see the real picture."

Now we all know what "astronomy" means. It consists in taking photographs of the stars, and using them as evidence against the observations made at the eye-end of a telescope. **T. B. W.**

TEMPERATURE AND RAINFALL IN 1886.

[26656.]—

—	Mean temperature.	Deviations from averages (20 years ending 1880).	Rainfall in inches.	Deviations from averages (10 years, 1867—1876).	Number of rainy days.
January ...	34·1°	− 2·5°	3·28	+ ·36	24
February ...	33·4	− 5·7	·85	− 1·41	6
March	38·4	− 2·2	3·10	+ ·63	14
April.........	45·4	− 1·8	1·99	− ·02	17
May	51·1	− ·8	6·00	+ 3·73	19
June	56·1	− 2·3	1·15	− 1·13	11
July	61·2	− ·4	2·86	− ·02	18
August......	61·6	+ 1·1	1·36	− 1·18	10

December...	35·3	− 2·6	4·35	+ 1·14	18
Year	47·3	− ·9	32·83	+ ·90	185

It will be observed that the temperature was in general below the average, noticeably so in February—the coldest February, indeed, during the last 20 years. March, too, was colder than the average, the first fortnight with a mean temperature of 30·5°, or more than 6° below the average of January, being probably the coldest on record. The spring and summer months were not distinguished by anything particularly worthy of notice, with the exception, perhaps, of June, which was unusually cold. The first week in October was marked by a spell of almost sultry weather, the thermometer on the 5th rising to 75° with a mean temperature for the 24 hours of 65°, or considerably above the average of July.

The only remarkable feature in connection with the rainfall was the extraordinary record of 6in. for the month of May, which I believe is unprecedented in this neighbourhood. Of the total of 6in. no less than 3·49in. fell during the 48 hours ending 9 a.m., May 13th, 1·65in. being due to the 12th, and 1·84in. to the 13th. This also established a

"record" both for 24 and 48 hours, at least as far as this district is concerned. In conclusion, I may state that my thermometers are placed in a Stephenson screen 4ft. from the ground, and my rain gauge is at an elevation of 529ft. above sea-level. **B. A.**

Handsworth.

THE SNOWSTORM AND THE WIRES.

[26657.]—THE almost complete destruction of the telegraph system in the home counties on the 26th ultimo raises the question whether its risk might not be partially avoided by a different method of hanging the wires. Travelling in Western France last autumn, I noticed that the wires, instead of being hung on cross-pieces from the poles, had their insulators fixed directly to the poles by short metal brackets. I have never seen this method in use here. It seems to me that while a certain amount of carrying capacity per pole is lost by it, it is more than made up by the much less liability of the line being blown down by a solid mass of snow being formed in the wires: for the wires being formed almost perpendicular, must give hardly any lodgment to snow, which would be blown clean through them by the wind instead of settling on them as it does in the English horizontal system. It also appeared to me that the poles were considerably slenderer than English ones of equal capacity, owing to the less heavy nature of their superstructure. Perhaps a telegraph engineer will let us have his opinion on the subject.

January 3rd. **H. C. Sothern.**

SUGAR ANALYSIS.

[26658.]—ERRATA in letter 26633.—Paragraph 3, line 4: Instead of "To the clean filtrate add sodic sulphide so as to remove the whole of the lead in excess," read, To the clear filtrate add sodic sulphite, &c. **M. O. H.**

RAILWAY SPEEDS AND MYTHS—TIMING OF TRAINS—DEFECTIVE METHODS AND "PERSONAL EQUATION"—ECCENTRIC RESULTS.

[26659.]—AS there seems to be a revival of the public interest—seldom long dormant—in the splendid work now being done by our English express trains, I venture to offer a few hints on the subject with a view to securing the most useful results from the systematic timing of them which appears to be carried on regularly by many fellow correspondents and others. I need hardly say that I am in a position to speak somewhat as an expert, and I feel sure that some friendly hints will be acceptable.

In the first place, it is advisable to have a clear understanding as to the actual possibilities. Do not run away with the notion that speeds of 90, or even 80, miles an hour can be attained by any engines now in use. The former has never been done. The latter (80 miles an hour) was reached on a trial trip by one of the Bristol and Exeter double-bogie engines with 9ft. single driving-wheels, down 1 in 90 *with no load*. But with *one* carriage attached 78 miles an hour was the maximum that could be managed. The G. W. 8ft. engines, specially tried down 1 in 100, could not get beyond 78 miles an hour because of back pressure. No modern engines are adapted for beating these records, as weight-dragging has had to be considered as much as speed. Thus the G. N. 8ft. engines, which have the same cylinder-diameter (18in.) as the G. W., have 4in. longer piston stroke in order to draw heavier loads. This increases their pulling power, but also largely increases the piston velocity required to attain a given speed, consequently lessens the likelihood of their rivaling the G. W. engines in absolute maximum. The Caledonian 8ft. singles would be more likely to reach a higher maximum with light load, as they have only 24in. stroke; but then they have smaller cylinder diameter ($17\frac{1}{4}$in.) and boiler power. This applies also to the L. and N. W. "Cornwall," No. 173. No other engines running at the present time can be expected to achieve higher results, as it has been necessary to aim at weight-pulling power and the maintenance of a fast average up and down hill rather than at extreme rates with light loads or any loads. Hence it may be assumed at starting that speeds of 75 miles an hour, or a fraction over, are the quickest that will be found by *accurate* timing, and that even these will only be met with under very favourable conditions—i.e., moderate loads and falling gradients.

Secondly, it may safely be taken for granted that speeds much exceeding 60 miles an hour even with light trains are *never* attained on rising gradients, and rarely maintained even on the level. This could easily be demonstrated *à priori* on sound theoretical principles, but it is convincingly shown by practice. During my recent tests of every leading type of English express engine, extending over about twelve months, I found this to be an invariable rule. Even the slight ascent of 1 in 1,320 which prevails on the first 50 miles of the G. W. makes a wonderful difference to the engines as compared with the similarly slight descent going the other way. With the average number of carriages composing the two fast expresses (absurdly named the "Flying Dutchman" and "Zulu") the G. W. 8ft. "singles" have usually quite as much as they can do to pass Didcot (53 miles) in the 60 minutes allowed. I have known "Prometheus" in fine weather with six coaches (including five bogies)—equivalent to about 120 tons weight—run through Didcot in 57 minutes; but that was quite exceptional. On the other hand, "Tartar," with seven on (five bogies) and a head wind, lost six minutes to Didcot and eight to Swindon; and "Courier," in fine weather, but with eight on (seven bogies)—weighing about 165 tons—lost five minutes to Didcot and $7\frac{1}{2}$ to Swindon. It is very seldom that 60 miles an hour is steadily maintained, or at any point exceeded in the down run to Swindon, notwithstanding the fast timing. The quick time is made by the maintenance of a high average which is practicable owing to the easy character of the road. When time is exactly kept the distance of 66 miles from Ealing to Shrivenham is run in just 72 minutes, giving a travelling rate of exactly 55 miles an hour. There is a slight loss through the slack at Didcot, and this is made up by temporary acceleration on the short lengths of 1 in 1,320 down between Hayes and Slough, and between Twyford and Reading, also on the level near Moulsford. On those parts 60 miles an hour is sometimes reached, and occasionally 65.

In Vol. XXXIX., at p. 7, you quote an article from the *Engineer* in which this sentence occurs: "The Great Western broad gauge 'Flying Dutchman' and 'Zulu' express trains between London and Swindon run daily on portions of the journey —*where the line is perfectly level—at more than 80 miles an hour* for such short distances." Unless the "80" be a misprint for "60," this statement is wildly inaccurate. Such a performance with any engine now running or ever yet built is simply impossible, as repeated experiments have conclusively proved. As a matter of fact, the G. W. expresses attain a lower *maximum* speed between London and Swindon than any other expresses running out of London, excepting, perhaps, those on the L. and S. W., between Waterloo and Basingstoke. On all other lines higher speeds have to be run down hill to keep time after the loss in climbing to the summits. The G. N. after Potter's Bar, Knebworth, and Stoke Box; the L. and N. W. after Tring, and on the Northampton Loop; the Midland after Elstree, Leagrave, Sharnbrook Summit, and Desborough; the G. E. after Elsenham and Brentwood; the L. B. and S. C. after Merstham and Balcombe, all have to run at 65 or 70 miles an hour down hill to keep time, and even the S. E. and L. C. and D. driving have to exceed 60 at certain points. The G. W. run, where high speeds are really done, is not on the $53\frac{1}{4}$ mile an hour length from Paddington to Swindon, but on the following piece to Bath, which is only timed at 47 miles an hour. (It may be mentioned here that the 11.45 a.m. is not due at Bath till 2.0, and leaves at 2.3 instead of 1.58, as stated in "Bradshaw," the time of the up "Dutchman" at Bath being also given five minutes too early—viz., 12.23 instead of 12.28, the correct time.) Down the Wootton Basset Bank of 1 in 100 passing Dauntsey, and again down the similar incline through Box Tunnel, the trains almost daily run at 70 miles an hour, and often more. On the occasion above mentioned, when $7\frac{1}{2}$ or 8 minutes were lost to Swindon, 4 minutes were gained in each case between Swindon and Bath by running at over 70 miles an hour down the 1 in 100 banks. The up trains, on the other hand, from Swindon to London have a falling gradient nearly all that way, and so the up journey is very much faster. There is nothing to prevent its being run in 77 minutes with moderate loads, and it is usually done under time; but when the weight exceeds 140 tons, if the weather be at all adverse, time is apt to be lost. There is also an invariable reduction of speed up even the short bits of 1 in 1,320 after Reading and Slough. My experience, indeed, has been that the most powerful modern engines feel the slightest rising gradient as a severe check. Let them be running 70 miles an hour just before, directly they get on a rise, down goes the speed by degrees, first below 60 and then to 50, 40, or even lower if the ascent be at all sharp or the trains at all heavy. A speed of 61 miles an hour up 1 in 176 was recently quoted in these columns, but that arose from a pure misconception as to the gradient. The part where that speed was run was in reality 1 in 200 *down*. This, therefore, suggests also that those who time trains should make themselves acquainted with the sections of the line; else they are apt to mislead themselves and others.

But it may be asked, "How is it, then, that we see speeds of 80 miles an hour, or more, recorded in the public prints"? Simply through error or through exaggeration, possibly unintentional. A common mistake on the G. W. is made through the way the mileposts are marked, the number of the mile being repeated with each quarter (from London to Didcot) thus: "$\frac{30}{III}$" for $30\frac{3}{4}$. This has led many persons unaccustomed to the extreme quickness of sight needed for correct railway-timing to mistake three-quarters for a mile. Thus three-quarters (supposed to be a mile) done in 45 seconds would appear to be 80 miles an hour, instead of 60. It is within my personal knowledge that such a mistake has often arisen in this way. Another source of error is in the inaccurate statement of station-distances in time-tables. Of this there are abundant instances in these columns which I could quote if space permitted. A still more fertile source of error is mere looseness of recollection. We can all remember the fierce dispute in these pages about the alleged feat of a G. N. engine which was asserted to have run 12 miles (down the Stoke bank) in 8 minutes. I have no doubt whatever as to the origin of this error. It arose through the common disposition to underrate time and overrate distance in such cases. A friend of high scientific attainments and accuracy who was at a trial of the G. W. 8ft. engines in 1847, told me truly some years afterwards, when I was a boy intensely interested in railways, that the speed reached (down hill) was a mile in 48 seconds (i.e., 75 miles an hour). I noted this down at the time and kept the record. But some years afterward, as his memory of the fact became less distinct, he used to say it was "a mile in forty-odd seconds." Ultimately the fraction disappeared from his mind, and he asserted positively that the mile was run in "40 seconds," and did so in perfect honesty and good faith. I am convinced that in the G. N. case the distance was a small fraction over 11 miles, and the time a small fraction under 9 minutes; say, 11 miles 5 chains, in 8 minutes 55 seconds, a perfectly practicable feat. That would soon become "*over* 11 miles in 8 minutes and some seconds," and then "nearly 12 miles," and finally the fractions would be dropped, and we should get "12 miles in 8 minutes."

Other sensational records are pure exaggerations, though possibly unintentional. On p. 303, Vol. XXXIX., it was stated that an American engine on the Philadelphia and Reading line ran 2·8 miles in 2 minutes, equal 84 miles an hour. An expression of doubt as to this statement brought out Mr. Barnet Le Van (Vol. XXXIX., p. 516) in defence. But his own figures actually showed (apparently unnoticed by him) that the time was $2\frac{1}{2}$ minutes, which at once brought down the speed to 67·2 miles an hour! Another correspondent in these columns some years ago asserted that the L. and N. W. "Precedent" engine ran 80 miles an hour. But he, fortunately, gave us a test of his accuracy. He added that they weighed 53 tons, had 7ft. driving-wheels, and took the 8.15 a.m. down train. As they did not weigh 53 tons, but only 32 tons, 19 cwt., had not 7ft. wheels, but only 6ft. 6in., and as there was no 8.15 a.m. down train, we had little difficulty in appraising the value of that correspondent's "80 miles an hour." A writer in another scientific paper declared he had *driven* a L. and N. W. "Bloomer" ("Una") at 84 miles an hour, and even gave the timing to seconds. But he, too, gave his gauge. He went on to say that the load was 14 coaches of 14 tons each, and that the engine had 17in. cylinders with 24in. stroke. As those coaches weighed barely 12 tons each, while the cylinders are only 16in., and the stroke is but 22in., we could judge of *his* accuracy very easily. The same writer gave an equally mythical account of a run with the 7ft. 6in. Bloomer "Caithness." Yet one more illustration of the eccentricities of "personal equation." A writer asserted that in a "special" from Didcot to Swindon he had run the 24 miles in 17 minutes, or at 84 miles an hour, including starting and stopping, the distance being uphill all the way, at the rate of about 1 in 700. Evidently he must have miscalculated by at least 5 minutes, and possibly much more. But he gave his measure by also alleging that the G. W. engines have "8ft. 6in. drivers," and that they are timed to run the "Dutchman" to Swindon, 78 miles, in 80 minutes, the correct figures being respectively 8ft., $77\frac{1}{4}$ miles, and 87 minutes. It is by this slip-shod way of writing that we get all those fabulous speeds of 80, 90, or 100 miles an hour.

I fear I am trespassing grievously upon valuable space, and therefore will compress the remainder of my remarks. Let me caution all "timers" against trusting to memory. Nothing is more unreliable in such cases. I say unhesitatingly that timing is worthless unless written down when taken. It is also of comparatively little value unless taken with a chronograph or stop-watch. Few people are aware how difficult it is to catch the precise moment of passing a quarter-mile post at high speeds. The tendency is to be late in taking the first and too early with the second. People omit to take the time till the first is well past, and they take the second post directly it comes in sight. Also, they are apt, in the veritable hurry of the moment, to put down minutes wrongly. If a post is passed at, say, 24 minutes

58 seconds, the minute hand is in appearance over 25 minutes, not 24, and so it often happens that the record shows 25 minutes 58 seconds, thus losing a minute in the next length. When an interval of some miles occurs without a post being caught (as must frequently happen through stations, tunnels, or trains intercepting the view) this may be a fertile source of error. Timing through stations is, of course, not a trustworthy test of speed, unless the distances be exactly known; but still, the times should always be recorded, for it will often be possible to know the distance subsequently, and so a good run, whose record would otherwise be lost, might be recorded. It is well, for the same reason, to note times of passing particular tunnels, bridges, and other recognisable landmarks.

I hope these hints and remarks, which are based on large and special experience, may be found most useful and interesting to my fellow correspondents.

Wellington, N.Z. **Charles Rous-Marten.**

RAILWAY SPEED.

[26660.]—It is pleasing to see that Mr. C. R. Marten, p. 393, throws cold water on 90 miles an hour. It is all moonshine. A 9ft. wheel on Bristol and Exeter may have run just 80 miles an hour, but no other broad-gauge engine ever has, and certainly no narrow gauge one ever has.

Time what trains you like, and where you like, and you will not find a higher speed than 75, and seldom more than 72 miles an hour, and plenty fast enough, too, is the opinion of

Practical Man.

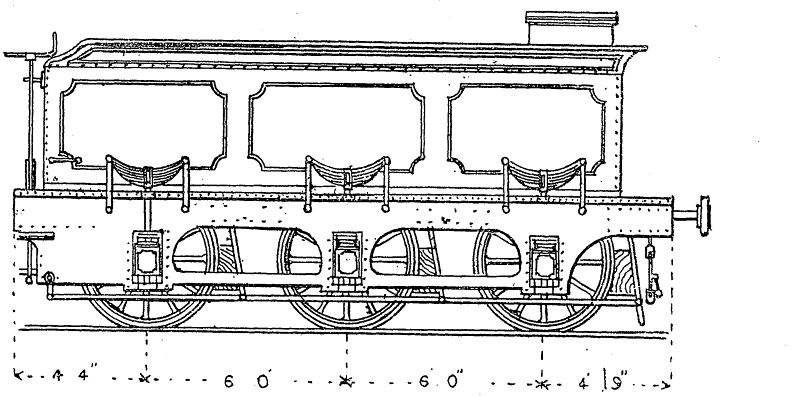
LONG RUNS ON RAILWAYS.

[26661.]—In *Whitaker's Almanack*, 1887, it is stated that a train runs 165 miles, from Dublin to Cork, without a stop; and Edinburgh to Newcastle —124 miles. Would some of our readers say if they have ever travelled in those trains, and if they *do* perform these runs?

Practical Man.

PASSENGER TRAINS AND PARTING COUPLINGS.

[26662.]—The use of some means of apprising drivers of the fact that they have lost part of their load is so important that it does not matter how it is accomplished provided it is accomplished effectually. I can think of no more effective means than an arrangement which would cause the engine whistle to sound, for that would effectually call the driver's attention. Any arrangement must depend upon human intelligence to a certain extent, and Mr. Rogers's objections 2, 3, and 4 would probably hold good; but they refer to details which are quite minor compared to the object of calling the driver's attention promptly to the fact that he has lost part of his load. Mr. Stretton says that an electrical contrivance to warn a driver when his train has parted is of no practical use, and he considers that an efficient automatic continuous brake is wanted to bring each portion of the train to rest. If that contrivance would give prompt warning to the driver, it would undoubtedly be best in the majority of cases; but at what period in the 20th century does Mr. Stretton think it likely that railway companies will fit goods trains with automatic brakes? The letter of "W. F." (p. 392) is a curiosity. Addressed to one of the daily newspapers it might pass; but in the "E. M."! Surely, "W. F." need not tell us that waggons which have broken loose on an up-gradient will run back; and as surely he might have remembered that the driver has a whistle on his engine, by means of which he can "alarm" any signalman within hearing distance, and cause him to promptly block his section. A smart driver would use his whistle directly he found his train had parted. Let us examine the subject. F. and K. are two stations nearly a mile apart; the line dips so as to form a sort of V, with a signal-box at the dip. A train of goods waggons leaves F. to proceed to K, and with the usual snap or jolt at starting a coupling nearly breaks; but a sufficient tug has been imparted to the train to cause the whole of it to follow the engine down the incline, and sufficient momentum is gathered to carry the whole train past the signal-box in the dip. The signalman accordingly gives "line clear," and the signals at F. are set for another train to follow. In climbing the other bank, however, the racked coupling parts, and the hinder portion of the goods train runs back, and if a train with insufficient brake power has been permitted to follow, it will in all probability run into the detached portion of the goods, and no one is to blame—except the companies which allow goods trains to be run without providing some means of acquainting drivers with the fact that they have lost a part of their trains. If the driver of our imaginary goods train had been made acquainted with the true state of matters, he could have sounded his whistle, and attracted the attention of the signalman, who would have promptly blocked the line. Your correspondent "W. F.," does not seem to be aware of the *fact* that in the smash referred to an up train was prevented from running into the débris simply because the driver of the down train which ran into the goods sounded the alarm on his whistle. If the driver of the goods had had prompt intimation of the break in his train, his "alarm" whistle would in all probability have prevented the disaster. **Nun. Dor.**



EXPRESS TRAINS.

[26663.]—I have lately been travelling on the principal English railways, and I now send a copy of my journeys on the Midland Railway. I send the best and the worst run I have had on that line, and I will do the same for my runs on the G. W.R., G.N.R., L. and N.W.R., L. and S.W.R., and G.E.R.

Trusting that you can find space for them, I will send the runs on one railway each week until they are finished, with the Editor's kind permission.

MIDLAND RAILWAY.

Kentish Town to Kettering, 3 p.m. ex St. Pancras. The best run. Oct. 25, 1886.

Miles.	Stations.	Booked Time.	Actual Time.	Speed.

5¼	Kentish Town...	2.52	3 0 0	45

REMARKS.—(A) Usual slack through Bedford. (B) Stopped by signals outside Luton for 4 minutes.

Load, 11. Loco 896. Chief dimensions of loco:—Cylinders, 17 by 24; coupled wheels, 6ft. 8in. Heating surface, 1,112 sq. ft. Consumption of coal per mile, 28lb. **French Loco.**

MIDLAND ENGINES, 800 CLASS.

[26664.]—I now send diagram of Midland tender (No. 804), which was drawn at the same time as the engine illustrated on p. 370. The tender ran on six wheels 4ft. 1½in. diameter, and carried 2,000 gallons of water and 3½ tons of coal. Length of tender-frame, 21ft. 1in.; distance between engine and tender at sides, 6¼in.; from centre of trailing wheel of engine to first wheel of tender, 9ft.; total length of engine and tender over frames, 47ft. 2in.; total wheel base of engine and tender, 37ft. 6in. The total weight given, p. 370, 60 tons 14 cwt., is in average working order.

Clement E. Stretton.

Consulting Engineer Amalgamated Society of Railway Servants.

Leicester, 24th December, 1886.

NEW MIDLAND ENGINES

[26665.]—Yes, the new 1667 engines have just been in shops; 1669 has a new boiler, and is doing fine work with the Scotch trains from London now. This shows that all the fault has been in the small boilers. **Loco.**

DOUBLE-ENGINE RUNNING ON THE MIDLAND.

[26666.]—In your journal of Nov. 26th, p. 286, there was a letter by Mr. C. E. Stretton about the long empty trains on the Midland. That, I hear, has made no small stir at Derby; anyway, stir or no stir, it has soon had a good effect. The trains have just been reduced in weight; the empty stock taken off; with the result that one engine can now work its train and save coal, and do it without a pilot engine. Why was this not done months ago? They say attention was not called to it. Then, sir, I say some officials must go about with their eyes shut. Everybody might have seen two engines and a lot of empty carriages day after day, week after week, and month after month. The letter in question in your columns seems to have got before the directors' meeting, and resulted in a resolution to cut down the useless weight. On Monday, 20th ult., the directors' order came into play on the Scotch expresses; the empty Pullman car to and from Edinburgh was taken right out of the train, and two short eight-wheeled bogie coaches took the place of two 60ft. twelve-wheelers —total reduction of train, 30 tons dead weight. Well done, directors, say I. Better late than never; but better if it had been done last September. I hear the Great Northern is to be the first to consider the idea of third-class dining and sleeping carriages. I wish our Midland had been the first, because there is a grand future for this sort of traffic—at least, that is my opinion.

Leeds. **M.R. Shareholder.**

RANGE OF BAROMETER.

[26667.]—I am obliged to I. W. Ward, letter 26653, for his communication. It will be cut out of the "E.M." and put in my notebook. But then, alas, the inmates of a hospital will suffer, because my "read" copies go to a hospital. I know also that a reading-room in a Yorkshire village to which I send the "E.M," (Ours) wouldn't like a mutilated copy.

May I make two suggestions suitable for this period of the year? Let some subscribers club together copies of "Ours" to, say, St. Bartholomew's, Guy's, St. Thomas's, Royal Free, King's College, University of London, Charing Cross, and, say, three or five other hospitals, and let the poor inmates whilst suffering have something worth reading.

I know that I often get rid of weariness or of a headache by reading "Ours," though *sometimes* reading "Ours" gives a headache if subject is too abstruse; or another ache if questions or answers are too absurd. If any of my questions or answers have caused this ill effect, pray let me apologise.

But to return, 2d. a week for 52 weeks is 8s. 8d., and 12 times 8s. 8d. is £5 4s. If approved, put me down 17s. 4d., and ask for cash down. If 15 copies, put me down £1.

(2) Having cared for others and for you (!), Mr. Editor, now one word for myself and the other subscribers to "Ours." I think it would be acceptable if we had a weekly barometer record, to be placed in the same position each week in each issue—say, just before "Letters to the Editor."

and the weekly lecture as to our good manners (!), followed by memoranda of any special rise or fall outside London. This would be a lasting record. I long to see this enduring record, which a newspaper record may be but is not, for the multitude who cannot keep files of newspapers.

A. P. Bower
(A now very old subscriber and well-wisher, constant reader, and constant spoiler of the columns by Queries and Replies).

HORIZONTAL WIND-POWER.

[26668.]—IF I have mistaken Mr. Philip Vallance's definitions, 26632, p. 389, I am afraid I must put some of the blame on him. When we are told that "the sails are made of half a 14ft. deal cut diagonally," &c., we naturally understand that the sails are 7ft. high, or long. But it appears that they were to be really made of a whole 14ft. deal cut diagonally, &c., though the first idea was not disturbed by the context. And when we learnt further on, from Mr. Collingridge, that sails of 7ft. height on arms of only 8ft. length would yield, on Mr. Vallance's principle, a power of four horses, it seemed quite consistent with the greater power claimed by Mr. Vallance for his 14ft. arm, and proportionately greater spread of sail, without going any higher. Such a height as 14ft. never entered my head; and if it be necessary to have so much lumber on a series of arms near the top of a lofty pole in order to obtain a working power horizontally, I do not see what advantage over the old vertical mill is to be obtained by it.

Mr. Vallance, I presume, is aware that it takes a broad sail to exercise any appreciable power ahead at sea when lying within six points of the wind; and that a plank 9in. wide should do so with a weather edge 2½in. thick, may pass with the marines; but the sailors would never believe it. This would render the sails worse than useless for six points on each side of that which brings them dead against the wind, or more than ⅓ of the circle. Also, though it is only at one point that the thick edges of the sails are driven against the wind, yet as they all on the same arm are in the same position, the five, instead of 2½ft., must together present a resistance of 12½ square feet, and this incessantly. For if the machine were making only six revolutions a minute, the interval would be less than a second of time between each of the arms taking the place of its precursor. The thickness of the arms also would offer some square feet of resistance in addition, which makes it all the more wonderful that Mr. Vallance achieved so much success with it: Against all these difficulties he assures us that the story of the seven ploughs is true. But I cannot help regretting that he has to go 40 years back for his witnesses. I was in hopes we, of this age, might ourselves bear testimony to its extraordinary powers, whatever they be; but the question, "Where is it to be seen at work?" remains unanswered.

Mr. Vallance says "the weight is no objection." To my mind it is the greatest barrier of all. Who, for instance, would sleep easy in his bed with such a machine swaying away over his house-top, or even near his dwelling, in gales far short of those that tear down telegraph poles and uproot oaks?

The chief recommendation of a horizontal wind engine is that it can be erected anywhere, provided it is carried above immediately surrounding trees, or builings, and where it is open to a free current of wind from all quarters. It is therefore difficult to understand Mr. Collingridge's excuse for not increasing the power of his windmill. The works below would occupy much less room than a steam-engine with boiler and cylinders, and above, space for enlargement is unlimited, if there were no objection from neighbours on account of its weight and unwieldiness, and the danger of its being shivered to pieces and doing mischief in rough weather.

With regard to the opinion of Mr. B. Boothroyd (26631), backed by his American authorities, wind-power still is applied to many useful purposes besides those he mentions. Is he aware that, apart from those in private hands, there are stated to be no fewer than 12,000 windmills constantly at work in Holland draining and dredging the canals and polders, at an expense to the country of about 4,000,000 dollars per annum? Also his estimate of the average velocity of wind cannot be accepted as decisive. Sailing-vessels have gone to Australia and back to England at an average speed of more than 200 miles a day, calms, light airs, and head winds included both ways; and seven miles an hour, at which he fixes the average of wind, is but 168 miles a day. Besides, there are regions in the latitudes of the Trade winds where an alternate land and sea breeze of good power are almost as regularly looked for as night and morning by those who inhabit there.

A good handy horizontal windmill would be likely to obtain public favour just now; but I very much doubt if it is to be gained by a wooden turret of 30ft. diameter, 14ft. in height, constructed chiefly of loose deals, altogether over two tons in weight, and placed on the upper part of a lofty shaft. Mr. Vallance himself suggests that it would be only suitable for wildernesses and waste places (Dec. 17, p. 346). Something light and handy is wanted that might be set up in our business premises, or over our own workshops. Its medium of propulsion might be canvas, like a British ship, not topheavy *louvre boards* like a Chinese junk.

London, Jan. 3 **Raymond Browne.**

[26669.]—AS the horizontal windmill power has been already illustrated in Vol. X. page 631, I should not think of asking for it again; but if Mr. Boothroyd has any thought of erecting anything of the sort, and will communicate with me at Cootham, Pulborough, I will lend him a working model of one I have.

Wind at seven miles per hour has a pressure of about ¾lb. on the square foot, and I think about 4H.P. may be got from such a mill as I have described. It is true that wind is too uncertain for dependence to be placed on it for any constant supply of electricity, so that it would require to be accompanied by a steam-engine to do the work when the wind failed; but if the position were good, the engine would be seldom required.

Philip Vallance.

[26670.]—I HAVE been much interested in the letters on "Horizontal Windmills." While the field was occupied by the three first writers I did not feel inclined to interfere; but now we have another in the person of Mr. B. Boothroyd, who gives us some facts collated by him during seventeen weeks, which facts have made him an unbeliever in the practicability of horizontal windmills for electric lighting. Seventeen weeks is a very short term to decide a matter of this importance. If Mr. Boothroyd could give us the figures showing the variations in the speed of the wind during that period, it would greatly assist your readers to judge of the correctness of the conclusions he has arrived at. Taking the bare statements, they do not appear to me to justify his conclusions. If there was an average of seven miles an hour during the term, there must have been a speed exceeding, say, fourteen miles during a great portion of that time, and the wheel which would give 2H.P. at eighteen miles would give 1H.P. at fourteen miles an hour, and 1H.P. free of expense for electric lighting is not to be despised. Accumulators that would receive this charge for eight hours would light six lamps of 15c.p. for fourteen hours, or more than four and a half hours for three days. We must not forget that there are twenty-four hours during which the windmill may work, while the light is only required for a few hours daily.

Gwalia.

THE AMERICAN ORGAN.

[26671.]—"COUNTRY SOLICITOR'S" friend has unwittingly bestowed a good bit of praise on the American organ. "You can only pray on it," and let *me* add *always*, and it does the praying so well that there is no need to swear *at it*. I mean Mason and Hamlin's. Some of the family might well draw imprecatory groans from you; not that I have a word to say for such excess of temper. Perhaps the best way to deal with it is to ask those who have long used it, Does it accomplish a fair amount of the promises its sponsors are responsible for? Or, is it like *Punch's* hopeful youth, when asked what his godfathers and godmothers had done for him, replied, "Nothing whatever—neither before or since"?—a perversion of the original intention, I must add. **H. Ussher, B.A., M.D.,** Surgeon.

CHURCH ORGANS.

[26672.]—AMIDST the trade competition as to who shall make the most noise for the least money, it is refreshing to find Mr. Audsley advocating the good old plan of adequate scales and low pressure. It is the only plan to get tone as distinct from mere noise, though the high-pressure scream may be absorbed to some extent in large resonant vaulted buildings. The art *par excellence* of organ building consists in the welding together of unison, mutation, and chorus work into one satisfactory whole, but the high-pressure organs will not stand a proper "chorus."

Mr. W. T. Best holds that no organ requires more than 50 stops. Adding five to this for my particular hobby of a pedal swell organ, I find that everything can be worked in that is necessary, and for this number three manuals are ample with a reasonable system of control.

I quite agree with Mr. Audsley that in a three-manual organ the great should be the lowest.

Thomas Casson.

CHAMBER ORGANS.

[26673.]—I FEEL sure that there are many who, like myself, are glad to welcome the return to articles and correspondence on organs and organ-building in your pages, and it is no breach of confidence to tell you that my attention (as an amateur) was called to it by an organ builder of great celebrity in London, with the result of my taking current numbers, and buying Vol. XLIII. in its entirety.

I think Mr. Audsley would confer a very great favour on many besides myself if he would describe more fully the scale, design, and constructive particulars of two of the stops he has spoken of—one the euphone (known so well in Continental organs), and the wooden violoncello stop of the Schultze model. We have not all the opportunities of seeing pattern pipes; but a drawing would be of great assistance.

I am greatly interested in the articles on Church Organs, and I am extremely glad to see stated the fact, so often omitted, that the great West organs of foreign churches are seldom used for accompaniment purposes. There is invariably, where funds are sufficient, the second organ in the chancel, designed solely and entirely to accompany the choral parts of the service. Would that such a course had been adopted in our Anglican churches! How many fine West organs would have been saved from being boxed up and spoiled in inadequate organ chambers!

I add, for the benefit of those interested, the specification of one of C. Coll's model chancel organs. It is well to notice it is constructed with the object of giving a solid accompaniment to the unison singing of plain song tones and masses.

GREAT.	
Bourdon (metal and wood)	16ft.
Montre	8ft.
Flûte harmonique	8ft.
Prestant	4ft.
SWELL.	
Viole de Gambe	8ft.
Voix céleste	8ft.
Flûte octaviante	4ft.
Plein jeu (5rgs.)	
Basson—Hautbois	8ft.
Trompette	8ft.

No pedal stops; usual couplers.

The pressure of wind is, I believe, rather heavy, and the effect of this organ in the church is most solemn and dignified. **J. B. Croft.**

Barnham Vicarage, Thetford.

CONCERNING THE LUMINIFEROUS ETHER.

[26674.]—IN the letter of your valuable correspondent, Wm. John Grey, F.C.S., last week, it appears to me he makes a very common mistake in asserting that "Sir Isaac Newton imagined that light was actual transference of matter, and upheld this view till the last." This notion appears to me to have been offered by Newton as an hypothesis only, and I can recall to memory many instances where he equally favours the theory of vibration of etherial matter, of which, as far as I know, he may have been the author. Thomas Young, who may be quoted as a good authority, says in his Bakerian Lecture on this subject, "A more extensive examination of Newton's various writings has shown me that he was in reality the first who suggested such a theory." At any rate, Newton says: "Were I to assume an hypothesis it should be this, if propounded more generally, so as to determine what light is, further than that it is *something or other capable of exciting vibrations in the ether*; for then it will become so general and comprehensive of other hypotheses as to leave little room for new ones to be invented" (Birch, Vol. III. p. 249). With Laplace the matter is quite different: he demonstrated mathematically Newton's emission hypothesis to give the only possible mode of propagation of light; but we have had every possible and impossible hypothesis come through this mathematical ordeal, so that we may now take this hypothesis at its worth, it being no longer popular philosophy.

With regard to the ether, this is believed in by many, and it appears to me a very necessary kind of matter for the expostulation of the professor, who would have his reputation seriously injured if, with unbelief, he should have the intellectual and moral courage to assert that he did not know the mode of propagation of light, heat, and electricity through bodies and space by its agency, whereas the amateur may hold any opinion on the subject, or none.

For the above-mentioned sciences you may make the ether just what you require to satisfy the particular case in hand; but for astronomy you must give the ether no property of matter whatever, even the very first indications by which we know matter as such. Thus it must possess no gravitation and no momentum, or no resistance to other matter moving through it; in fact, in relation to the lightest astronomical bodies, it must be *immaterial* or *non-existent*. Some of the demonstrations of the presence of ether are amusing if we refer back a few years: thus Young says it is demonstrated by the *electric fluid*, which it resembles in a certain degree. Sir John Leslie, the

able and original experimenter on heat, demonstrates it by its similarity to *caloric*, which he showed was a kind of liquid heat; but, of course, these ideas are now only ridiculous when the popular theories are past by which they were supported. It appears to me that ether is now made to fill the gap in physical science where we should otherwise be obliged to admit ignorance, and it takes at present a somewhat equivalent place in certain sciences to the once assumed universal forms of matter in relation to ordinary matter, which preceded positive chemistry.

Wm. F. Stanley.

THE LUMINIFEROUS ETHER.

[26675.]—I SEE that Mr. Grey (26642, p. 391) accuses me of writing "in an exceedingly disrespectful manner" about the luminiferous ether; but I must submit that he has confused things a little. What elements of disrespect may be found in my remarks are not applicable to the luminiferous ether at all; I was writing about the newly-generated *electrical* ether, and my disrespect was directed entirely, not even to that imaginary entity, but to the people who take upon themselves to call it from the vasty deep, and, like other conjurors, build up a ghost out of the rags and figments of their own imagination, and try to pass it off as something real.

As a matter of absolute fact, all that we *really know* on the subject is that there is a *something* in space which transmits light; we call that something ether, and there is an end of our *knowledge*. Anything else is either mere guessing, or more or less justifiable hypothesis (the scientific name for guessing), based upon induction from observed facts. Now, such hypotheses are not only legitimate, but useful in science, as long as they are recognised as merely preliminary attempts to form a theory, or as mere experimental illustrations; but it is neither useful nor legitimate to try to give them a fictitious validity, and to convert a guess into a dogma, merely because the guess is that of a great thinker, or appears to offer a convenient explanation of obscure facts. I have nothing to say against the data referred to by Mr. Grey; but I do say that the deduction is absolutely worthless (worthless that is, as to this jelly-like ether), for what is the reasoning? Certain facts are taken as to the relation of elasticity and density to transmission of energy by wave motion in ordinary matter, subject to gravitation and internal friction. Granted; but there is a great gulf fixed between those facts and their application to the unknown something, as to which all we know is that it is *not* subject to gravitation and has *no* internal friction. I refuse to jump that gulf. I say it is sounder wisdom, truer science, to admit humbly that I know nothing whatever about the mode in which this something which we call *ether* transmits energy. *A pretended explanation not only disguises ignorance, but tends to perpetuate that ignorance.* I deny that we are bound to provide some explanation for everything we do not understand. Let us wait.

When Mr. Grey, adopting the dogmata taught by professors who pretend to explain what they know nothing about, says, "This medium, whose properties are rather those of a solid or jelly than a gas, is the luminiferous ether," I have no great objection to offer; but when he goes on, still adopting these dogmata, "it pervades all ordinary matter, no doubt packing itself away among the molecules," I fancy he has got outside his knowledge and within the region of guesses. For my own part, I have considerable doubts. I am by no means sure that this hypothetical ether pervades ordinary matter; or that, in space, it is anything but matter in the ultra-gaseous condition of Crookes's vacua.

But to come back to my remarks, p. 310. Not content with *the fact* that this ether, be it what it may, does transmit light, and making more or less probable guesses at the process, these guessing philosophers are taking to asserting that this ether is electricity—a matter as to which they have not one particle of real knowledge. They seem to think that as they do not know what ether is, or what electricity is, they may properly assert that the two unknowns are one known jelly, and that they may mould and season this "precious jelly" at their pleasure.

I had listened, a few days before I wrote, to a lecture by one of our best professors, who was pleased to tell us all about this jelly, which he said is an elastic, incompressible fluid, filling all space, but contained in a sort of network of material not permitting the fluid to pass, but freely traversed by all ordinary matter. He even showed us a model of the processes by which this fluid is transferred, so as to produce electrical phenomena. The fluid disagreed with me, and my remarks were the result of that mental indigestion.

I had previously made notes of certain remarks by the same professor for future purposes. "The transparency of an electrolyte may be explained by supposing that the percentage of dissociated atoms is too small to perceptibly affect the properties of the liquid in bulk."

Now, the existence of such dissociated atoms is itself a mere wild guess, opposed to known facts. Another time he says, "What if we get 'through the looking-glass' . . . in search of new principles. . . . Helmholtz says that electricity is probably as atomic as matter . . . a substance of negative weight is not inconceivable." Now, I protest against applying the principles of "Alice in Wonderland" to scientific hypothesis. Nor do I admit that the mere circumstance of a guess being made by Helmholtz makes it what the Jesuit casuists call a "probable" dogma—that is, one to be safely adopted, true or not. I once objected to being asked to walk up to the top of a ladder, and then turn its lower end up into space for the next ascent, and I say that all this kind of stuff is worse than nonsense. Another time my friend, the professor, remarks, "There are two obvious ways of *explaining* the transparency of an electrolyte on the electro-magnetic theory. One is to *assume* that the minute and rapidly reversed electro-motive forces *which constitute* light, &c. . . ; the other is to *assume* that electrolytic conduction only occurs among dissociated atoms, &c." I protest that all this is not science; it is pure and simple rubbish, and mischievous rubbish. How can we *explain* anything by *assuming* that something exists of which we have no sort of evidence?

Of course, we may pretend to explain anything, if we can invent whatever conditions we like; but this is dreaming, not teaching. Its result upon its students can only be to produce a set of conceited pedants, who fancy they know all the secrets of the universe, while they are really lost in the fogs of a contented ignorance.

I, at all events, will always be found among those who refuse to bow the knee to this modern Baal. I seek to follow the light of Truth alone. When I do not see that light I am willing to wait. I will conclude with a very pertinent quotation from an American review of my "Electricity," where it is said: "He rattles up the dry bones of scientific dogma in a most uncomfortable manner, but persistently adheres to proved laws in preference to mere hypotheses. He bears particularly hard on the practice of giving a phenomenon a name, and then using the name to explain the phenomenon. This practice has been so much followed in elucidating electrical matters that the author of this book seems to be undermining scientific structures when he tells us that 'we know absolutely nothing about forces which every schoolboy is ready to explain'; yet a little reflection convinces us that popular knowledge did not grasp the principle, but merely the name." The writer of those words has truly perceived the principle which I hold to be the true path of scientific progress.

Sigma.

MR. HIGGS'S COIL.

[26676.]—IN compliance with the desire of Mr Benjamin Boothroyd in his flattering mention of my coil in last week's issue of the "E. M.," I beg to state that I shall have much pleasure in furnishing as many details in the construction thereof as may be required by the readers of your valued weekly.

The instrument was constructed solely for the purpose of working the electrodes in spectrum analysis, a short description appearing in the "E. M." of Oct. 22, 1886, and although it has been in working order (but in an unfinished state) for several months, giving 7½ to 8in. sparks, it did not equal my expectations, which previous experiment had justified—viz., that of obtaining sparks the length of body of secondary or terminal to terminal, a distance of 10in.

It was finally completed only on the day previous to the meeting of the Associated Science Soirée, on which occasion the points were kept at 9in. apart for the greater part of the evening; since then it has been doing the whole distance of the terminals, which is a trifle over 10in., with the same battery power.

Seeing that the subject has been somewhat exhaustively treated in previous volumes, I propose in an early number merely to give sufficient particulars, which, if closely followed, will enable those of your readers so disposed to construct for themselves a coil equal, at least, in performance to the above-mentioned.

Tue Brook, Liverpool. **George Higgs.**

ROAD REFORM.

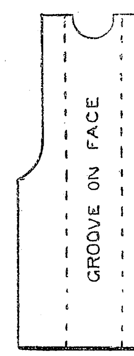
[26677.]—I HAVE long desired to see a reformation of our common roads or highways. I fail to see why such reformation has not taken place ages ago. It is supposed that many of our roads were originally laid out by sheep making their paths between gorse, &c., when the country was in a wild state; and the crookedness of many of our roads seems to confirm this. Other roads were probably made to go out of their direct course over hills in order to keep the pack-horses out of bogs and swamps that existed in times remote; but why such roads should continue to impede traffic in these modern vehicular days, now that Old England has the world to compete with in matters of trade and industries, I cannot reasonably imagine. It cannot be that such roads are expenseless, for on many of them a one-horse load requires from two to four horses, and there is lost time, distance, and fatigue to be added. In many places the distance is nearly double what it needs to be, roads zigzagging and leading over hills for no purpose.

There is no sense in retaining such roads now, for they cannot ease road rates, and they cause the country to pay for an immense amount of work for which there is no return. Suppose an unnecessary road-hill to be twenty yards in altitude, and that the weight of daily traffic up it (including all that there moves) is thirty tons: then the daily work caused by such hill is 4,032,000 foot-pounds, which in a year amounts to 1,471,680,000 foot-pounds, which means 10,950 tons to be lifted at public expense. This for one small hill for one year only! Would it not be better to lift such hill out of our way "once," than that that hill should stand and cause us to lift (in the future) a thousand times its own weight in traffic over it? Perhaps some of our readers and cyclists can give a rough estimate as to how many such hills as the above could (taking high and low together) be averaged in the country, for if this was generally known, I cannot think that road reformation would be far in the future. **Norfolk.**

CUTTERS.

[26678.]—WILL some of our skilled mechanics kindly give an opinion on a suggested alteration in the construction of vertical and other cutters that have grooves on their ground bevels?

What I would propose is to cut a groove on the face of the tool of such a section that would, by its junction with the bevel, produce the desired form of the hollow at the end; the process of sharpening would then act on all the cutting parts simultaneously, and their form and depth would be unaffected by wear. I have tried the plan on the accompanying form only (this is magnified to



make plain my meaning); but I see no reason why it could not be made applicable to all such tools.

In practice I find that a few circular rubs on the iron slab charged with crocus, the bevel lying quite flat, keeps the tool in working order.

The section of the groove on the face of the tool is something of this form, and it ought to extend a little beyond the internal diameter of the hollow at the end.

Ant's Hill, Langharne. **A. Bedford.**

NOTES UPON THE WIMSHURST ELECTRIC MACHINE: ERRATA.

[26679.]—SOME errors have crept into letter 26634 which call for correction. Thus, in the 33rd line, for "unavoidable" read "unavailable"; and I would here add that anyone trying this method would be very liable to be placed in an awkward predicament, by reason of some of the cement getting upon the pin fitting the boss and thus becoming a fixture. On page 390, for "boxwood" read "baywood"; where 4ft. is printed in connection with the grooved standards for glass case, it means the feet or ends of same. The diagram showing the construction of the sectionally made up disc has been left out. **A., Liverpool.**

DOES VACCINATION PREVENT SMALL-POX?

[26680.]—IN reply to your correspondent "Lavant," I assert, with Dr. Allinson, that the national vital statistics of this country, published by the Registrar-General, lend no support to the theory that vaccination is a preventive of small-pox; on the contrary, they prove irrefutably that, concurrently with the extension and most rigid enforcement of vaccination by a despotic law, small-pox has increased.

If we take the annual reports of the Registrar-

General for the years 1854-83, which cover the whole period during which the compulsory law has been in force, we find that whilst in the first 15 years—1854-68—the deaths from small-pox in England and Wales were 54,700; they increased during the following 15 years—1869-83—under the strictest enforcement of a law which secured the vaccination of 95 per cent. of all children born, who survived the age of three months, to 66,447, giving a total of 121,147 under a régime of 30 years of compulsory vaccination.

"Lavant" says that vaccination would be still more preventive if repeated at the ages of 16 to 18; but if the vaccinated die in large numbers under 10 years of age, how are they to be saved by re-vaccination at 16?

Now, the reports of the Registrar-General before quoted show that of the 121,147 small-pox deaths recorded in 30 years no less than 67,472 were of children under 10 years of age.

The fact is, there is not the remotest connection between the small-pox death-rate and vaccination unless the latter *increases* the former, which it would not be difficult to prove; indeed, other conditions being equal, an unvaccinated person is far more likely to recover from an attack of small-pox than one whose vitality has been lowered by vaccination.

Atlantic-road, S.W., Dec. 28. **Wm. Young.**

A QUESTION IN COAL ECONOMY.

[26681.]—REFERRING to the remarks of "Nun. Dor." (letter 26620, p. 369), it should be borne in mind that coals and slack in a chemical works are not exclusively used for generating steam power, but also for mixing purposes and concentrating solutions. The extent of the operations in some of these works may be understood when I state that in the works of the Widnes Alkali Co., Ld., where I am engaged, the annual consumption of fuel is about 170,000 tons, of which not more than 32,000 tons are for engine purposes.

There are also used 40,000 tons of lime and limestone, 17,000 tons of sulphur ore, and 65,000 salt and salt cake, &c., from which result caustic soda, bleaching powder, and other products.

Chemical.

LIFEBOATS.

[26682.]—THE method of anchoring is not the only thing which prevents lifeboats from righting when capsized, for I see that "the self-righting capabilities of the Looe lifeboat have just been tested. The boat was turned over successfully, but failed to right herself, and the two men who were in her narrowly escaped with their lives. A second attempt was made, but no better results were attained. The boat in each case remained on her side." As a matter of fact, lifeboats seem to remain in much the same state as they were when the exhibition of life-saving apparatus was held at the London Tavern somewhere about 1870. There are few of the modern devices stationed around the coast, and it might possibly be advisable when a donor presents a new boat to stipulate for an improved pattern, if such a thing is to be had. Meantime, some dreadful nonsense has appeared in the papers about lifeboats and the means of propelling them. In the course of a leading article upon the recent disastrous loss of lifeboat crews, the *Times* suggests that electricity might be made available as a motive power for lifeboat service. "Accumulators," thinks the *Times*, "might possibly be fixed so as to form a portion of the ballast." To which the *Electrician*:—"Certainly they might, though as ballast they would be somewhat expensive, and for any other purpose storage batteries would be utterly out of place in a lifeboat. It is decidedly unfortunate that the leading English journal should entertain such hazy ideas upon a matter of this character. Apart from such fundamental objections as to the impossibility of keeping the cells always in a condition for active service at a moment's notice, we doubt whether any makers of accumulators would be prepared to supply cells guaranteed to stand the amount of knocking about which must be undergone in such service. The *Times* is possibly aware that accumulator cells cannot be hermetically sealed up. In this connection we may, however, mention that, notwithstanding this difficulty, the E.P.S. Company, after very numerous experiments, have recently succeeded in designing a form of cell which will bear repeated and rapid inversion without serious loss of liquid. In this case, however, the application is only upon a small scale, and any failure of action would tend to the preservation rather than the destruction of human life—that is to say, the cells were designed for use upon a self-propelling torpedo, which will shortly be brought out by Mr. Nordenfelt. One of the boats which capsized off Southport made a voyage of 12 miles out to the vessel. We should be glad to get some idea of the power required to propel a boat with a crew of twelve men at the rate, say, of 10 or 12 knots an hour through a storm such as that of the 6th inst."

It is unfortunate, as your contemporary says, that the "leading English journal" should set out such hazy ideas; but what can be expected from the daily press which talked of a million foot-pounds of force in a small box, and bonneted for the electric light, spring sewing-machine motors, and all sorts of new batteries. This lifeboat business is, however, a serious matter, and a committee of experts, which should include of necessity a number of old beachmen, ought to be formed to report upon lifeboats generally. **Nun. Dor.**

THE HYDRAULIC RAM.

[26683.]—REMEMBERING a dispute in your pages about the hydraulic ram and its principle, I think the following, which I found in the *American Machinist*, may interest some of your readers. The writer says:—

"I received a forcible illustration last summer of the principle upon which the hydraulic ram operates. By a blast in the quarry about 75ft. of 5in. suction pipe was shaken down, the break taking place at an elbow. The pipe lay at the bottom full of water, with the open end about 4ft. above the foot-valve. Wishing to empty it as quickly as possible, I thrust my hand into the valve and pushed the 'clack' open. It opened easily, and the water started out with a rush, but the rush shut the valve with a force that nearly left me fingerless. By substituting a stick for my hand I soon had the pipe ready to put in place again. But the elbow was a wreck, and another one was not to be had very soon, so I extemporised one from a 4in. oak plank. Two pieces 12in. square were cut off, and from two sides at right angles with each other large semicircular grooves were cut to the centre, just fitting the outside of the pipe. Then, with a ⅝in. bolt in each corner, the two halves of my wooden coupling were squeezed upon the pipe. A crack or seam about ¼in. between the two blocks was caulked with hemp, and the pump started. A new iron elbow is patiently waiting now for the wood one to give up its grip; but I think it will take more than the frosts of one winter to end its usefulness."

T. K. C.

APPARATUS FOR PRACTISING CHANGE-RINGING.

[26684.]—I HAVE recently invented an apparatus which can be fixed in a private house for practising "change-ringing." A large room being available, two strong beams, about 18ft. apart, may be fixed across from wall to wall, the ends being built into the walls; smaller cross beams, mortised into these, form with them the lower frame. Upon this a frame, in which the dumb bells are hung, is erected in the usual manner; but the beams, which are above the strong beams, are also built into the walls. There are eight small pits measuring 4ft. 7in. by 10in. In each of these pits is hung a cast-iron dumb bell, with proper wheel attached. The dumb bell is so designed that the centre may be far from the centre of revolution; this result is partly produced by the casting being thicker at the lower part of the bell. The effect of this is that, while the dumb bell only weighs 170lb., it gives the same resistance as a church bell of a much greater weight. In the upper part of the casting is a slit 3in. by 1in., through which passes the wrought-iron stock, on the ends of which gudgeons are turned in one piece with it. To support the wheel a piece of wrought iron passing diametrically across it is bolted to the lower part of the dumb bell, and is firmly fixed to the stock and bolted again to the upper part of the wheel. Its end projects beyond the wheel, and may be used as a stay; but in practice it is found better to ring these bells without sliders. Across the two lowest spokes of the wheel, and concentric with it, is fixed a curved piece of wood, a segment of a circle, the horizontal section of which is also curved on one side, but straight on the other, with flat ends, which are attached to the said spokes. As the projecting part passes its lowest position it presses a button, which forms part of a pneumatic bell apparatus, and thus a gong, placed at some distance below the frame and just above the ringer's head, is made to sound. Instead of the pneumatic, an electric apparatus may be used with the frame. If the gongs are not required to sound, small taps may be opened to let the air out of the tubes. The above should always be used in connection with the well-known "Clapper Stay," which is giving great satisfaction in various parts of the country.

Glanvilles Wootton, Dorset. **E. R. Dale.**

THE new list of members of the Institution of Civil Engineers, corrected for the New Year, shows that there are now on the books 1,556 members, 2,231 associates with corporate privileges, 488 non-corporate associates, 20 honorary members, and 929 students attached, or a total of 5,224. The gross increase in the past twelve months has been 252, or nearly 5¼ per cent.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[60092.]—**Navigation.**—I am sorry I have been so long in acknowledging "R. E. F.'s" kindness in offering me a solution to this query; it is owing to my being unable to get the "E. M." sometimes for months after publication. I send an address this week that will find me. Since sending above query I find that there are tables published by Captain Lecky for finding the distance from a headland or mountain by the altitude; but I have not seen them as yet. Perhaps some of the readers of the "E. M." can inform me what formula they are deduced from. The problem is not in common use amongst merchant seamen, as far as I am aware of. I believe it is taught in the R.N.; but it is not in the requirements of the Board of Trade for merchant seamen. The solution given by "A Fellow of the Royal Astronomical Society" is quite near enough for my purpose, as it is only an approximate distance I require (not a rigorously exact one), and one which can be readily found by such tables as are always at hand. I may state the purpose I most frequently use it for is to get an approximate latitude for finding the longitude by chronometer, and also for checking the position so found. My address will be found in the "Sale Column."—D. SHEARER.

[60936.]—**Oxygen.**—I simply mean that by adding salt to the mixture of $KClO_3 + MnO_2$, the production of oxygen can be regulated by applying different amounts of heat.—HOLLAND.

[60982.]—**Chronic Inflammation of Nostrils.**—"Misery" has found many counsellors. May I add my experience (described in my letter to "Necessitous"), which, in my own person, was such as to enable me to assure him of hope. Dr. Allinson, beyond doubt, does good in advocating less animal food; but were he a large employer of labour, as, say, a railway contractor, he would find that if he made his system of dietary compulsory with all his men, their comparison would convince him that his theory is very imperfect. When at the age of 25, I had some six months' treatment at Malvern, confining myself to a purely cereal and vegetable diet; drinking water, and water only; spending the whole day, from sunrise to sunset, excepting meal times and a snooze after dinner, in the open air; a 3lb. loaf of bread being my breakfast, and yet, leaving me still hungry. I ask your scientific contributors to enlighten "our" readers by accounting for this enormous appetite and digestion; after which I propose to offer a few items showing some of the evils of the system which, in hopes of obtaining that which I had never yet possessed, i.e., in health, I had been persuaded to so ascetically follow at Malvern.—THE DISPENSER AT THE FREE DISPENSARY, LYDNEY.

[60990.]—**Steel-McInnes Brake.**—This brake is, to all intents and purposes, extinct, having been taken off the Caledonian engines. For further proof of this, and details, I refer "Inquirer" to Mr. Stretton's "Safe Railway Working," page 169.—C. R.

[60994.]—**Waggon Couplings.**—A plan for tightening up the coupling was shown at the Inventions; but whether all the new couplings work with loose couplings or not depends upon what is meant by "new." If those in actual use, it may be said they are all loose.—J. S.

[60995.]—**Engines.**—Engines which have a small leading wheel run better than those coupled in front.—LOCO.

[60998.]—**Cottage Range.**—This querist can procure a suitable range from any of the foundries which cast things of the kind. There are several patterns, and a good fire at the side of the oven is all that is necessary to cook any joint that can be got into the oven.—P. P.

[61000.]—**Pipe Moulding.**—As the subject of pipe moulding is attracting some attention in your columns, the following notes, contributed by Mr. T. Wathey to the *American Machinist*, may interest your readers. The writer says: Some time since I had to make some special pipes. They were straight on the inside; but the outside looked more like a big jar. They were 2in. thick from the socket to within 8in. of the top; from there they were 1in. thick, so as to be of the same diameter as common pipe. There were 20 pipes 36in. diameter, and 40 which were 30in. The order was like most foundry orders—to be filled yesterday. There were some casings in the shop, used to ram up pipe in; but these pipes could not be rammed up in them because the casings were oblong, and on two sides there would not be more than ¼in. space for the rammer. The casings were made, or supposed to be, in half-segment circles 6ft. long; the pipe wanted was 12ft. long, so four of these segments

would make the length. I made a furnace on the bottom where the pipe was to be loamed up; it was a cheap affair, but answered the purpose very well indeed. I made two plates 3 by 4ft., with two square holes in each to hold the bearing bars. The bars were square, with a shoulder about 2in. from each end to hold the plates against falling in; the bank held them against falling out. A plate for the bottom and a few grate bars made everything complete. The casing being in 6ft. sections, a man standing inside could loam up one very comfortably. Get the two casings on the floor, one over the furnace and the other alongside it. Get inside and put on loam, about ⅜in. thick. If, after you have the loam on, and are congratulating yourself on the nice job you have, it should all slide off, don't get disgusted; that is exactly what happened to me, and I can sympathise with anyone in the same fix. While you are in the casing, let one of the boys get a lot of sticks and shavings ready; then, as soon as you are ready, hoist one section on the other, keeping the joints clean, so as not to throw them out of line. Get a fire started as quickly as possible, or you may have a land-slide. Have a brisk fire for ten or fifteen minutes; then slack it down a little by putting on a plate, with a brick or two under it. The steam will soon begin to come out of the holes; when it ceases you will know the loam is dry. Now for the centres. There are plates for the bottom of the casings that the pipes are cast on. These are turned up in the lathe so you can get a cross with three arms for the bottom and the same for the top, with a hole in the centre for the spindle. As soon as the loam is dry rake the fire out and let down the bottom centre. The most common way of setting sweeps is to put in the spindle and then put the board on; but this will not work well in this case. The best way is to fit the sweep to the spindle, and lower all together, then put the top cross on and centre it. It is a long way to reach from the bottom of the mould to the top, so I made a scaffold, using two pieces of 2in. by 4in. wood, and bored a hole in it 2in. diameter for the spindle, and two holes to bolt the pieces together. To each of these pieces I nailed a half-round board fitted to the spindle. These bolted together will never slip. Get into the casing as soon as possible after getting the fire out, for if it gets cold the loam will be liable to slip off again. One man and two boys made one 36in. pipe in one and a half day, and one 30in. pipe in one day. I had the top end of the spindle squared, so that a wrench 5ft. long would fit it. This was very handy in turning the spindle; one of the boys could turn it. Some moulders may wonder why I had three instead of four arms to the cross. When a man gets into a casing directly after the fire is withdrawn he may want to get out very quickly. Three arms offer less obstruction to his exit than four. The casings are made with a rammer on the side from the top to the bottom. The rammer is rammed up with a draw gate at the bottom. Use this rammer to fill up the socket, or to a foot above the bottom. The other rammer is made by a core that fits around the top of the pipe and outside the centre core, with 12 or 14 grooves cut in stem for rammers, so when you have about 12in. of iron in the bottom rammer you can get it over into the other as quickly as possible. The mould can be dried either where it stands or put in the oven.—P. M.

[61005.]—**Combination.** — It is not easy to answer such a question as this without knowing something of the construction of the rather peculiar organette with 31 reeds. It is possible that the tubes might be closed with pallets, and so "A. B. C." might achieve what he desires with the ordinary harmonium action—that is, keys depressing levers carrying pallets, which, opening the mouths of tubes, would allow the wind to enter. That arrangement could be made removable, so that either paper or keys could be used.—ORGANON.

[61006.]—**Length of Belting.**—As one of the correspondents who replied to this, I have, for satisfaction sake, referred to Rankine, and he gives the length of the straight portions of the belt, when crossed as $\sqrt{C^2 - \left(\frac{D+d}{2}\right)^2}$, which is the same as cosine of angle. Using "Miller's" own figures, this gives $\sqrt{145^2 - 60^2} = 130{\cdot}5$in. nearly, or 261in. for the two straight portions, which is the only point "Miller" seems in doubt about. This agrees pretty well with the 22ft. I gave in my correction, and which was calculated from the nearest table of cosine I had by me. I believe other correspondents were a little more accurate; but an inch or two on such a long belt would not matter much.—T. C., Bristol.

[61007.]—**Polishing Whalebone.**—Whalebone can be polished with pumice dust and water, and a felt rubber, the finish being put on with dry-slaked lime—that is, quicklime allowed to slake in the air, and sifted. Of course, the polishing can be done on a wheel, and the speed may be anything the querist likes.—SAML. RAY.

[61010.]—**Donkey Pump.**—A direct answer to this query would read much like an advertisment, if one is compelled to choose between two good pumps. "Tug-Boat" should endeavour to see other pumps at work, and then, knowing exactly what he wants to do, he will be able to form a better idea of which pump will suit him than can be gathered from his query, and he will be able to answer it himself.—MARINE ENGINEER.

[61022.]—**Leather.**—In complete ignorance of what this querist wants to do—whether he wants to use the colouring matter or to bleach the leather, I can only suggest that after soaking his leather in water he should hang it in a warm bath of sumac, or dip alternately into baths of sugar of lead and sulphuric acid—the latter, of course, very dilute.—NUN. DOR.

[61033.]—**Panorama.**—You want a frame, preferably of iron, and gas-piping will answer and be convenient for different-sized stages. The rollers must be supported in standards, which are held together and apart by the gaspipes, and both should be fitted with a bevel gear at the top, so as to be driven by crank and flywheel, and preferably gear acting on a small horizontal shaft carried on the top of the standards. Gear is better than belt, as there is no slipping, and both standards should be arranged for affixing the gear so as to roll the canvas backwards and forwards.—J. T. M.

[61035.]—**Re cutting Fret Saw.**—There must be some mistake about this fret saw, for blades of the kind generally used for sawing frets are sold at from 4d. to 1s. a dozen. Whatever saw it is, it will scarcely pay a "Young Turner" to grind off the old teeth and recut.—C. K. P.

[61041.]—**Joints in Hot-water Pipes.**—Rust joints would be best, made with sal-ammoniac and iron filings; but perhaps a mixture of white and red-lead well rammed in will answer all purposes. Spongy cast tubes are not fit for boiler work.—T. L.

[61042.]—**Seeds.**—Coat the seeds with gelatine.—J. T. M.

[61043.]—**Power of Gas Engine.**—The power of such an engine will be about one horse.—C. T.

[61045.]—**Spring Motor.**—This is a matter for experiment. There is no formula to answer such a question.—D. G.

[60948.]—**Electrical Replacement Indicator.** —TO "JULIUS."— Thanks for your kind notice. You are quite right in surmising that the diagram in question was drawn under pressure. In any, even the quietest, home circle there is always considerable pressure on anyone attempting to write on scientific or mechanical subjects, unless he can manage to lock himself up in a separate room—a boon that, I fear, few of "ours" possess. I cannot, however, detect any error in the drawing, though possibly I should recognise it instantly on its being pointed out to me. I have, therefore, published my address in the proper column, and should esteem it a favour if you would write to me direct, pointing out what you refer to, as we shall get at it quicker this way than through the "E.M.," and, if it is as you infer, I can publish a correction in the usual way.—EDWARD CONRY.

[61070.]—**Reversing Gear.**—The form of reversing gear for screw-cutting lathes most in use by English makers was designed by James Nasmyth, and a sketch of it is given in the Appendix to his Autobiography published last year. The sketch will enable a mechanic to construct one. Nothing can work better.—R. R. N.

[61070.]—**Lathe.**—The rocking plate rocks on the stud which carries wheel D, which same stud carries the first of the change-wheel train. It is in, or out of, gear, according as the driving is done through the wheels B or C or not. In the

FIG. 1 FIG. 2

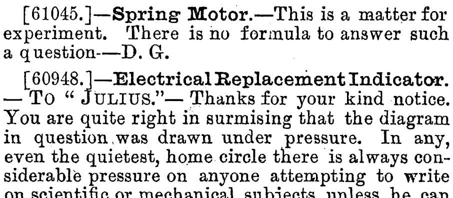


figure the lettering corresponds with my answer given on p. 331. At the two extreme positions of the wheels the plate is clamped with a bolt passing from the back of the headstock through the slot-hole, or in some cases there are two round holes in the plate corresponding with the extreme positions of the gears, through which a pin is thrust to lock the plate. Fig. 1 shows the plate in one position, Fig. 2 in the second position, and the arrows show the direction of motion. The wheels B and C run loose on studs set in the rocking-plate.—J. H.

[61071.]—**Planing Machine Tools.**—I do not see why the dragging of which you complain should occur. A slight amount of angle from the perpendicular is sufficient to throw the tool off. Is there stiffness in the plate? Does it pivot freely?—J. H.

[61099.]—**A Rule of Grammar.** — Having failed to get an answer from Mr. Hall as to who made the rules of syntax, I should like now to ask Mr. Van Eys (p. 395) what is a "grammatical error" —an expression he uses several times?—G. W. M.

[61101.]—**Stars Visible from Bottom of Well.**—"E. D." will remember that I made the statement at which he takes exception simply as a deduction from the opinion of Herschel quoted by him. That it is correct so far as the stars which he mentions are concerned is self-evident, for of these γ Ursæ Majoris (Phecda) has a declination of 54° 22′, and thus in the latitude of London is 2° 52′ from the zenith at its meridian transit; ζ Ursæ Majoris (Mizar) has a declination of 55° 33′, and so similarly never approaches the zenith nearer than 4° 3′; whilst β Cassiopeiæ (Chaph) is even worse situated than either of the two former, having a declination of 58° 29′, and so in its most favourable position a zenith distance of 6° 59′. Surely this will content "E. D." In conclusion, I have to express my thanks to "F.R.A.S." for his kindly reply to my query of last week.—B. A.

[61145.]—**Does it Boil?**—What is boiling? It is merely the steam or vapour generated by heat rising to the surface of the water. It is no index to the heat—i.e., it is no test of the water being at 212° F. Take the late storm, when the barometer was at 27·87 or 28, or 28·2, or 28·5. No water in an open vessel during that storm attained 212° F. If water is heated in a partial vacuum, ebullition will take place many degrees below 212° F. If under pressure, then the ebullition point is raised. The term "boiling" misleads.—R. S. T.

[61145.]—**Does it Boil?**—It appears from the remarks of "Weald," p. 374, that his particular point is simply the distinction between boiling and evaporation. The distinction is very simple: evaporation takes place at all temperatures and pressures—at a rate which is, however, related to temperature and pressure; even solid ice evaporates. But there is a point of temperature, variable with pressure, at which the liquor can no longer be heated beyond that temperature; all excess of heat applied is used up, not in heating the liquid, but in converting it into vapour—that is to say, the distinction of the boiling point relates to the liquid, not to the vapour; but the rate of evaporation increases as the temperature rises, and appears to increase suddenly at the particular boiling point, because when that point is reached there is a sudden increase in the available heat.—SIGMA.

[61145.]—**Does it Boil?**—TO MR. S. BOTTONE. —Thanks for yours, p. 374; so explicit and clear. Neglecting more palpable manifestations, would you not say that displacement of atmo. by vapour is characteristic of boiling, and that in all non-boiling evaporation the requisite expansive stress is wanting? And in non-boiling condition, however hot the water, is vapour "given off" otherwise than passively (i.e., surrendered to absorbent atmo. above)? Does increasing steam as boiling approaches, with cauldron upon fire, result from growing expansive stress, or is increase solely due to increasing temp. of solvent (viz., air above surface, with analogy to solution of sugar, &c.)? If the latter, then any idea as of semi-ebullition, so seductive, is absolutely wrong. This is the point. Advice from a mind necessary; no good applying to any scientific book or Book (on legs). To "W. A. S. B."—I must object to your statement that I "concealed" a presumed belief in my query; and also to the insinuation, on whatever ground, that the query was other than bonâ fide and sincere, as I have explained it to be. The protest against "polysyllabic ebullition" at which you rejoice is your own and not mine; my own remark had a different bearing, which you missed.—WEALD.

[61171.]—**Electric Railway Signals.**—The new system now worked through the Severn Tunnel is Spagnoletti's improved plan. When one signalman accepts a "be ready" for a train, he unlocks the lever in the box in the rear, that man takes off the signal, then he puts it back to "on" after the train has gone, and the first man locks it again till that train is clear; it is very good and simple. —ELECTRIC.

[61167.]—**Water Tanks.**—If you take an ordinary carpenter's slide rule and look on the C line for the number of gallons you are dealing with, under that on the D line you will find a number which expresses the depth and width. If your dimensions are all in inches refer to the A line for the gauge point 174, below that on the B line will be the length of your tank. If your dimensions are in feet, or feet and inches, the gauge points will be different. By varying the position of the slide you can alter the dimensions to any extent, whilst the capacity remains the same. Although

I have taken some time to describe it, the actual operation is a matter of a few seconds. I give an example what are dimensions of a parallelopiped to hold, say, 56 gallons; I say nothing of frustrums of cones:—

174 gauge point		A
39 length		B
	56 gallons	C
	20in. square	D

—J. F., Auld Reekie.

[61218.]—**Lighting Optical Lantern.**—I use a 24-cell battery by Schanschieff, which gives 36 volts and supplies current to an incandescent Swan lamp of about 20 volts resistance, the result being that the lamp gives a very white and steady light of some 75 to 80 candle-power. One charge of the battery suffices for four hours' work, which can either be taken continuously or by instalments. The energy of the liquid is not then exhausted, and the solution can be transferred to the cells of a dark room or other lamp, and afterwards worked out. The solution costs 5s. per gallon, which at first sight appears rather high; but as each gallon produces from 27 to 30 ounces of quicksilver, which the maker repurchases at one penny per ounce, the cost of work is really brought to a very moderate figure, and when the very simple management of the battery and its thorough efficiency are taken into consideration, the results, in my opinion, are thoroughly satisfactory. No porous pots are used, and no fumes or smell produced. The battery is charged by simply pouring into each cell so much of the solution as will about two-thirds fill it, and the whole of the elements are let into the cells simultaneously, and as easily taken out. The battery is, in fact, as easily used as an oil-lamp; whilst it is free from the great heat, smell, smoke, and other objectionable features of oil, and also gives a far better light. Schanschieff's advertisement appeared in the "E. M." early in the year, and Mr. Christopher Davies spoke very favourably of the battery early in the summer, I think. The portable box containing my battery measures 21in. long by 8½in. wide by 14in. high, and forms a convenient stand for the lantern.—LANTERNIST.

[61223.]—**Balancing Millstones.**—I presume "Chatteris" has not the patent balance to his stone, so it is of no use to try to instruct him in that; but may be he has a great lump of lead in the back of the stone to obtain the standing balance. If so, this is undoubtedly the reason of its "dipping" when running, as its raises the "centre of gravity" upon that side. He may obtain a remedy by getting a piece of iron D-shaped in section, about 1in. thick and 1½in. broad at centre, tapering both in breadth and thickness to ends, length about 1½ft. to 2ft., and putting this upon opposite side to where dip is well up the top hoop. "C." might find it advisable to try it at one or two places temporarily before fixing, with a small bolt in each end, either tapped into the hoop or the hoop cut through and nuts leaded into the side of the stone. If "C." does this, I think I may promise him a sure cure for the stone dipping. P.S.—To find the exactly opposite place to the dip, get a piece of wood, shape it to thin wide point, rest it on the bed-stone, then gently cant it up when the stone is in motion, and it will just touch where it dips. If "C." now takes his colour brush which he uses for his staff in one hand, holding his piece of wood in the other, he can touch the back of the stone at the same time as it touches his stick, and so show the heavy side.—WILL.

[61233.]—**Permanent Way.**—The only kind of rails used on the Continent are those with flat bottoms. They are nailed on wooden sleepers, or fastened with a little iron wedge to steel sleepers. —HOLLAND.

[61233.]—**Permanent Way.**—A full description of the construction and working of Continental railways is given in Mons. Ch. Couche's work on "Permanent Way," translated from the French, sold by Messrs. Dulau and Cie, 37, Soho-square, London, dated 1877. A description of Mr. Webb's metallic permanent way was given in the *Engineer*, May 1, 1885, p. 497.—T. ATKINS.

[61239.]—**Circular Saw.**—There is not, that I am aware of, any exact relation in size; but for a saw ranging from 12in. to 18in. diameter, the shoulder would be about 3in. in diameter; for one from 6in. to 8in. diameter, from 1½in. to 2in. If the saw heats, it is in consequence of being forced or from want of packing and oiling. The guide need not be so long as the diameter of the saw; but a considerable portion of its length, one-half or more, must stand ahead of the saw, so that the wood may have a certain amount of initial guidance as the saw commences its cut.—J. H.

[61241.]—**Chronic Catarrh.**—This will probably be called ozœna, resulting from, not climate nor diet, but scrofulous constitution, and inherited. I have had the treatment of several somewhat similar conditions, and although marked improvement generally soon followed, yet permanent cure was tedious. "Necessitous" can at once commence one of the most useful remedies thus:—At any chemist's shop get a long glass-stoppered 1oz. phial, half-fill it with a mixture of equal parts glycerine and sulphurous acid. Close the mouth and one nostril, inhale or sniff the vapour into the open nostril, the quantity of vapour being regulated by covering more or less the mouth of the phial with the tip of finger. Act in same way with the other nostril. Do not attempt at being heroic, but cease for the time being, when the vapour causes pain. Repeat the operation several times daily for, say, a week. A week's treatment with sulphurous vapour will no doubt induce "Necessitous" to study the medicinal action of other drugs in attenuated doses, the medicinal action of which is now admitted by the great authority, the *Lancet, vide* the paragraph p. 366, on Borated Fish, in "Ours." "Necessitous" will also find kali bichromate, 3 ×; mercurius 10 datus, 3 ×; mercurius cum creta, 3 ×; silica, 3 ×; graphites; phytolacca; and many others, one and all, afford convincing proof of benefit.—THE DISPENSER AT THE FREE DISPENSARY, LYDNEY.

[61243.]—**Failure of Amalgamation.**—If this querist will turn up No. 1,122, Sept. 24, 1886, page 82, second column, he will find particulars of what I have found to be a "splendid dodge." Nothing can be easier, cleaner, or quicker. Price about £8.—S. BRETTON.

[61243.] — **Failure of Amalgamation.** — Thanks to "Sigma"; but I had noticed his reference to the addition of oil. I really am afraid to try it, lest it should introduce further complications by getting on the carbons and in the pores of the porous cells that are none too open already. Perhaps he will tell me where I can see an account of the original experiments and the exact method of mixing, and much oblige.—M.M.I.SC.S.

[61249.]—**Boiler for Boat.**—I have used successfully, for the purpose of heating a boiler to drive a pair of marine engines, 1in. stroke, ⅝in. cylinder, three of those French spirit lamps where a centre tube contains a wick, outside of which is another circular wick. These three burners I have transferred from their lamps and fitted them into one cistern 8in. long by 5in. wide, 1½in. deep. They keep up easily 30lb. of steam. The arrangement of open wicks supplied by a cistern outside of boiler, as usually sent out by the London firms for this purpose is a delusion and snare—the spirit is wasted, the wicks are charred, and probably the boat catches fire.—C. H. F. C.

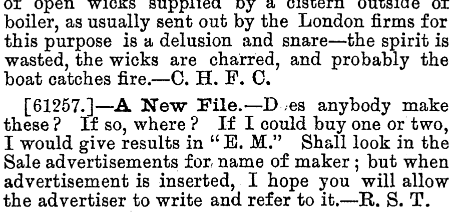
[61257.]—**A New File.**—Does anybody make these? If so, where? If I could buy one or two, I would give results in "E. M." Shall look in the Sale advertisements for name of maker; but when advertisement is inserted, I hope you will allow the advertiser to write and refer to it.—R. S. T.

[61260.]—**Dip for Brasswork.**—Warm your previously-cleaned work, give coating nitrate of silver, 60 grains to the oz.; blacklead if necessary, then lacquer.—S. BRETTON.

[61261.]—**Mirror Galvanometers.**—If brass bobbins are used, they should not be metallically connected. The insulation resistance is higher with ebonite bobbins. A galvanometer for condenser-work should have a large number of turns, and the needles should be damped as little as possible. I have fitted galvanometers with removable vanes and dampers. They can then be used for a variety of work.—G. BOWRON.

[61264.]—**Safety Valve.**—"London Brum" will find the blowing-off pressure to be 55lb. per square inch (nearly) by the following:—28lb. weight × 13½in. length of lever = 378; this divided by 2·75 area of valve, multiplied by 2·5 fulcrum (6·875) = 54·981b. per sq. in.—DROFSIDDE, Belmont.

[61266.]—**Induction.**—Mr. A. E. Conti, one of the cleverest practical electricians of the day, has devised a simple method of effecting this. Let L represent the disturbing circuit (be it telephonic



or telegraphic), and F the telephonic circuit influenced by it. Let the wire F be coiled into a parallelogram as shown, so that at X it comes close to the disturbing wire. By duly regulating the number of coils, it will be found possible to make the induction set up in X, exactly balance and neutralise the contrary induction in F.—S. BOTTONE.

[61268.]—**Soldering Lamp.**—I find Hacking's patent soldering blowpipe answers excellently for this purpose; price about 1s. 6d.—S. BRETTON.

[61274.]—**Cell.**—Many thanks. Have advertised address.—FIX.

[61278.]—**Hot-Air Motor for Organ.**—I have used a Rider's hot-air engine to blow my chamber organ during the past eight years, and have found it admirably adapted for the purpose. Hayward Tyler and Co. are the makers, and they will, if you have gas, supply a gas burner as the source of heat, which gives positively no trouble. You must, of course, have special bellows. Mine I made myself, with automatic arrangement for the feeders to feed into one another when the reservoir is full, and to return to their duty when the reservoir is about three-parts empty. Ordinary ingenuity will enable you to effect this. My bellows are about 20ft. from organ; but the supply of wind is perfectly regular and always ample.—C. H. F. C.

[61279.] — **Rhea Fibre.** — In reply to Geo. Edwinson, I hope shortly to have some band, round and flat, suitable for lathework, &c. I will then advise where it can be got. At present I have some hundredweight of line for twisting, which can be seen at 218, Gresham House, London, E.C.—URTICAN.

[61280.]—**Link Motion.**—If you can refer to "Rankine's Steam-Engine," page 498 will answer your query as to Stephenson's link motion, and possibly the others also. The method given is a close approximation, and finds the equivalent throw and lead of a single eccentric to do the work of the two eccentrics when the block is in a given position of link. The result is that the throw is reduced as the block moves to centre of link, until ultimately it is less than the lap, so that the port is not opened in mid-position. If you cannot obtain access to Rankine, the Editor will possibly reproduce the diagram if you desire.—T. C., Bristol.

[61281.]—**Worm-holes in Violin.**—Reply to 61195 applies equally to your case. See last week's "E. M."—S. BRETTON.

[61281.]— **Worm-holes in Violin.**—Remove strings, bridge, tailpiece, &c. Dissolve 1oz. of naphthaline (albo-carbon) in 4oz. of good benzoline. Pour the mixture liberally over the instrument, so that it soaks well into the wood. Cover the instrument with a blanket for an hour or so, then stand it in a current of dry air. You will be bored no more.—S. BOTTONE.

[61282.]—**Length of Belting.**—Using Rankine's formulæ, as in my reply this week to 61006, the length of each straight portion of belt (when open) is $\sqrt{C^2 - \left(\frac{D - d}{2}\right)^2} = \sqrt{186^2 - 24^2}$ = 184·4in., or 15ft. 4½in. nearly. The single angle is evidently $\frac{4}{31}$ = ·13 nearly, or 7½° as nearly as my tables give; so that arc of large pulley embraced = 180 + 15 = 225°, and of smaller pulley 180 − 15 = 165°. Total length of arcs = $\pi\ 10 \times \frac{225}{360} + \pi\ 6\frac{165}{360} = \pi\ \frac{3240}{360}$ft., or 28ft. 3⅓in. Total length is, therefore, 28ft. 3⅓in. + 30ft. 8¾in. = 59ft., say.—T. C., Bristol.

[61282.]—**Length of Belting.**—In this question the formulæ will differ from those of (61008) p. 329, being with the same notation for open belting.

$$\text{Sin. } \phi = \frac{D - d}{2\ c}$$

$$L = \left\{ D\left(\frac{\pi}{2} + \varphi\right) \times d\left(\frac{\pi}{2} - \phi\right) + 2\ c \text{ Cos. } \phi \right\}$$

In this example D = 10ft., d × 6ft., and c = 15·5ft.

$$\therefore \text{Sin. } \phi = \frac{4}{3} = \text{sin. } 7^\circ\ 24'\ 49''$$

$$\therefore \phi^\circ = 7{\cdot}4136^\circ$$

Hence arc. ϕ = 7·4136 × ·0175 = ·1297

$$\frac{\pi}{2} + \phi = 1{\cdot}5708 + {\cdot}1297 = 1{\cdot}7005$$

$$\frac{\pi}{2} - \phi = 1{\cdot}5708 - {\cdot}1297 = 1{\cdot}4411$$

$$\therefore D\left(\frac{\pi}{2} + \varphi\right) = 10 \times 1{\cdot}7005 = 17{\cdot}005\text{ft.}$$

$$d\left(\frac{\pi}{2} - \phi\right) = 6 \times 1{\cdot}4411 = 8{\cdot}6466\text{ft.}$$

$$\text{Cos. } \phi = {\cdot}99165$$

$$2\,c \text{ Cos. } \phi = 31 \times {\cdot}99165 = 30{\cdot}7411\text{ft.}$$

$$\therefore L \qquad \therefore L = 56{\cdot}3927\text{ft.}$$

Erratum.—In the result of (61008) p. 329 there is an error: L there should be 42·4171, not 22·4171, as will be obvious from the preceding line.—MILVERTON.

[61284.]—**Electro-Magnet.**— Two Leclanches give two to three volts, and an indefinite number of ampères, according to resistance. Use a bar of good soft iron, 15in. long, ⅝in. in diameter; bend it into a horseshoe, so that the legs stand about 4in. apart. Wind each limb with about 1lb. No. 22 s.c. The attractive power of an electro-magnet varies inversely as the cube of the distance.—S. BOTTONE.

[61285.]—**Screw Tool.**—Where is your difficulty? Are you striking the thread by hand-chaser, or cutting up in a screw-cutting lathe? In either case if you can strike the thread to correct pitch and not "drunk"—the thread, I mean, not yourself—I can't see why you cannot get them to fit, unless the inside and outside tools are of different angles of thread.—T. C., Bristol.

[61286.]—**Heating by Means of Paraffin.**—If I understand rightly, you cannot use this effectively without a blast of steam or air, and therefore it is not fitted for boilers for heating a greenhouse. There may be a paraffin oil which burns like ordinary oil without blast. If so, my reply will not apply to such paraffin oil.—R. S. T.

[61286.]—**Heating by Means of Paraffin.**—After wasting some pounds in experiments with hot water, I find by far the cheaper and most effective mode is to use Gillingham's hot-air stoves; the price ranges from 35s. upwards. A paraffin lamp is used as the heat generator. No attention required after lighting for nine hours.—S. BRETTON.

[61286.]—**Heating by Means of Paraffin.**—I should try a large flat lamp of tin with several wick apertures, as many as you may think necessary for the size of your boiler. You could make it yourself, soldering up the tin and soldering and riveting (with little rivets made out of thick copper wire) the wick tubes, which must be a good fit to the wicks. The little toothed wheel of the ordinary paraffin lamp will not be necessary, as you can pull the wick up to the requisite height with the fingers or a pin each day. Keep the bottom of the boiler scraped pretty clean from all coatings of soot, tar, &c. If your lamp should not burn well, and the wick should get soon charred, cut a hole in the top, say, 2in. diameter, and cover it with wire gauze soldered carefully all round the edges.—EDWARD CONRY.

[61287.]—**Tempering Gun-Lock Springs.**—Heat the spring to a red in a charcoal or clear fire, judging the colour in the dark; harden in water. Smoke it all over with a candle or gas smoke, and heat it on a hot plate until the smoke has burned off, then drop into water. N.B.—A little practice is required, and even when that has been obtained, failures occur occasionally.—SAML. RAY.

[61287.]—**Tempering Gun-Lock Springs.**—To harden and temper gun-lock-springs, go to work as follows:—(1) Make your spring of a bright red (not a white welding heat), dip in cold water; (2) take out of water, hold over fire for a few seconds, keeping it on the move till the water on the spring is dried up, and the spring is just hot enough to be held in the hand. Now dip the spring in oil, any oil (candle is often used). Turn the spring over and over, so as to distribute the grease evenly. (The object of warming the spring is to cause an even distribution of the oil). Now have a clear fire. No more smoke than possible. Lay your spring on the top of the fire, turning it in all ways, sides, top, and ends, every second. Do not let it rest more than a second without shifting or turning. Soon you will find your spring all ablaze, or rather the oil on it; when you see the oil blaze, with a tongs lift the spring off the fire, hold it over the fire, say, 6in. above; hold the spring during all stages by the small wire-like stud; but never forget, while the oil is alight, to still keep turning the spring over and over. As soon as the grease ceases to blaze give the spring one or two turns on the fire, but not for more than two or three seconds. Now take spring away from the fire and allow to cool—do not cool it. The foregoing is the method we gunmakers adopt, and if you can follow out the instructions you can't fail. Mind, if your main spring is too long or too short, no matter how well it may be tempered, it is apt to come to grief. Then, do you forge your own? But give your address in the "E. M." if you don't succeed, and I will give the whole secret from beginning to end. No, it is no secret; but I am diffident about taking up too much of the Editor's space. Springs for ordinary locks. Do you mean door and box locks, same as for gun locks? I have made hundreds of them; but where the box-lock spring, &c., is small, it is best to use a penny dip or spirit lamp and blowpipe.—ARMOURER.

[61288.]—**Carmine.**—The following recipe I have tried myself, and have obtained excellent results; it is from a work by Piesse:—Take 9oz. of carbonate of soda and dissolve it in 27 quarts of rain-water, to which are added 8oz. of citric acid; when brought to the boiling-point, 1½lb. of the best cochineal, ground fine, is added and then boiled for 1¼ hour; the liquor is then strained or filtered, and set by to cool. The clear liquor is then boiled again with 9½oz. of alum for about 10 minutes, and is again drawn off, and allowed to cool and settle for two or three days. The supernatant liquor is then drawn off, and the sediment which is fallen to the bottom is filtered and washed with clean cold soft water, and is finally dried by evaporating all the moisture. The result is fine carmine.—CATO.

[61291.]—**To Impart the Appearance of Age to Delicate Wood-Carvings.**—Prepare metal box or cupboard as nearly air-tight as possible, and in it expose your work to the fumes of ammonia. S. BRETTON.

[61291.]—**Ageing Wood Carvings.** — Ammonia gas darkens wood very sensibly; but the stains most used in France and Switzerland are: (1st) Dried walnut shucks boiled in eight times their weight of water; apply cold. (2) Red American pearlash, ½oz.; burnt umber, ½oz.; water, 1 pint. This is very intense in colour, and must be diluted with water if required for lighter tints. Both these dyes to be applied with a stiff brush to insure touching the hollows.—S. BOTTONE.

[61292.]—**The Serious Accident at Carlisle.**—The hose pipe got frozen up between the engine and tender, hence vacuum could not be created. No. of Midland engine 1580, has since been sent to Derby for repairs.—ROVER.

[61292.]—**The Accident at Carlisle.**—The serious accident at Carlisle, which very fortunately was not as disastrous as it might have been, was caused by the failure to act of the non-automatic vacuum brake upon the 8.50 p.m. London and North-Western mail from Euston. The North-Western engine, City of Liverpool, came into collision with Midland engine No. 1580 a considerable distance north of the Carlisle platform. To save the reputation of the dangerous brake, the blame is, if possible, placed upon the unfortunate driver. A rule says, "Drivers must, when approaching, leaving, or passing through the citadel station Carlisle, proceed with caution, and have their engines or trains under sufficient control to be able to stop short of any obstruction that may be upon the joint line, whether the signals indicate danger or not." In the present case the driver did his best to obtain control over his train; but when the brake failed to act he was powerless. This accident is another which results from the North-Western Company neglecting to adopt an efficient automatic continuous brake. — CLEMENT E. STRETTON, Consulting Engineer Amalgamated Society of Railway Servants, 40, Saxe Coburg-street, Leicester, 1st Jan.

[61293.]—**Compound Loco. on Cal. Ry.**—The engine proved useless. It left Perth for Carlisle with the Highland express on Saturday, Dec. 18, but failed between Carstairs and Carlisle; at the latter place, when it arrived, the gear was all out of place and only one cylinder in use. The Saturday previous, with the same train, the engine failed utterly at Carstairs. Yes, the number is 124, and it was at the Edinburgh Exhibition. The engine has since been patched up and sent to St. Rollox, where it is being attended to under the direction of Mr. Drummond.—ROVER.

[61295.]—**Turning Slate.**—Use carbonado. Slate will never (in reason) turn the nose of the tool; it will cut rock, rock-crystal, and hardened steel.—R. S. T.

[61296.] — **Gas - Burners.** — In reply to "W. S. A. B.," burners consuming a mixture of gas and air have the gas jet so adjusted that a certain definite proportion of air is drawn in with the gas. When the burner becomes heated the air expands, and as the burner is constructed to pass only a definite *bulk* of air, the expansion by heat reduces the actual quantity of air drawn into the burner, destroying the correct proportions, and causing the flame to have a deficiency of air mixed with the gas. If the burner is cooled the proportions correct themselves and the flame again becomes clear.—THOS. FLETCHER.

[61297.]—**Pepper Mill.**—I am not engaged in this; but the foreman at Messrs. Dell, of London, told me French burr stones are used for grinding pepper, but that there is a little difference in the dress of stones to that for wheat, &c., the ordinary stones, with a top runner, being used.—T. C., Bristol.

[61298.] — **Armature.** — The Cabella armature will be found fully described in the recent edition of Prof. S. P. Thompson's book on "Dynamos," at p. 124.—BOBADIL.

[61298.]—**Armature, Cabella's.**—A form of ring armature recently devised by Signor B. Cabella closely resembles the form of Gramme armature. It is built up of copper strips. These are separately cut out, and consist each of a straight piece, having two arms projecting at right angles; a sleeve of insulating material is placed over the axle, and round this these copper pieces are arranged to the number of some 240 or so, having their arms projecting symmetrically round in two radial sets, one near one end and the other near the other. The channel formed thus between the two sets is lined with insulating material, and then entirely filled up with soft iron wire wound round. Then straight strips of copper 8 millimètres broad and 2 millimètres thick, are screwed across the outside, nearly parallel to the axis, from the ends of one set of radial projections to the ends of the others, forming a parallelogram section. But in order to connect the ring all round in a continuous circuit, these external strips of copper are connected at their two ends to pieces which project, not from the same internal copper strip, but from adjacent strips. Thus an external bar will connect the anterior end of the first strip with the posterior end of the second, and so on. Every third strip is carried along the axle, and connected to a segment of the collector. According to Prof. Ferrine, one of Cabella's armatures placed between the poles of a 60-light Edison ("Z," old pattern) instead of its ordinary armature, increased its powers so that it could be used for 150 lamps. More recently Signor Cabella proposed to make the external strips of iron and very deep radially, so as to dispense with the iron wire winding. See Thomson's book on "Dynamo-electric Machinery," pages 125 and 126.—S. BOTTONE.

[61299.]—**A Capricious Dynamo.**—I should suggest that the caprice is that of someone who has meddled with the connections of the field-magnet coils.—SIGMA.

[61299.]—**A Capricious Dynamo.**—The series coils on your field-magnets are the cause of your trouble. The back current from your bath flows round them and reverses the magnetism when the shunt coils are nearly inactive. You are also probably working the machine at a lower speed than it was made for. As for the residual magnetism, seeming irregularities in a mass of iron, which is made of hard and soft metal united, are not worth puzzling over. Disconnect the series coils of your field-magnets and use the shunt only. The machine was not intended for plating purposes; but will do very well without the series coils.—L. MILLER.

[61301.] — **Amateur Workshop.** — Brass foundry; yes. I believe it is a rule absolutely without exception. It is so in the case of the most refractory metals, as gold and platinum, as well as in that of metals used for solders and fusible alloys. —J. H.

[61304.]—**Emery Wheel.**—Buy them. Don't try to make unless you have plenty of leisure, plenty of apparatus, and, above all, plenty of spare cash. If you want extra good, get them made of corundum by the makers of dental wheels. If you will try and make them, first make sure (of which I am far from sure, and even believe to the contrary) that glue will not be found to be the real and efficient binding material—certainly not if to be used wet.—R. S. T.

[61304.]—**Emery Wheel.**—The querist who wishes to make an emery wheel of emery and glue should insure his life before he attempts to use it. If he wants a solid emery wheel, let him buy one properly made, or make some emery buffs by procuring suitable discs of willow or alder, coat the edge with glue, and sprinkle on emery, renewing as required. A wheel compounded of emery and glue would be what is known in the shop as a "caution"—that is, it would not only be dangerous, but it would not do what it is required to do, which, by the bye, is not stated.—SAML. RAY.

[61305.]—**Aluminium in Dentistry.**—"Story" overlooks the fact that aluminium is extremely soluble in weak organic acids, such as vinegar, and is therefore unfit for dental purposes.—THOS. FLETCHER.

[61305.]—**Dental Composition and Aluminium Solder.**—"Story's" last question as to solder is perhaps right and proper to be answered, and is, indeed, an interesting query; but is it right to ask manufacturers how the "compositions" of their trade are made? "Story" may be an opponent. "Godiva" is a well-known article. Should the makers be expected to give the receipt?—R. S. T.

[61305.]—**Dental Composition and Aluminium Solder.**—Seeing that the "Stent," "Godiva," and "A 1" modelling compositions are private property, it would be more in keeping with the "fitness of things" for "Story" to apply to the proprietors for the formula. Up to the present date there is no aluminum plate or solder in the market suitable as a base for artificial dentures, because it is subject to oxidation in the mouth, very much the same as zinc, as also being deficient in the needful strength to resist wear and tear, like the gold or dental alloy plate.—DENS.

[61306.]—**Question in Mechanics.**—This has been answered very fully by "M.I.C.E.," in October or first half of November, I believe. Perhaps "M.I.C.E." will give you the number. —T. C., Bristol.

[61306.]—**Question in Mechanics.**—A similar query to this was replied to by me in the "E. M." of Sept. 24th, page 91, under the heading "Hydrostatic Pressure." The resulting equation being $x = l(1 - \sqrt{1 - s})$ where l is the length of the rod or beam, x the length of submerged portion, and s the specific gravity. In the present case $l = 12$, $s = \cdot 7$. If these are substituted in the above, we get $x = 5\cdot 43$ft., which agrees with the answer given

in the query. As regards the thread taking a vertical position, the submerged portion is pressed upwards by a vertical force acting at its centre of gravity, the other portion being similarly acted upon downwards, both these being vertical forces. Now, if the suspending thread is sloping, there will be a horizontal pull or thrust, and as there is nothing to counterbalance this, the rod must move sideways until the thread is vertical.—M.I.C.E., Bath.

[61308.]—**Amateur Workshop.**—You can only get such small quantities by applying at a brass foundry, where you could no doubt get a bag full for a few pence.—J. H.

[61309.] — **Photographic — Removing Varnish, &c.**—Make a strong solution of common washing-soda in hot water. When cold, immerse the plates in one by one. Allow them to stand 12 hours. The varnish films will be found to float off. If the plates are gelatine plates, they must be put in a saucepan with cold water, and a bit of soda as big as a walnut, and then boiled for five or ten minutes to melt the gelatine. Methylated spirits will dissolve varnish; but not gelatine. If, however, it be desired to remove the varnish from the negatives, without destroying the film, methylated spirits will do for collodion pictures, and benzole for gelatine. The second query would require an advertisement to reply to it. Look in the advertisement sheets of this year's *Photographic News Almanac*.—S. BOTTONE.

[61310.] — **Electricity.** — An induction coil giving 3in. spark would do this effectively. Price about £8.—S. BRETTON.

[61310.]—**Electricity.**—To kill a dog, perhaps a strong battery of Leyden jars would be most suitable. They would, of course, require to be charged by a good electric machine. A powerful induction coil might also do; but the jars would be be cheapest.—BOBADIL.

[61310.]—**Electricity.**—A good induction coil, giving about 2in. spark, and costing about £2 to make, would kill a dog if the shock were made to pass along the spinal column. But would it not be more merciful to use prussic acid, or the carbonic-acid chamber?—S. BOTTONE.

[61310.]—**Electricity.**—This is a large question. It goes from the battery for the diamond light on the hair made in a thimble to the biggest dynamo made. A man was killed at one of the exhibitions by putting both his hands on a dynamo, and so "short-circuiting." If so, a dog could be made to do so, and he would be killed on the spot as the man was. The query suggests a possibly humane death for half-starved or injured animals. Only let the current be strong enough to insure instant death—no lingering.—R. S. T.

[61310.]—**Electricity.**—It depends a good deal on the dog and the degree of vitality he possesses. There are certainly electrical machines in existence, and plenty of them, that would kill a dog, or 20 dogs, in an instant; but the cheapest are far beyond what any humane society would care to spend, as they range from the £500 arc-lamp dynamo to the £20 induction coil. I have killed a cat with a 1in. spark, and should certainly think the same means would do for a dog; but these powerful coils are dangerous playthings. Any experimenter who gets even a ½in. spark through him will have cause to remember the incident for a very considerable period; and in handling and adjusting coils, unless great caution be observed, the experimenter is very apt to get an accidental shock, and such an accident, with a coil powerful enough to kill dogs, might possibly produce entire or partial paralysis for life. Probably a specially-wound coil would have to be made, as some current (i.e., a fat spark) is required. A ¼-amp. spark at sufficient tension will kill almost any of the more highly-organised living creatures, from the human species downwards. A much more satisfactory way of disposing of animals is stifling with charcoal fumes, morphia, or ordinary coal-gas. The latter is the method employed at the Dogs' Home.—EDWARD CONRY.

[61310.]—**Electrical Slaughter.**—There are plenty of machines which would kill a dog, or an induction coil would do it. The best way would be to charge a battery of Leyden jars up to the required degree.—SIGMA.

[61311.]—**Water-Resisting Cement.**—Is there any objection to marine glue?—S. BRETTON.

[61311.]—**Water-Resisting Cement.**—Will not Portland cement—either neat, or 1 of sand to 1 of cement—do for this?—T. C., Bristol.

[61311.]—**Water-Resisting Cement.**—The cement made of rubber which can be dissolved in naphtha called water-proof cement. I forget its other name. It is made of rubber and shellac. Buy it; don't make it, or be careful of setting yourself and the house, or both, on fire.—R. S. T.

[61311.]—**Water-Resisting Cement.**—Under what conditions is this cement to be used? Hydraulic cement will answer the conditions stated in the query; but perhaps "Selim" wants something more. Aquarium cement may possibly suit him: Take three parts each of litharge, fine white sand, and plaster of Paris, and one part powdered rosin. Mix into a paste with boiled linseed oil, to which a little driers has been added, and let it stand for several hours (mix at night and it is ready in the morning); but five is long enough. Be sure to have all ingredients reduced to fine powders and mixed intimately.—SAML. RAY.

[61311.]—**Water-Resisting Cement.**—There are various kinds of cements, each adapted for a special purpose. You do not say for what purpose you want the cement. For insulators—sulphur, lead, or plaster of Paris mixed with a little glue to prevent too rapid setting. For tanks—Portland cement. For glass and metal—best and purest gum arabic put into a small quantity of water, and left till next day, when it is of the consistency of treacle. Calomel is then added to make a sticky mass, and well mixed on a glass or china plate with a spatula or knife-blade. No more should be made than is required for immediate use. The cement hardens in a few hours, but it is better to leave it for a day or two.—EDWARD CONRY.

[61313.]—**Making Cotton Fabric Fireproof.** Prepare a solution of tungstate of soda in water, about 4oz. to the pint. Soak the articles in this solution, and hang them up to dry.—S. BOTTONE.

[61313.]—**Making Cotton Fabrics Fireproof.**—What is meant by "fireproof"? A solution of alum or sal-ammoniac will render most textile fabrics uninflammable; but the best thing is a solution of tungstate of soda, to which a little phosphate of soda has been added.—NUN. DOR.

[61313.]—**Making Cotton Fireproof.**—Soak it in strong solution of alum in water. Experiment with different strengths on small pieces of material, as if you have the solution needlessly strong it crystallises on the threads and renders the fabric clammy in wet or damp weather.—EDWARD CONRY.

[61314.]—**Footpaths.**—If the footpaths have ever formed part of a "right of way," the farmer must not plough them up, even if they traverse his fields.—SAML. RAY.

[61315.]—**Joints in Water-Pipes.**—Ten years ago I laid similar pipes, only of larger size, under the bed of a navigable river, and used rings of sheet lead to make the joints. The work was and is entirely satisfactory.—SILEX SEADRIFT.

[61315.]—**Joints in Water-Pipes.**—If faced joints, use red-lead putty, and as little as you can, pulling the joint well together; or you might obtain some soft "vulcanised fibre" washers from Mosses and Mitchell.—T. C., Bristol.

[61315.]—**Joints in Water-Pipes**—1. Get some old rope, worn and soft, and rub red lead well into it (red lead, in powder, worked up to a paste with boiled oil); then lay the rope in a ring on the surface of one flange, lapping the ends neatly over one another, having previously worried them out pretty loose, and bolt other flange down on it and pull up tight. 2. Similar old rope, with powdered chalk and water in a wet paste. 3. Similar old rope, or thick cord plaited in three and well-rubbed with powdered plumbago and grease, as little of the latter as it will work with well. 4. Ordinary flat-plaited lampwick with red lead (as in 1), or white and red lead powder (two-thirds to one-third), or chalk; this makes a very neat joint. For cold water all these will do, and without no extreme pressure are about equally good, with perhaps the first for preference.—EDWARD CONRY.

[61317.]—**Gilding on Glass.**—There is a process described in "E. M.," December 18th, 1885, page 315, in which the glass is painted with nitro-muriate of gold and the gold then reduced by hydrogen. I do not know whether this is the process you mean; but I hope it may be of use.—LONDINIENSIS.

[61319.]—**Photographic.** — To "BOBADIL" AND G. EDWINSON.—The acid must be entirely driven off the chloride of gold by heat.—BOBADIL.

[61320.]—**Static and Potential.**—The former case is, as you state, potential, as the spring tends to recover itself; but, in the case of the string, the stretching is practically *nil*, and has, therefore, no perceptible tendency to fly back. Of course, it stretches a trifle, and if the weight rested on the table it would compress that a trifle; but it would not jump up if weight were suddenly removed, however light the table.—T. C., Bristol.

[61321.]—**Brake Failure.**—The vacuum brake failed to act promptly. Midland vacuum, engine 1748.—ROVER.

[61321.]—**Brake Failure at Appleby.**—The Midland up express ran past Appleby because the automatic vacuum brake failed to bring it to a stand at the platform. The number of the engine was 1748.—CLEMENT E. STRETTON.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

QUERIES.

[61322.]—**Induction Coil.**—To MR. BOTTONE OR E. CONRY.—I am constructing a coil; but when asked what sort of coil it is I cannot answer, as I get confused with the terms induction, medical, and intensity. Please say if they are all got up the same way. If not, what is the difference? I would like an intensity coil, also to be used as a shock coil. Can I use a tube regulator?—D. NICOL.

[61323.] — **Back Shaft for Sliding and Surfacing.**—To "J. H.," OR OTHERS.—Would it be asking too much if "J. H." would give particulars for applying a back shaft to the lathe he described in his articles some time back, or will someone do the same for a 6in. centre lathe?—T. C. C.

[61324.]—**Hardening and Tempering Small Saws.**—Would someone oblige with instructions as to the best way for doing this? Saws 1½in. in diam., and very thin. They are used entirely for cutting metal, and the difficulty is to avoid warping.—T. C. C.

[61325.]—**Fitting Glass Stoppers.**—Will someone instruct querist how to grind the stoppers of cruet bottles to make them a good fit?—W. CHICK.

[61326.]—**Pump Valves.**—May I trouble "T. C., Bristol," further to tell me the length of plug and shell of ¼in., ⅜in., ½in., ¾in., and 1in. steam cocks of first-class quality, with highest pressure they will work well? Is it better to screw them up in their place with a lead washer, or screw up with red lead and hemp?—YOUNG TURNER NO. 2.

[61327.] — **Potentiometer.** — To "SIGMA." — In measuring the E.M.F. of a cell by the potentiometer method, two other cells are usually employed—viz., a standard cell in series with a galvanometer, and a cell or battery having an E.M.F. greater than that of the standard cell, against which it is balanced by means of a variable resistance. Is this second cell essential? Would it not answer to connect the ends of the potentiometer wire with two Daniell cells in series, thus giving a difference in potential of $1{\cdot}079 \times 2 = 2{\cdot}158$ volts, and divide the potentiometer wire into 2,158 equal parts, so that by using one galvanometer in series with a cell, its E.M.F. could readily be determined to ·001 volt? I wish to fully understand this subject. Will you kindly assist me?—ELECTRICAL STUDENT.

[61328.] — **Electrical Measurement.** — To "SIGMA."—I am experimenting with different voltaic combinations, using for my experiments small single cells (elements about 3in. by 1in.), and wish to construct a compact form of instrument to measure the E.M.F. and current yielded by each combination. I have thought of a tangent galvanometer having a ring about 8in. diam., wound with one turn of copper band for measuring current in ampères, and a great many turns of fine insulated wire for measuring E.M.F. in volts. Would an instrument so constructed be likely to answer my purpose? A range of eight or ten ampères and three or four volts will be sufficient. What must be the resistance of the fine wire coil? Will 500 ohms be sufficient?—ELECTRICAL STUDENT.

[61329.]—**Dynamo.**—Many thanks to Mr. Bottone for his prompt and specific reply. I will follow his advice and make my dynamo of the A Gramme pattern. I mean to have the F.M.'s forged, and want to know the diameter, and whether there would be any advantage in forging the pole-pieces, or is cast iron better? If a casting, is it essential it should be soft? There appears in figure of Gramme a plate joining the pole-pieces. Is it of brass, and is it insulated from the pole-pieces? There also appears a rod from lower pole-piece to the right-hand side of frame. Is there one from upper pole-piece to left side of frame, and what is their use? How many sections should I have in the armature, and what the diam. of the commutator? Is it 3lb. of No. 16 on each magnet? 8lb. is what is recommended in 61119, where the power is only half. It will require 16lb. of No. 16 to give "a little more" resistance than the 4lb. on armature. No one will more gladly welcome your article on ring armature than—BRIAN BORU.

[61330.]—**Legal—Bad Dry Plates.**—I bought some plates for lantern transparency, and I found they had lost their sensitiveness. I returned them to the vendor, who said he was only an agent. He spurned the idea of allowing for them, or exchanging. He advised me to take them to the makers. I told him that as he had taken the money he was responsible to me, and not the makers. There was no fault in development. I am an expert hand at the same makers' plates. This is a question which concerns many besides myself. I believe the plates became damp while in the agent's warehouse. I shall be glad to know the law on this point.—J. W. ELPHEE.

[61331.]—**Electric Light.**—Will any kind reader of "Ours" inform me if a cable containing 19 copper wires No. 18 B.W.G. will supply more than twenty 20c.p. incandescent

lamps a distance of 300 yards from dynamo? Also what is the cause of filaments breaking in two, about ½in. from connection of platinum wire? I have two of Edison-Swan lamps gone in this way.—ELECTRIC.

[61332.]—**Speeding Millstones.**—To "T. C., BRISTOL," OR "GLATTON."—I have a water corn-mill. Water-wheel shaft runs 5 revs. per minute, which is unalterable. On the end of water-wheel shaft hangs a bevel wheel of 120 cogs, 3in. pitch, which works into a pinion on vertical shaft of 40 cogs. On top of vertical shaft is a spur wheel of 180 cogs, working into the stone pinions of 24 cogs equal to 112 revs. (I am aware the size of spur wheel must be guided to some extent by the number of stones placed around it); but if we leave this out of the question, it amounts to this: the power makes five revs. and the stones are required to go 112. How is this speed best obtained? I have heard some say they do not like to get up too much speed in the first motion; others that you cannot get it up too soon. Does it cause any waste of power whether you get it up in the first or last motions? If you will give me your opinion, and state your reasons fully for such opinion, I should take it as a very great favour, for I am at a loss to decide, and as I am about to have a new set of machinery in, I am anxious to obtain some reliable advice (which I cannot obtain in my neighbourhood), and the opinions of the men here who will do the job are so opposite.—A COUNTRY MILLER.

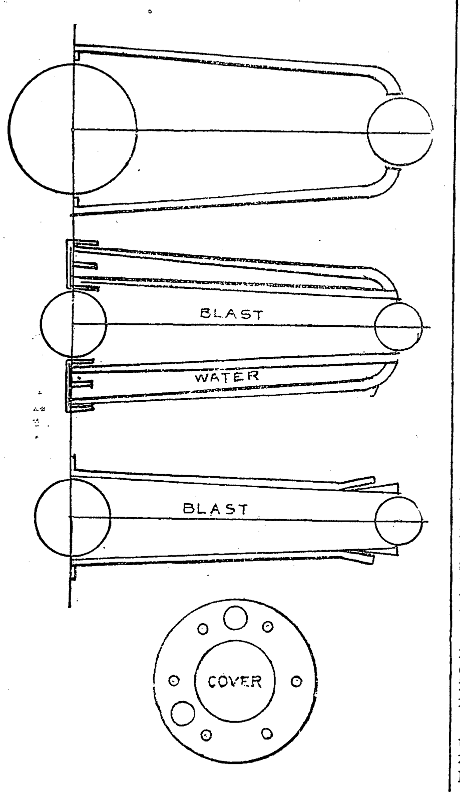
[61333.]—**Air Compression.**—I require an air-pump that will compress air to the highest pressure possible rapidly. Will your readers give me information how to make one, and the means usually employed to obtain the above results which I require? I have looked through "E. M." (as many as I now have of them) since it came out at a penny, but the information seems very imperfect. Also, will any reader give me his opinion which maker is the best for my purpose?—UNSUCCESSFUL.

[61334.] — **Preparation for Mixing Bronze Powder.**—Would "Nun. Dor." oblige by giving further particulars of the special varnish he mentioned in last week's issue, and is the powder mixed in the varnish, or is it simply varnished after the powder is on, and will you give proportions of lime and turps used?—R. BENNETT.

[61335.]—**Clark's Soap Test.**—Will any reader tell me how to use Wanklyn's standard soap solution and a graduated dropping tube? I have to ascertain the degrees of hardness in water, and how many grains carbonate of lime does one degree mean, and how much washing soda will precipitate one grain of carbonate of lime?—BOX 4, Northallerton.

[61336.]—**Geometrical.** — If the sides of a right-angled triangle which contains the right angle be the diams. of two circles, prove that the square on the part of the common tangent included between its points of contact with the two circles will be equal in area to the triangle.—PUZZLED.

[61337.]—**Brazing Copper Water Tuyers.** — Would some reader inform me the best appliances for brazing copper tuyers, as shown in drawing? There is a



ferrule fitted in the single tube, which I cannot succeed in brazing to circle. Could it be done in a forge fire, or is a furnace required for such class of work?—IMPROVER.

[61338.]—**Coiling Wire.**—Could any correspondent tell me how to coil a continuous length (or otherwise) of wire, rectangular in shape, such, say, as the coils used in the manufacture of the expanding metallic garter? When I wrap a piece of wire round a flat piece of steel (rectangular) I find I cannot get it off; but when forced off, instead of lying flat as the coils of Garter does, the "spring" comes out of wire, and they form a sort of Archimedean screw.—WILLIAM.

[61339.]—**Steam Boiler.**—Will any of "ours" kindly inform me what working pressure a vertical copper boiler will safely stand 3ft. high from crown to bottom, diam. 1ft. 6in., thickness of body, 4-16ths; crown and bottom, 6-16ths; 30 copper tubes, 1in. diam. Also, what power would it be considered?—W. F. D.

[61340.]—**Gramme Dynamo.**—I think of making a Gramme dynamo of the following dimensions: Armature, 3in. long, 4in. diam., ½in. thick, made of 18 B.W.G. iron wire, covered with tape, 3lb. of 18 d.c.c. wire on armature; F.M., 12in. long, with 3½lb. of 16 d.c.c. wire on each F.M.; pole-pieces, 5in. high, 3in. wide, 1½in. thick. The poles are 1½in. round, wrought iron, and 7in. long. Please say if it is as it should be, and what power I may expect.—ANXIOUS.

[61341.]—**Colouring on Parchment.**—Would any kind reader inform me how to colour plans on leases, &c., properly? My colour penetrates into the parchment here and there when it is an inferior skin, and looks patchy. Is it usual to damp the skin, or apply any kind of preparation before colouring?—T. GRIFFITHS.

[61342.]—**Problem.**—Will some mathematical reader kindly solve the following problem in solid geometry? Given three planes, A, B, C, cutting each other. The inclination of A to B is α, the inclination of B to C is β, and the angle between the line of intersection of A and B, and the line of intersection of B and C is ω. Find the inclination (θ) of A to C. Can any correspondent recommend a good work on the analytical geometry of—THREE DIMENSIONS?

[61343.]—**Milling Machine.** — Which is the best milling machine extant for brass tap and valve making? Sketch will oblige—BRASS FINISHER.

[61344.]—**Lathe Matters.**—Will any master of the lathe kindly instruct me how to chuck corozo (vegetable ivory) and coquilla nuts, and the best articles to turn them into and tools to use? I have had a few of such presented to me.—A NOVICE.

[61345.] — **Pneumatics.** — Given two air-vessels balanced in water (gasholder fashion), the larger of which contains 200 cubic feet of air at a pressure of 5lb. per sq. in., and the smaller 14 cubic feet at a pressure of 5¼lb. per sq. in. (both above atmosphere). If the two vessels are connected by means of a pipe, what would be the diminution of bulk in the lesser vessel due to the distribution of a part of its contents in the larger vessel, it being understood that before making the connections the larger vessel is full and unable to rise, and that any increase in pressure in it can only be met by displacement of a part of the water in which it is balanced? What is the specific volume of air at each 5lb. per sq. in. increase to 100lb. above atmospheric pressure, and what work is there on pneumatics dealing explicitly with the subject?—PNEUMATIC.

[61346.]—**Cementing Lenses.**—I am desirous of cementing together a 3in. Grubb view lens, which I have taken apart to clean. The Canada balsam I have seems to bear a yellowish tint. How can I decolorise it? Should I mix anything with it? Am I right in assuming the above lens will cover 12 by 10?—J. H.

[61347.]—**N.E.R. Locos.**—Could any correspondent give a description and dimensions of the new compound express and goods engines which have lately been built for this railway? A description of the cabs in particular would be acceptable; they seem just the thing that has been wanted. A sketch would interest many of our readers.—W. T. C.

[61348.]—**Length of Chord.**—Is there a simple arithmetical method of finding the length of chord when the radius and the length of arc are known?—J. F., Auld Reekie.

[61349.]—**Spinning Metal.**—Will one of these, our kind friends, give me a few hints on spinning metals in the lathe? Have heard of such a process, but am quite ignorant how to proceed.—A NOVICE.

[61350.]—**Air-Gun.**—A reader of the "E. M." has an air-gun. It is made of gunmetal, and shaped to imitate a walking-stick. There is a screw about 1ft. from the handle end of the gun. On unscrewing this, a nipple (like that of a pistol) is seen on the longer part of the gun. In the shorter part, or head, of the stick is seen a strong spring. Should this spring be close against the trigger? How is the air forced in to load the gun?—HEXHAMONIAN.

[61351.]—**Dip for Ironwork.**—Having a quantity of light wrought-iron work to black, would be glad if any reader would help me. Have tried dipping them in tar, but they take too long to dry. I want to do them cold, if possible, and dry quickly.—VILLAGE BLACKSMITH.

[61352.]—**Lantern Exhibition.**—Would some kind reader aid me in the following? I intend giving a magic-lantern exhibition, to last during three hours. How many slides ought I procure for that time, and what subjects would be most suitable? Can good slides be made from the "lithographic lantern pictures," which I see advertised?—TERRANOVA.

[61353.]—**Spiral.**—I would be much obliged if any reader would give me any formula, or describe any means of, estimating the length of a spiral. I have books showing how to estimate circumference of circles, &c., but no mention of a spiral.—SPIRAL.

[61354.]—**Photographs.**—(1) Why do photographs turn yellow after having been mounted? Red spots also frequently appear. (2) With what plates can moonlight photographs be taken?—DUSTY MILLION.

[61355.] — **Astronomical Photographs.** — Will "F.R.A.S.," or others, kindly give a little of the *rationale* of star photography—(1) an idea more or less of the photo. instrument employed, (2) length of exposure, (3) if for fixing position of a group of stars an instantaneous exposure would be sufficient, so as to avoid use of equatorial as in the particular case unnecessary? Whether, for instance, a Zenith arrangement is made so as to compare with star map after photo. is taken? Meaning of "southings"?—PYNX.

[61356.]—**Force Pump.**—I have an ordinary lifting pump, which I want to replace by a force pump, the water to be lifted from a depth of 25ft. and discharged to a height of 80ft. over a distance of 120 yards. Will some talented reader kindly say what kind of pump would meet the purpose best, what diam. of pipe would suit best, and diam. of pump barrel? Water required daily, say, 150 gallons. I was thinking of driving pump from a horizontal shaft with eccentric and flywheel, with two handles, one each side of framing, and put a couple of men at each. Would this do?—YOUNG MILLER.

[61357.]—**Shafting.**—I have ten brackets and shafting to fix to wall. Shafting, 13ft. from the ground. How am I to commence about the job and have shafting level and in line? Is such information to be had from any book?—ANOTHER WORKMAN.

[61358.]—**Dead Point.**—How am I to get the dead point of a horizontal engine, so as to test slide valves?—ANOTHER WORKMAN.

[61359.]—**Engine Brasses.**—How are the brasses accurately marked for boring in the bearings of triple expansion engines of the vertical type, and how are the tunnel bearings accurately lined for the shafting?—ANOTHER WORKMAN.

[61360.]—**Revolving Apparatus.**—I am using as an advertisement in my shop window an octagonal frame carrying panes of ornamental glass with lettering. Stands 9in. high, diam. 10in., weighs about 4lb., and revolves on a spindle worked by a band passing from the grooved wheel to an electro-motor. I wish to make something like clockwork, which can be wound up in the morning and run several hours without trouble, as I find the motor a trouble. Can any reader assist me? The simpler the mechanism the better, the motion to be very slow, so as to enable the lettering to be read as it revolves.—S. N. P.

[61361.]—**Orthographic Lens by Ross.**—I have seen one of these lenses, ⅝in. diam. (combination), and was struck with the marvellous definition and depth of focus. I am told by the makers they have discontinued to manufacture this kind of lens. Will any of your readers who know something about this lens kindly give me their opinion about its general usefulness? I am aware it is slower than the more modern lenses.—A. B. C.

[61362.]—**Faulty Dynamo.**—To MR. BOTTONE, OR E. CONRY.—I have made a series-wound dynamo, with upright wrought-iron cores and laminated pole-pieces top and bottom. The cores are 4in. by 3½in. by ⅜in., the yokes 8in. by 4in., weight 20lb. It is wound with 7lb. No. 16 d.c.c. wire. The armature is laminated, 4in. by 2⅜in., and wound with ¾lb. No. 20 d.c.c. wire. The insulation is all right, and when run at 2,000 revs. does not give as much current as a pint bichromate cell; but when the cell is coupled in circuit with F.M.'s it makes two 10c.p. lamps red, coupled in parallel. I have tried it coupled in every way I can think of, with no better results.—R. M. G.

[61363.]—**Decrease of Sun's Heat.** — Balfour Stewart says ("Elementary Physics," p. 220) that the decrease of the sun's heat when it is near the horizon is due to the greater obliquity of the surface of the earth to the sun's rays. Surely this can only account for a little of the difference, as a surface, held even perpendicular to the sun's rays, when it is low in the sky, is very little heated. Is not the absorption by a greater extent of atmosphere the chief cause?—J. C. O.

[61364.] — **Driving Lathe.** — Will some of our engineering friends give me the best practical way of driving a 4½in. screw-cutting foot lathe with a 2-man Bischop engine (gas)? The pulley on engine is 13½in. diam., with 5in. face. The lathe has V-pulley and wheel for gut. I am desirous of knowing size of pulleys, and best plan of placing them to get the necessary speeds for general turning of wood or metals, the shafting to be suspended from ceiling.—C. A. F.

[61365.]—**Paraffin.**—The other day I asked an old gunsmith what he used to keep his guns, &c., free from rust, to which he replied neatsfoot oil, and on my suggesting the mixing of a little paraffin with it, he said that all mineral oils turn more or less to water. Is there any foundation for this statement? I have used paraffin often enough on machines of my own without the least appearance of water.—G. M. S.

[61366.]—**Super-elevation of Railway Curves.**—Will any kind reader give simple rules for super-elevation of outer rail on curves? I note the Gov. Inspector, reporting on the accident on the G.N. of Ireland, talks of the "ordinarily received rule" giving for a 30-chain curve at 45 miles an hour 4½in. elevation. How to work that out in simple figures is what will oblige—A PLATE-LAYER.

[61367.]—**Weight of Engine.**—After the run off at Portadown, the engine was weighed with chimney towards Dublin and then towards Belfast. I see by the papers the engine was heavier when in one direction than the other. How can this be?—LOCO.

[61368.]—**Newcastle and Carlisle Ry.**—Wanted, the date when this line was opened and the class of engines first used on it.—INQUIRER.

[61369.]—**Gedge's Railway Coupling.**—Will any reader say what this coupling is, and also if it was tried at Nine Elms or Derby?—CAR. DEPT.

[61370.]—**Block Tin.**—What is it? Tin plate, we know, is iron or steel coated with tin. A block tin saucepan I have always understood to be the same, only better, and more thickly coated with tin; but a block tin pipe—what is it? Is it not a pipe made of tin, or an alloy of tin, for we seldom nowadays get anything made of a pure material?—R. S. T.

[61371.]—**Tempering and Doctoring Steel.**—Is not the compound of rosin, linseed oil, glycerine, and powdered charcoal (described in letter 26645) the same as charcoal and lime in its action, only in a liquid state? Charcoal and lime (CaCO), not really lime, but chalk, is a wonderful agent for steeling surface of iron.—R. S. T.

[61372.]—**Electro-Magnetism.**—Could anyone tell me how an electro-magnet could be constructed so that when Morse signals were sent through it at about 20 words per minute, it should remain permanently attracted, but should rise as soon as the sending was stopped?—A. J.

[61373.]—**Theatre.**—Would any of your readers oblige by giving information how scenes are rolled up—if they can be pulled up by one person, and how?—J. BEARD.

[61374.] — **Vegeto-Alkaloids.** — Can any correspondent inform me of a work that treats on the above, as to preparation, properties, &c.? Also the price?—G. J. MOULTON.

[61375.]—**Chemist (Dispensing).** — I shall feel obliged if any of your experienced correspondents will inform me of the course of training most suitable for, and required to enable, a person to qualify as a dispensing chemist; also a short statement of examination it is necessary to pass.—SCRUPLE.

[61376.]—**Moss.**—A very common plant used in ornamenting rockeries, &c., is called "golden moss." It bears yellow flowers. Is it really a moss, and what is its botanical classification? Give its life-history.—DISCIPULUS.

[61377.]—**Arc Lamp.**—Will one of our electrical contributors kindly give me the proportions between the wires of the main coil and the shunt coil in an arc lamp, taking 45 volts and about 15 amps.? It is to run sometimes with incandescent lamp and sometimes without. Under the present arrangement the current in the small coil increases when the arc shortens. Is that necessary when running glow and arc lamps together? How would it do if I arrange the wires that the current in the shunt increases with the main current, and, of course, reverse the action of the brake?—ARCHER ASHBY.

[61378.]—**Mechanics.**—Many thanks to "T. C., Bristol," and others, for noticing my queries. I should be pleased for help in the following questions: The breadth of a water passage closed by a pair of gates is 10ft., and its depth is 6ft. The hinges are placed at one foot from top and bottom. What would be the strain on the lower hinge when the water rises to the top of gate on one side? Also how to find the pressure on the internal surface of a sphere when filled with water? Is it equal to three times the weight of the water in the sphere?—NOVICE.

[61379.]—**Trocadero Organ.**—Would some correspondent give the specification of the concert organ at the Trocadero, Paris? There is, I believe, a very wonderful "Mixture," the details of which would be interesting to amateurs.—C. C.

[61380.]—**Engine Query.**—Will any reader kindly tell me if an engine with two cylinders, 2in. in diam., 6in. stroke, will turn a circular saw 12in. in diam., and how much steam I should require? I have had 15lb. of steam, and cannot get it to turn the saw. The band works off the flywheel. Flywheel is 20in. in diam.—R. S. C.

[61381.]—**Opal Plates.**—Will someone kindly give me a few instructions in taking pictures on the above plates? I have tried them with the Beach developer (by contact printing), and I obtained such extraordinary results that I am quite puzzled to know when exposure is correct and development complete; also when to tell when they are fixed?—A. P.

[61382.]—**Instantaneous Exposures.**—During the summer I tried a few, and was surprised to find them much under-exposed. I started at a view lighted up as strong as possible by the mid-day sun, using the full aperture of a R.R.S. lens and a drop shutter without a band, so that it only fixed slow-moving objects. I used the Beach dev., which I am told is well suited for all kinds of work and several kinds of rapid plates. Can anyone tell the cause of my failures?—A. P.

The Archæology of Artificial Limbs.—The history of medicine is all but silent on orthopædic surgery. And yet the Greeks and Romans, who, as archæology has shown, had anticipated much of modern dentistry, cannot have been without artificial substitutes for limbs lost in the vicissitudes of peace or war. Herodotus tells us of a captive who amputated his foot to free himself from the shackle, and thus escaped to his friends, who replaced the limb by a wooden one. The Elder Pliny ("Nat. Hist." vii. 28, ed. Mayhoff) records the case of M. Sergius, great-grandfather of Catiline, who lost his right hand in his second campaign, was wounded twenty-three times in two campaigns, and thus had the complete use of neither hand nor foot. Twice made prisoner by Hannibal, he twice escaped, after twenty months spent in chains. He fought four battles with his left hand only, and then made himself a hand of iron, which he fastened on to fight with, and, thus accoutred, raised the siege of Cremona, protected Placentia, and took twelve camps of the enemy in Gaul. Similar substitutes for amputated arms or legs must have been in use even before the time of Sergius; so, at least, we may infer from the treasure-trove turned up at Capua in 1885, in a tufa-grave. Among the contents of this tomb was an artificial leg, made of bronze, wood, and iron, the skeleton being entire, save the bones represented by the artificial limb. This (probably unique) relic is now in the Museum of the Royal College of Surgeons of London, and is thus officially described: "Roman artificial leg. The artificial limb accurately represents the form of the leg. It is made with pieces of thin bronze, fastened by bronze nails to a wooden core. Two iron bars, having holes at their free ends, are attached to the upper extremity of the bronze. A quadrilateral piece of iron, found near the position of the foot, is thought to have given strength to it. There was no trace of the foot, and the wooden core had nearly all crumbled away. The skeleton had its waist surrounded by a belt of sheet bronze, edged with small rivets, probably used to fasten a leather lining. Three painted vases (red figures on a black ground) lay at the feet of the skeleton. The vases belonged to a rather advanced period of the decline in art (about 300 B.C.)." Commenting on the above, General H. H. Maxwell says: "It is important to add, from other sources, that the upper third of the leg was hollow, while the lower two-thirds were filled with wood."—*Lancet.*

White to play and mate in two moves.

SOLUTION TO 1,023.

White.	*Black.*
1. K R to R 5 or R sq.	1. Anything.

(Twelve variations.)

NOTICES TO CORRESPONDENTS.

CORRECT solutions to 1,023, by A. Bolus (duals if 1. Q takes P, B-Kt 8, or R-K 4), V. S. Pochin, F. Krasser, Link; to 1,022 by Link, W. Hewson-Kilbee, E. J. Cooper.

W. J. CARPENTER.—Name entered for Tourney B. The conditions are the same as in previous Tourneys, the principal being that full solutions must be sent to score full marks (see ENGLISH MECHANIC for Dec. 24).

E. G. COOPER.—Thanks for new two-er. It shall have due attention.

A. B.—B-Q Kt 3 was certainly intended. The problem is all right.

W. HEWSON-KILBEE.—We see no mate in your solution of 1,023 if 1. $\frac{\quad}{\text{P takes R}}$

V. S. P.—There is no objection whatever to your entering Tourney A on payment of entrance fee to it.

J. J. SPENCE.—We have entered your name for B 1. Kt-Q 4, discs. check.

T. H. BILLINGTON.—Thanks for problem and good wishes.

Taking Train Speeds in Prussia.—For the regulation and checking of train speeds, the Prussian authorities, after trying a number of speed recorders without full satisfaction, have concluded to introduce an "electric contact" apparatus, which has now been in use for nearly ten years, and on the Elberfeld system of Prussian roads is used on 144 miles of track. It consists of electric keys with strong springs placed outside the rails at regular intervals, the most approved distance being one kilomètre. The keys are depressed by each wheel, and the current thus sent through a wire to the next telegraph office causes a strip of paper moved by clockwork to be dotted for each depression. The paper moves at the rate of 4 centimètres a minute, and the distance apart at which the first dots of each two successive series appear shows the rate of speed at which the train is moving. When the operator at a station gets word from the next one of a train's departure, he sets the paper in motion, and lets it run until the train reaches his station. The strip of paper which has run off in the meantime is marked by cross strokes at its end, and the date, the number of the train and engine, and the name of the engine-runner are written upon it. The operator soon becomes accustomed to recognising the speed from the appearance of the spaces, and he is charged with the duty of noting any obvious excess of the speed allowed. At the end of the day the strip is removed and sent to headquarters as a part of the office report, the work of inspection being made easy by the notes on the strip. The runner is placed in position to check up his own speed, as the contact-keys are visible by day and recognisable by their click at night. This method is reported as highly satisfactory in checking the tendency of runners to save coal by "loafing" up hill and running down at full speed, the apparatus being arranged to show the speed for any desirable distance, or at any point shows whether express trains slow properly in passing stations, and it also indicates very closely the occurrence of a breakdown and its position.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 332, *Strand, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

BACK NUMBERS.

WE receive so many queries asking for directions how to make many instruments and appliances which have been fully described in back volumes, that we have compiled a list, which we shall insert in this column at intervals, of those most frequently sent, and as the numbers are still in stock, new subscribers should consult the list before sending their questions.

Bookbinding: No. 613.
Electric machines: Nos. 1,009, 1,025.

Lacquers: No. 866.
Pattern Making: Nos. 938, 941, 943, 945, 948, 950, 952, 954, 955, 956, 958, 959, 962, 963, 969, 974, 978, 986, 989, 993, 995, 998, 1,000, 1,001, 1,003, 1,004, 1,008, 1,009, 1,010.
Silver-plating: Nos. 1,009, 1,010.
Varnishes: Nos. 478, 619, 675, 723, 775.

The following are the initials, &c., of letters to hand up to Wednesday evening, Jan. 5, and unacknowledged elsewhere:—

S. W. PARTRIDGE.—E. R. Dale.—D. Capron.—P. Vallance.—F. Hotham.—R. Judd.—Pearl Assurance Co.—Rev. J. H. Cole.—E. A. Williams.—J. Mabson.—J. B.—Electrode.—Churchill.—G. S.—Wm. Hosken.—Colliery Manager.—Bewildered.—A. B.—Under Strapper.—W.—Arthur Mee.—Abergwili.—Wm. Tebb.—Nonconfident.—A Youth.—A. Stanley Williams.—W. Holden.—A. C. Chambers.—D. Grimshaw.—T. E. Espin.—Galen.—J. B., Leeds.—Hendon.—Williams.—A Fellow of the Royal Astronomical Society.—A. J. J.—Milverton.—G. A. Audsley.

H. G. J. (First query answered so recently as pp. 159, 178, this volume; but as a matter of fact the teacher of any class will advise you as to textbooks. There are now so many equally good that it is almost invidious to recommend any special works. Longmans, Lockwood, Cassell, Macmillan, and several others amongst the large publishers issue suitable textbooks.)—A. HENDRIE. (Are not the instructions on p. 53 of this volume sufficient? If not, you will find details of other coils in back volumes; but look at p. 53 first.)—DEFENDER. (We are not aware that any new rifle has been accepted; but experiments are in progress with several.)—PERPLEXED. (If the two are identical, the earliest application will be the only valid patent; but you say the inventions are different in detail, and one far superior to the other. If that is the case, the superior device could be made the subject of a valid patent; but it will be necessary to have the specification drawn by a skilled agent.)—INQUIRER. (The question was opened in an early number of this volume (see pp. 64, 84, 155); but so far does not seem to have attracted much attention. The only alleged advantage of a dome that is worthy of consideration is the facility it offers for obtaining dry steam—that is, steam with few, if any, particles of water; but Mr. Wilson, in his "Treatise on Steam Boilers," says pertinently, "Notwithstanding the general opinion that the presence of a steam dome is essential for obtaining dry steam, and as a remedy for priming, it should be regarded, as a useless and expensive appendage to a boiler, and as frequently applied a source of real danger.")—F. A. C. (When they are japanned or enamelled they are also stoved so as to set the varnish hard. If you want to do yours, try the best varnish paint, that is the ground colour mixed with copal varnish instead of with oil and turpentine. If it must be black, procure the best coachmaker's japan or one of the special enamels advertised by those who supply cyclists with their wants.)—LUCENDO. (The substance is not itself sensitive to light. The instrument is the radiometer, and the vanes are usually made of mica blackened on one side, and they revolve when exposed to either light or heat.)—YOUNG TURNER. (The articles on "How to Make a Cheap Lathe" appeared in Nos. 970, 972, 974, 977, 979, 980, 983, 985.)—17 YEARS' SUB. (We do not know; but no doubt the Secretary of the Amalgamated Society of Engineers, 90 Blackfriars-road, S.E., can give you the address.)—F. BAKER. (A meerschaum pipe is cleaned by plugging the mouthpiece and filling the bowl with spirits of wine—methylated alcohol will do; but see that you get it pure—that is, without any resin in it. Rub the outside of the bowl with white wax, or, preferably, with a little cream.)—J. G. G. (You can obtain instructions in electricity, with laboratory practice, at the Finsbury Technical College.)—R. (We cannot do more than refer you to the decisions. Apparently any telephone with a diaphragm, except the ENGLISH MECHANIC telephone, would be held to be an infringement. What is wanted is a legal definition of what is not a diaphragm. See "The United Telephone Co. v. Bassano.")—A. B. (Directions for making oxygen gas in any textbook of chemistry, in back volumes, and in all the magic-lantern manuals.)—PIVOT. (The query is not definite. Do you mean how are they compensated and regulated, or what?)—J. TOMS. (Probably because there is not suffi-

cient gold in the solution. See a reply on p. 376, ante.)—STICKFAST. (Put some acetic acid or nitric acid in the paste, or try the recipe given in No. 1030, p. 338, or that in No. 1039, p. 550. 2. See back numbers for brazing. We should not care to work a brass boiler at 75lb.)—PUZZLED. (A man can do what he likes with his personal property by will. He is not obliged to leave anything to his wife.)—T. MORRIS. (If you breathe through the nostrils instead of the mouth, probably it will not affect you so much. Strong coffee would, no doubt, prevent the nausea.)—H. T. W. (The composition of a multiplex copying apparatus has been given many times even recently. Four parts glycerine, one part glue, and sufficient whiting or baryta to colour. If any one prefers to use the best gelatine and chemically pure glycerine, there is no reason why he should not. It has been frequently stated that it is not necessary to wash off the ink.)—STORM. (What you refer to is not a chemical barometer, but a so-called "storm-glass" of no utility whatever. The solution is said to be composed of camphor 2 drachms, nitre 1½ drachm, sal-ammoniac 1 drachm, proof spirit 2¼fl. oz. Place in a thin glass tube 12in. long, ¾in. diameter, and tie over with bladder, or cover with a brass cap having a needle-point hole in it.)—PHOSPHORES. (The phosphorus bottles are usually made up in the proportion of 12 grains of phosphorus to ½oz. of olive-oil. Mix in an ounce bottle and immerse in hot water, shaking well until mixed.)—ANOTHER GAS-ENGINE. (Any patent agent would supply it, charging a small fee for finding the number and date. 2. The dimensions vary with different makes. See the illustrations of gas-engines in Vol. XXXIX. 3. The marks are not easily removed. Try strong vinegar or spirit.)—ELECTRIC. (Given many times. The Leclanché is the best battery for bell work, and that is excited by a solution of sal-ammoniac; about 2oz. to the pint of water.)—A SKATER. (There is a good deal about skates and skating in back volumes. See Nos. 828, 829, for instance; but for teaching beginners there are several little manuals which you can no doubt find at any large booksellers.)—ANXIOUS. (One would be required for each chimney in which there is a down draught. The cause is a difference of air pressure; hence, another remedy is to bring a pipe from the external air to the hearth immediately below the fire-grate.)—A. B. (In each case carbonic acid and water, with organic matter in the case of the breath, and a little sulphurous acid in the case of the gas. In the case of the fires the products of combustion usually go up the chimney, but dull fires no doubt produce some carbonic oxide, which may find its way, or a portion of it, into the room.)—JEPSON. (Is there not sufficient information in No. 1121, p. 53, this volume?)—OPERATER. (Two wires only are required, one going, the other returning. A sketch in No. 972, p. 225. The keys ought to work their own needle, as well as that at the other end of the line.)—FITTER. (You will find several in back volumes. See No. 1068, p. 40; No. 1008, p. 432.)—A. L. L. (They are made of rectified spirit; but trouble is incurred in removing the resins, which give rise to the muddy appearance when mixed with water.)—R. S. T. (Yes. We do not know where they can be obtained, nor the price; but we suspect that the common mussel-shell will answer the purpose.)—W. GEE. (Full directions for making an American organ were given in Vol. XXVI. It is out of print, but you can doubtless obtain it on loan or by purchase if advertised for.)—HUGH HUGHES. (We should not send sixpence for it!)—PATIENS. (We said the same week it was impossible for such a medical query to be answered satisfactorily in these pages. Why don't you submit your query to Dr. Allinson, the medical editor of the *Weekly Times and Echo*?)—PERPLEXED. (If the property is personal, the three sons, or their representatives, share equally—that is, the children of the dead sons take their fathers' shares; if freehold, the surviving son inherits all.)

Egg Explosions.—The following rather extraordinary paragraph appeared in the *Liverpool Mercury* as a "Science Note":—The explosion of an ostrich egg in the hands of a scientific man is not a common occurrence, and the recent accident at Yale College has excited considerable comment. Mr. Bauer, at the Peabody Museum, New Haven, Conn., was boring a hole in an African egg, weighing about three pounds, when it exploded and knocked him senseless, injuring him severely, and wounding some of the bystanders. Such explosions on a small scale are a common incident on the Chinese coast. A common fashion of preserving hens' eggs for sea use is to pack them in lime, and if properly packed they will keep sweet for months; but they are not always thus packed. Sometimes a vessel leaves a Chinese port with a large supply of eggs, warranted to keep all the voyage home; but in a week or two they begin to go bad in a most extraordinary manner. The lime has such an effect on them that it generates a peculiar foul-smelling gas, and the moment the shell receives a crack it explodes. At first the explosions are rare and very mild; but in a few weeks the "preserved" eggs go off with a report like a pistol, with an ever-increasing odour and frequency, and are finally relegated to the sailors, who find considerable amusement with them. The explosion at Yale, which has ended so disastrously to Mr. Bauer, is doubtless due to the same cause; but the strong shell of the ostrich egg has intensified the evil result.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

6s. 6d. for Six Months and 11s. for Twelve Months, Post Free to any part of the United Kingdom. For the United States, 13s., or 3 dol. 25c. gold; to France or Belgium, 13s., or 16f. 50c.; to India (via Brindisi), 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office Order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 4d. each to cover extra postage.

Messrs. JAMES W. QUEEN and Co., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes, they must be paid for at the rate of 4d. each copy, to cover extra postage.

Vols. IV., VII., XXVI., XXVIII., XXX., XXXII., XXXIII., XXXIV., XXXV., XXXVI., XXXVII., XXXVIII., XXXIX., XL., XLI., XLII., and XLIII., bound in cloth, 7s. each. Post free, 7s. 9d.

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in February and August, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d. each, through any bookseller or newsagent, or 2½d. each, post free from the office (except index numbers, which are 3d. each, or post free, 3½d.).

Indexes for Vols. I., VI., VII., VIII., and IX., 2d. each. Post free 2½d. each. Indexes to Vol. XL., and to subsequent vols., 3d. each, or post free, 3½d. Cases for binding, 1s. 6d. each.

CHARGES FOR ADVERTISING.

	s.	d.
Thirty Words	2	6
Every additional eight words	0	6

Front Page Advertisements Five Shillings for the first 40 words, afterwards 9d. per line. Paragraph advertisements One Shilling per line. No front page or paragraph advertisement inserted for less than Five Shillings. Reduced terms for series of more than 6 insertions may be ascertained on application to the Publisher.

ADVERTISEMENTS in EXCHANGE COLUMN—for

	s.	d.
Twenty-four words	0	3
For every succeeding Eight Words	0	3

ADVERTISEMENTS in the SIXPENNY SALE COLUMN.

	s.	d.
Sixteen words	0	6
For every succeeding Eight words	0	6

*** It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions and in cases where the amount sent exceeds One Shilling, the Publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement, and charged for.

Advertisements *must* reach the office by 1 p.m. on Wednesday, to insure insertion in the following Friday's number.

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a PINK Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

OUR EXCHANGE COLUMN.

The charge for Exchange Notices is 3d. for the first 24 words, and 3d. for every succeeding 8 words.

What offers for 52in. **Bicycle**, in good condition, with lamp, bell, spanner, &c., strong, and suitable for a beginner. Can be seen by appointment. Wanted good air-gun, and part cash. For value see Sale Col. advt.—C. E. K., Lady Cross, Gayton-road, Harrow.

Wanted, modern half-plate folding **Camera** and LENS. Exchange perfect 20-candle-power Dynamo, with driving wheel, and cash.—LOWE, 11, Wills-street, Lozells, Birmingham.

Medicines (Homœopathic), strong tinctures, powders, exchanged for Belladonna Seeds by the DISPENSER, at the Medico-Botanical Gardens and Free Dispensary Company, Lydney.

Wanted, 1 H.P. **Engine and Boiler.** Exchange splendid Tandem Tricycle, cost £34, new condition.—Write, GRAY, 190A, Landor-road, Nottingham.

Magic Lantern, 10in. by 7½in. by 5in., 3in. condenser, movable o.g. in brass tube. Offers wanted in Leclanche Batteries.—ISHERWOOD, Somerton, Somerset.

Wanted, 7 or 8-horse nominal compound **Launch** ENGINE. Brotherhood 3-cylinder, 6in. by 7in., as part exchange.—S. S., 63, Palmerston-road, Southsea.

23 Vols. "**Encyclopædia Britannica**," first-class order, calf, for scientific, musical, domestic articles. Stamp reply.—SCOTT, 59, Queen's-crescent, London, N.W.

Wanted, 2 small **Lathe Heads** for housework, in exchange for set of Bottone's 20 c.p. Dynamo Castings, partly finished.—COLQUHOUN, 30, Scotia-street, Glasgow.

2 H.P. **Gas Engine**, complete, thorough working order. Will exchange for hand-power Band Saw and cash to value.—For particulars apply to C. E. CUTTING, High-street, Hanwell.

"**Photographic News**," 19 numbers of "The Amateur Photographer," "The Scientific American" for 1886, and five Plate Boxes to hold 12 doz. ¼-size plates, in exchange for plain light grey background, ½-plate Bath and Dipper, and folding Tripod Stand.—J. B., Tavistock-road, Westbourne Park.

Medical Coil, complete with battery, very powerful and compact, in mahogany case, with draw for handles, &c., cost £5. Wanted, Lathe for small metal work.—R. LEVERSUCH, Stanmore, Middlesex.

"**English Mechanic**," Vol. XLIII., in good condition, unbound. Anything suitable for a 2 man-power boiler taken.—W. MARTIN, 25, Willow-grove, Plaistow.

"**Boy's Own Paper**," Vol. VII., in good condition, and unbound. Take Fittings for a 2 man-power boiler in exchange.—25, Willow-grove, Plaistow.

Good Value Offered (cash or instruments) for all kinds of sound or repairable Scientific Appliances.—CAPLATZI, Science Depot, Chenies-street, near British Museum. Established 1862.

Boston Lever, good timekeeper, worth 50s. Telescope, draws out to 16 inches, in good leather case, worth 20s. Roman Harp, quite new, 10s. Will take in exchange a good Photograph Apparatus, or good Magic Lantern (oil), with lecture slides, complete.—WILLIAM NICHOL, Castle Eden Colliery, Co. Durham.

4in. **Lathe**, Banjo, "Popular and Technical Educators," "Spon's Recipes," &c., for Lathe with slide-rest.—J. STEVENS, 83, Great Northern-road, Derby.

A good 5in. centre **Slide Rest**, cash 19s. Exchange anything useful, or Engine, or Children's Tricycle Fittings.—THOS. ELLINGWORTH, Church-street, Leighton Buzzard.

Gladstone Bag, 20in. by 13 by 9, good as new, never been used. What offers?—THOS. ELLINGWORTH, as above.

One 6-hole **Pneumatic Indicator**, and one 3-hole, with pushes and pipe, all new. What offers?—BARNS, 13, Remington-street, City-road, London.

Engine and Boiler, drive lathe, half-horse, bargain; also splendid Greenhouse Stove with boiler, burns 24 hours once firing, cost £4 10s., quite new. Offers. Particulars sent.—MILLER, 1, Melbourne-square, Brixton-road.

Phonograph Clockwork. Exchange for Dynamo.—JONES, 346, Upper-street, Islington.

Dynamo, laminated armature, lights small arc, or 7 10 c.-p. lamps; worth £5; offers to value 60s.—A. J. SELLS, 104a, Mare-street, Hackney, N.E.

Sliding Resistance Box and Reflecting GALVANOMETER, by Varley; cost £9. Offers to value 60s., or ¼ Instantograph.—A. J. SELLS, 104a, Mare-street, N.E.

12 half-gallon **Bichromate Cells**, in first-rate order. What offers?—A. E. ROSE, 5, King-street, Kensington.

48in. **Bicycle**, ball bearings, hollow forks, equal to new. Exchange for Magic-Lantern and Slides, or Lathe.—ROBERT TURNER, 52, Peascod-street, Windsor.

Will exchange "**The Forge and Lathe**" for Holtzapffel's Fourth Vol.—Mr. E. CARKEEK, Vergan, Grampound-road, Cornwall.

Organ, 8 stops, 312 pipes, pedals, bourdon, composition pedals, interior new, noble mahogany case. Take Harmonium or American Organ, and cash.—J. HOLT, Ormskirk.

A 10 c.p. **Dynamo**, shunt. Wanted, Steam Engine Indicator.—Apply at once to JOHN R. KAY, The Camms, Helmshore, Manchester.

Wanted, a 4ft. 6in. **Vertical Boiler.** Advertiser would exchange for Gold Albert Pendant, 1½oz. weight.—Address J. B., 23, Skittle-lane, Plumstead.

Wanted, **Vertical Engine**, 1 H.P., with pump complete. Exchange Horizontal Engine, 1¾in. bore, pump, governors, and part cash.—ARTHUR KING, Pinxton, Alfreton.

Lathe, wood and brass, 5in. centre, 42in. bed, several chucks, box of tools, overalls, complete. Exchange for anything useful. Call by appointment.—J. SELLER, 4, Pond-place, Chelsea, S.W.

4½in. Screw-cutting **Lathe**, new, in exchange for Vertical Engine and Boiler Combined, 1½ to 3 H.-P., by good maker. See Sale Column.—64, Park, Eccles.

Treadle Lathe, iron bed and standards, 5in. centre, hand-rest and tee, complete, in exchange for Safety Bicycle, or offers.—GOUGH, 16, Haggar-street, Blakenhall, Wolverhampton.

Exchange magnificent 12-bore, double, modern, London made Breechloader, value 6 guineas, for Dog Cart. What offers?—C. E. HILLSDON, Woodman's-cottage, Sandgate, Kent.

THE SIXPENNY SALE COLUMN.

Advertisements are inserted in this column at the rate of 6d. for the first 16 words, and 6d. for every succeeding 8 words.

Economic Cookery.—Patent Heat Conductors for roasting, 2s. 6d., baking, 2s. 3d.; boiling, 2s. per pair, carriage paid. See ENGLISH MECHANIC, Oct. 15, 1886, page 147.

The Patent Heat Conductors save a family pounds a year.—Agent, TALLACK, 28, Hatton-garden, London.

New Illustrated Price List of **Screws, Bolts, and** NUTS for Model Work, drawn to actual size, sent on receipt of stamp.—MORRIS COHEN, 132, Kirkgate, Leeds.

Fretwork.—Catalogue of every requisite, with 600 illustrations, free for 6 stamps.—HARGER BROS., Settle, Yorks.

"**Beginner's Guide to Photography,**" one shilling. Wholesale of the publishers, LEJEUNE and PERKEN Hatton-garden, London.

"**Beginner's Guide to Photography,**" one shilling. Free from abstruse technicalities. Retail of Opticians and Booksellers.

Wimshurst Influence Machine.—Sole manufacturers of new and improved pattern. 12in. from 30s.—KING MENDHAM, and CO., Bristol.

Deposition of Smoke.—Complete Apparatus to perform this never failing experiment, with static electricity, 5s. 6d and 10s. 6d.—As above.

Standard Ohm, in boxwood cylinder, guaranteed correct to ten thousandth of ohm, 18s. 6d., with copper poles, 21s.—As above.

Galvanometer Cards for tangent and ordinary combined, vertical, astatic, reflecting, and unmounted compass cards.—As above.

Variable Resistance Incandescent Lamp STAND, invaluable for battery power, vide ENGLISH MECHANIC, Oct. 16, 1885, price 3s. 6d.—As above.

Write for **King, Mendham, and Co.'s** large new and reduced Price List, post free, 4 stamps.

Wood Planing.—Hand-power 120, steam-power 1,200ft. per minute. Illustrated circulars free.—G. HAZELAND, Par, Cornwall.

Mica or Talc cut for all purposes by C. JOHNSON 87, New Oxford-street, W.C. Mica chimney covers, &c.

Lathes, Files, Steel, Saws. Cheap, good. List, 2 stamps. Cash or hire.—ROBINSON, Catherine-street, Sheffield.

Lathe Castings, &c.—See T. Taylor's advertisement in ENGLISH MECHANIC every other week. Established 1847.

Electrical Stock.—Clearing surplus under cost. Medical Coils, plated, with slide, 15s. Invalid Bell Sets, 8s. 6d.

Terminals, 20 per cent. off list. Wire, Electro-Motors, Batteries. Write for list.—759, Old Kent-road, S.E.

Boilers, Vertical, Portable, and Cornish, one horse-power upwards.—GRANTHAM CRANK and IRON COMPANY (Limited), Grantham.

Second-hand **Phantasmagoria Lantern**, 3½ condenser, solar argand lamp, in case, £1 10s. Pair of Photogenic Lanterns, second-hand, 4in. condensers, rack and pinion, dissolving fans, in case, complete, with Aphengescope; cost £9 9s. £5 15s.—J. H. STEWARD, 406, Strand, London.

[*Continued on page* vi.]

The English Mechanic
AND WORLD OF SCIENCE AND ART.
FRIDAY, JANUARY 14, 1887.

MR. J. H. EVANS'S NEW BOOK ON ORNAMENTAL TURNING.

THE raison d'être of another book on the Lathe might well be questioned after the issue of Vols. IV. and V. of Holtzapffel's elaborate series. It must have needed no little courage on the part of Mr. Evans to persevere with such a volume as lies before us. But we venture to think that his energy will meet its due reward. In the first place, this handsome and beautifully-printed volume is not displaced by, any more than it displaces, its rival. There is of necessity some resemblance between the two; but there is an essential difference both in style and general arrangement. Mr. Evans dashes at once *in medias res.* His object is to treat of the modern lathe, and he therefore very sensibly ignores its past history. For him Plumier and Bergeron have no charm, and he is satisfied with the doings of his own times, and the very efficient products of his own workshop. The book commences, accordingly, with an illustrated description of a modern high-class lathe as manufactured by himself, the details of its construction, and the uses of its individual parts occupying a large part of the volume. Doctors differ, as usual, upon certain particulars; Mr. Evans upholding as his speciality the form of overhead which Holtzapffel condemns, and in this we entirely agree with him; but either pattern is adopted by turners of great experience, and we are happily engaged in discussing the merits of the book, and do not pretend to sit in judgment upon the apparatus which is therein described. At the same time a casual opinion may drop from our too-ready pen, which the reader is at liberty to accept or not at pleasure.

Passing over a short chapter or two upon chucking and adjustment of work, we come to a description of the Division Plate and Index—the latter in its simpler and also more complex forms, including one for automatic counting. In this chapter Mr. Evans speaks of a plan which we have seen nowhere else—viz., starting the zero points of the several circles of holes upon a curved line struck from the centre of the pin on which the index turns, instead of marking them on the usual radial line of the division plate. The exceeding advantage of this plan will be obvious to the ornamental turner, as he can shift the index from one circle of holes to another at any moment without endangering the accuracy of the work, and without any necessity for using the adjusting appliance commonly affixed to the bottom of the index. Mr. Evans illustrates the matter thus: "If, for example, a pattern has been started at the 192 division, it is possible that to suit the diameter of work, radius of cutter, or other of the various points to be considered, the exact distance required cannot be obtained in that particular circle; the index can then be moved to another without the necessity for adjustment in any way; whereas, if the starting points were drilled on a radial line, the point moving on a centre and describing an arc would consequently require adjusting each time a different division was employed on any similar object."

The automatic counting apparatus described is that of Mr. Ashton, a rather big-looking affair, but perfectly effective.

Grinding and setting ornamental drills and cutters is fully described and very clearly illustrated by accurate and effective drawings. A short chapter is devoted to overheads, to which allusion has already been made, and then the ornamental slide-rest and its fittings are fully and clearly treated—some improvements of great value being introduced.

We next have a chapter on cutter bars, of which several kinds are illustrated, each claiming some special advantage, and then we have illustrations of the usual fixed tools for plain turning with the slide-rest. From this point, the volume ranges through the whole scheme of ornamental turning, from simple drilling and eccentric work to the most elaborate results of combined apparatus. The specimens are beautifully illustrated by the autotype process, and with, perhaps, one or two exceptions, are as faultless in design as they are apparently in execution; but as Mr. Evans is well known as a master in this art, little need be said upon this point.

Naturally we seek novelty in such a volume, and therefore look beyond such well-known appliances as drills, eccentric and vertical cutters, the eccentric and dome chucks, and spiral apparatus, and we do not search in vain; for, in addition to various modified forms of older instruments and minor novelties, Mr. Evans gives us a description of a geometric rest, invented by Capt. R. Pudsey Dawson. This rest was very briefly described, if we rightly remember, in an early number of that fitful periodical, the *Amateur Mechanic's Journal*, which, comet-like, appears at rather lengthy and not easily predicted periods. Mr. Evans has here illustrated in a very effective manner a few of its capabilities. Its action is the reverse of the Rose engine, but similar to it—the tool with its holder oscillating under the action of cams or rosettes, while the lathe headstock remains immovable. Change wheels multiply these oscillations in any proportion as the work revolves, and the capabilities of the apparatus are capable of indefinite increase by using rotary cutters instead of fixed tools.

Such is briefly the nature of the volume which Mr. Evans has contributed to lathe literature, and having described its contents sufficiently for the purposes of a review, we feel ourselves called upon to add a few remarks upon its merits as a guide-book. Our idea of such a book is that it ought to be adequate for the instruction of those who were previously unacquainted with the art which they desire to practise. Apparatus should be clearly described, and its uses plainly shown, so that a learner may be able to ascertain what he will need, and how to set it up and use it when obtained.

If this view is correct, Mr. Evans's book fulfils the conditions. It does not, indeed, teach plain turning, which, as the author remarks, has been already treated so copiously that little can remain to be added to the volumes already published. But starting where these leave off, it commences with the easier examples and less costly apparatus and advances gradually to the more elaborate; and in each case instruction is given concisely and clearly in language that can "be understanded of the people." Comparing this book with its predecessors, we are confirmed in an opinion we expressed many years ago—viz., that the author of a volume on the lathe should be not only himself a skilful turner, but also a lathe-maker, acquainted with every detail of construction, and willing (as well as capable) to impart to others the knowledge which he has attained. No doubt there are trade secrets still; but there is not that reticence and unwillingness to give assistance to plodding amateurs that was almost universal half a century ago. Mr. Evans's book is no pretended help, but a real instructor of the ignorant; while even adepts in this fascinating art will find much to lead them yet further onwards. The volume is less comprehensive than Holtzapffel's, as it stands to reason that a book of about 300 pages cannot contain so much as one of 600; but the two cannot fairly be compared together. Mr. Holtzapffel's work was in a manner prescribed for him by the plan of the previous volumes written by his father, hardly leaving him a choice as to the method of treating his subject. Mr. Evans being untrammelled, was free to take a new departure, and was thus able to condense and concentrate where the former was almost compelled to an opposite course. Mr. Evans's book is therefore not smaller because of omissions, but by reason of conciseness and condensation. It is a handsome volume, worthy of the subject, and we heartly congratulate the author upon the satisfactory completion of a task, not only laborious, but necessarily expensive, and we trust that it will ultimately prove remunerative. A standard work deserves ample recognition.

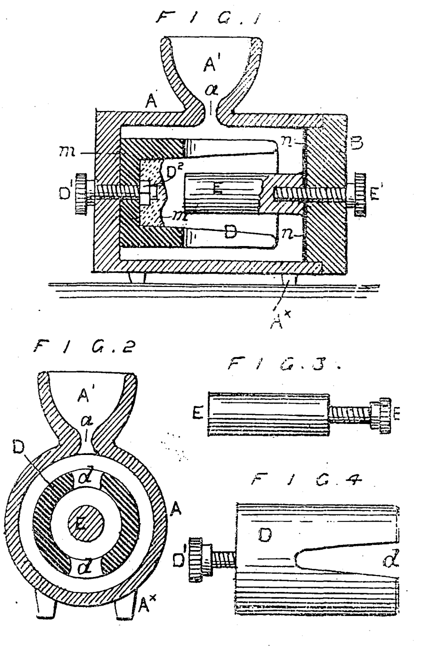
SOLDER FOR ALUMINIUM.

MOST of those who have had occasion to work with aluminium are aware that it cannot be easily soldered or joined, for reasons which Col. Ross pointed out in our columns on Sept. 30, 1881, the chief of which is that its heat-conducting power is so great that a part of a given piece cannot easily be raised to the fusing point. The only method is to coat the aluminium with some other metal or alloy which can be fused, and so made to unite two edges or two pieces of the metal. From time to time we have given various recipes, most of which consist of alloys of aluminium and zinc or tin, though some contain a variety of metals, including silver and copper. Thus on p. 510, No. 958, several alloys of aluminium and zinc are given as suitable solders, and the flux recommended is a mixture of copaiba balsam, Venice turpentine, and a few drops of lemon juice. M. Bourbouze told the Paris Academy of Science that he had discovered a suitable alloy, consisting of tin, bismuth, and aluminium; but we believe he did not present specimens of the work accomplished with it. In No. 1018, p. 99, we gave a solder for aluminium which Col. W. Frishmuth, of Philadelphia, was stated to have found practical; but it differed only in the proportions of the component parts from others well known, and it is probable that his alleged success was due more to the use of a suitable flux than to any peculiarity in the solder, for Col. Frishmuth used paraffin, stearin, vaseline, copaiba balsam, &c. Mr. J. S. Sellon, of the firm of Johnson, Matthey, and Co., Hatton-garden, E.C., has recently obtained a patent for a method of soldering aluminium which we must presume to be superior to the other known processes, as it has been thought worth while to protect it. According to the specification, Mr. Sellon's invention relates to a process and means for soldering the metal aluminium either to itself or to other metals or alloys. He provides an alloy preferably consisting of zinc, tin, and lead, which he applies to the aluminium at the part where soldering is to be effected, and employs as an intermediary a material which will prevent oxidation of the aluminium. If necessary, he first cleans by scraping the surface of the aluminium at the part where soldering is to be effected, and he then applies to that part paraffin wax or other suitable matter which will liquefy or flow at a low temperature. The prepared alloy is then applied with the help of heat; before the heating has reached a degree sufficient to injure or oxidise aluminium the paraffin wax or other equivalent will be melted, and will exclude air whilst and until the alloy becomes melted and attaches itself to the aluminium. Where aluminium is to be joined to aluminium both surfaces to be attached will be thus treated, but where aluminium is to be joined to other metal or alloy which can ordinarily be united by soldering, the aluminium only need be prepared in this way. The pieces of metal with the aluminium so prepared can be attached by any ordinary or suitable solder. It will be understood that if desired the alloy may be coated with the paraffin wax or its equivalent in substitution for or in addition to the coating of the aluminium surface. Whilst not limiting himself to the following procedure, the patentee gives it as the best means with which he is

acquainted for carrying his invention into effect as applied to soldering two pieces of aluminium together. He prepares an alloy of five parts zinc, two parts tin, and one part lead, and rolls it into thin sheets; he then scrapes the parts of the aluminium to be attached, and coats them with paraffin wax. On each of the surfaces to be united he places a piece of the alloy and applies heat. The wax first melts, and then when a higher heat is obtained the alloy melts, and on cooling will be found to be firmly attached to the aluminium surfaces, which can then be soldered together as ordinary soldering is effected. Where aluminium is to be soldered to other metals which do not require the foregoing preparation, such preparation is, of course, only effected with respect to the aluminium surface.

GATE'S PORTABLE BATTERY.

SOME suggestive improvements in portable batteries have been recently patented in this country by Mr. W. L. Gates, of Bayonne, New Jersey, who thinks the form shown may be used with advantage in many situations—e.g., as a portable battery for use by physicians and surgeons in various exigencies where electricity is required. It will serve well in sending or receiving telegraphic or telephonic messages on railway trains in motion. It is open, yet without danger of slopping or overflowing. In what the patentee considers the preferable proportions it may be inverted without spilling, because although the aperture is open the escape of fluid is prevented by the pressure of the air. The main body of the case or vessel in which the battery is mounted is a horizontal hollow cylinder, with one flat end formed in one therewith. Another corresponding flat end is fitted to extend a little way into the interior of the main part, and to form an absolutely tight-fitting plug therefor. The elements are bedded in pitch, and held by screws, which are kept out of contact with the exciting fluid by a covering of pitch. A screw holds one element against one end, and a corresponding screw holds the other element at the other end. The conducting wires are attached to the screws. When the removable end or plug is in place, the only orifice connecting the interior of the casing with the outer atmosphere is about the mid-length and connects with an open-ended funnel. The opposite side or lower side of the cylindrical case is provided with legs. Fig. 1 is a central vertical longitudinal section; Fig. 2 a vertical transverse section, and Figs. 3 and 4 are elevations representing certain parts detached. Similar letters of reference indicate corresponding parts. A is the body of the casing, made of hard rubber or other suitable strong non-conducting material in the form of a hollow cylinder, with one end closed and the other end open. A^1 is a funnel extending out at right angles to the axis of the cylinder A. The interior of A connects with the external atmosphere through a small orifice (*a*) at the junction of A^1 with A. B is a plane end or plug adapted to match tightly within the open end of A, and to form a practically tight joint all around. D is the carbon and E the zinc. Each is made in the form represented, the part D being a hollow cylinder, deeply notched as shown, and the part E being a solid cylinder of smaller diameter fitting within D, but out of contact therewith. The carbon D is held in place by a thumb-screw D^1 inserted through a hole in the closed end of the cylinder. The nut D^2 aids in making a strong and reliable job. Pitch (*m*) is applied between the carbon D and the interior of the closed end of the cylinder, as well as around and over the nut. The zinc E is held by a thumb-screw E^1 inserted through the removable end or plug B. Paraffin (*n*) is applied between the end of E and the adjacent surface of B. The positive conducting wire is connected by being wound around the screw D^1, and the negative wire is connected by being wound around the screw E^1. The pitch and the paraffin seal the joints around, and prevent leakage around the screws D^1 and E^1. The legs A* are formed in one with the cylindrical body A. The charge is introduced in the form of a dry powder, using one-third bisulphate of mercury and two-thirds sal-ammoniac, simply pulverized and mixed. When required for use, add sufficient water through the funnel A^1. Importance is attached to the fact that the body A is cylindrical, and that the plug B is of corresponding form. This form makes it easy to make and maintain a tight joint between A and B, while the orifice *a* being on the top side and about the mid-length, the battery may be shaken without much disposition of the fluid contents to escape through this orifice. The funnel A^1 is a convenience in filling with water, and a safeguard against overflow. In his experiments Mr. Gates has made the orifice *a* so small that the entire apparatus could be inverted without spilling, the fluid contents being retained by the pressure of the atmosphere, unless the device is shaken. Care should be taken in securing the carbon to have the



deep notches lie in the position represented, one at the upper side immediately under the orifice *a*, and the other at the lower side. These notches allow the upward escape of hydrogen gas, and serve, in a measure, to reduce polarisation. The notches also provide a clear space in line with the aperture *a* through which the powder may descend to the bottom instead of lodging on the carbon and obstructing the necessarily limited space which exists between the latter and the interior of the body A. These notches also, to a less degree, facilitate the emptying of the device. They should be so narrow as to subtract but little from the effective action of this element of the battery. The removable end B carrying one of the elements and making a tight joint with the part A enables the cell to be opened at any time with little trouble, and to exchange an element if such shall become necessary without damage to the body or cell A, or to any other part of the apparatus.

THE JUBILEE OF THE ELECTRIC TELEGRAPH.*

BY THOMAS MOY.

THIS is to be a Jubilee Year. We are going to do all sorts of wonderful things to impart renown to 1887, and our newspaper editors and others will boastfully write about the enormous progress of science during the latter half of the present century; but it may be wholesome to moderate our estimate of progress, and look hard facts in the face—not despising what has been done, but being careful to avoid boasting. As far as my experience has gone, I have found that the people of this country are very slow in making real progress, and very boastful when a persevering inventor has pushed his invention through the mountain of prejudice usually standing in his way, and that a man of progressive mind or a genuine inventor gets a great many kicks when living and a little posthumous praise when dead. When railways were in their infancy 50 years ago, I well remember the insane and ruinous opposition to their construction, and the immense efforts that were made in Parliamentary Committees to keep railway stations as far away as possible from the towns and villages, and to this day such places have suffered, and the shares of the companies have been heavily handicapped in consequence. When railways were pronounced a success, and John Bull's prejudice had been overcome, then came the jubilant fit, and the cant phrase was, "We have annihilated time and space by means of railways." But this boast, like a soap-bubble, has long since burst. And what is our position to-day, scientifically and progressively? We have learnt how to utilise a few of the materials around us. We have learnt to weigh, calculate, and estimate what is likely to happen if we put this and that together; but as to what the materials really are we are as much in the dark as ever. We give them names, and then persuade ourselves that we know what they are. The words written 2,500 years ago are still absolutely true, "That man cannot find out the work that is done under the sun, because, however much a man labour to seek it out, yet shall he not find it; yea, moreover, though a wise man think to know it, yet shall he not be able to find it." If an inquiring child asks, What is life? —Why do my lungs fill and empty themselves?—What is heat?—What is gravitation?—What is electricity?—What is light? —What is cohesion? we can only give vague answers, because we do not know. It seems as though the Creator had decreed that man should touch, taste, and handle these things, combine them, apply them to useful purposes, find new combinations, new uses, new results and applications, and there stop. Up to this time—this Year of Jubilee—we are compelled to admit, as Newton did, that we are but as children playing with pebbles on the sea shore, while the whole ocean of discovery lies before us. We live in the midst of mysteries, and, because they have become familiar to us, we forget that they are still mysteries; and one of those familiar mysteries is electricity, which, as it becomes developed, becomes still more mysterious. What is this which we call the electric fluid for want of a better name? If you think upon the subject you must wonder what it can be. We have found out various means of producing it, and have turned it to account in many ways, but without ever finding out what it is. The electric telegraph, with its various appliances, has grown, and is the result of the labours of many minds. We cannot say that so-and-so was *the* inventor; it did not burst upon the world as a complete discovery. Six hundred years before the Christian era it was observed that when amber was subjected to friction, it acquired the power of attracting and repelling light substances. This is, perhaps, the earliest record in existence. The next record is that Theophrastus, 300 years later, observed that a hard stone (supposed to be tourmaline), when rubbed, attracted light articles. Pliny, in the year 70, and others, noticed the same phenomenon. But none of these men appear to have possessed genius enough to follow up the inquiry, and it remained very obscure until Dr. Gilbert, towards the close of the 16th century, published in his work, "De Magnete," a list of all those bodies possessing the same property. Then followed Dr. Wall, about the middle of the 17th century, who succeeded in producing the electric spark by rubbing a cylinder of amber with flannel. Boyle and Otto Guericke followed, and added to the stock of knowledge. Then followed Stephen Grey, a pensioner of the Charter House, who appears to have been the first to discover the power of transmitting the electric fluid to a distance by means of an insulated wire. This was a great step in advance. Grey, in 1727, used a wire 700ft. long, suspended in the air by silk threads, to one end of which he applied an excited glass tube, while, at the other end, another person observed the effect. Grey and Wheeler, Desaguliers, Franklin, Dufay, Winckler, Dr. Watson, Muschenbroeck, with his Leyden jar, and Watson, all followed in building up the facts, and adding to the stock of knowledge. A person signing himself as "C. M.," in *Scot's Magazine* for 1753, suggested the idea of applying electricity to the telegraph; and his letter is such an admirable contribution that it is a great pity he did not sign his name to it. Lesage carried out, in 1774, almost the identical idea suggested by "C. M." I must pass over the doings of Lomond, Reusser, Don Silva, Betancourt, Cavallo, Ronalds, and others—who all used frictional electricity—to the period when voltaic electricity began to displace frictional electricity for telegraphic purposes. Sulzer, Galvani, and Volta carried on the progressive work, bringing it down to the year 1800. Then followed the discovery by Herr Sömmering, that water is decomposed into its constituents of oxygen and hydrogen by the voltaic current. Romagnesi discovered the phenomenon of the deflection of a magnetic needle by a voltaic current, an experiment which Oerstedt, and afterwards Ampère, vigorously followed up. Soon after Ampère the great Faraday entered this field of discovery, research, experiment, and invention, and paved the way for those two men, Cooke and Wheatstone, who combined great business capacity, energy, perseverance, practical ingenuity, and scientific attainments in their treatment of the subject. I ought here to mention that Bain at one

* A paper read before the Balloon Society, Jan. 7.

time lodged in Bream's-buildings, Chancery-lane, in a house kept by a gingerbeer manufacturer, and carried out many experiments in a garret, with batteries in gingerbeer bottles. Prof. Wheatstone worked at the subject from 1834, and in 1836 his acquaintance with William Fothergill Cooke commenced, followed by a partnership; the result of such partnership soon being made apparent by their jointly patenting, on the 12th day of June, 1837, the first really practical scheme in electric telegraphy. It is due to these men to say that 50 years ago they gathered up the facts that then existed, put them together in a practical form, added to them many valuable arrangements of their own, and thus presented to the world that which will ever make their names renowned. This patent was, of course, followed by others—the results of further experiments and discoveries; but the filing of their application on the 12th June, 1837—only eight days before Her Majesty's accession to the Throne—marks this year, not only as the jubilee year of her Majesty's reign, but also as the jubilee year of the practical application of the electric telegraph. You will bear in mind that I do not call Cooke and Wheatstone the inventors of the electric telegraph; but I do claim for them that they first established a telegraph for practical purposes on a large scale, and, whatever were the merits of less conspicuous workers, we must accord very high praise to those who apply the results of centuries of observation, and add thereto no small amount of invention, whereby mankind becomes permanently benefited. Wheatstone patented, in 1840, his well-known dial instrument, in which he established the principle of sending, from the transmitting station, a series of alternate currents through the line, which, passing round the soft iron of an electro magnet, moved an armature, and regulated the motion of an escapement similar to that of a clock. I think it was Steinheil who first discovered that the earth might be used as part of the circuit of the electric current. This was really a great discovery, and I remember it very well. It astonished everyone who was interested in the subject, and it remains a marvel to this day that all the conflicting currents thus carried by the earth should be effectual in completing millions of electrical circuits without any detrimental action arising therefrom, thus saving half the quantity of wire previously deemed necessary, and effecting enormous economy in telegraphy. A very bold and original attempt was made in 1862 by a gentleman named Haworth. This gentleman conceived the idea that the earth might be used as a substitute for both wires. The title of his patent (No. 843[62]) was "An improved method of conveying electric signals and telegrams without the intervention of any continuous artificial conductor." I felt certain at the time that it could not succeed, although encouraging signals had passed from England to Ireland without cable. But, although it failed, it was a meritorious experiment, and is well worth recording to his credit. It is also valuable to inventors and experimenters to know what has been tried in this direction. Although I have had to omit much that I might have said regarding the merits of Faraday, it must not be thought that he holds anything but a very high place in every one's estimation, and always will do so, as I am sure he does in mine; and at the end of this half-century of telegraphy there is very little that he did not forecast. In the year 1853, that which had been considered impossible was actually accomplished. I refer to the methods of telegraphing in opposite directions at the same time on a single wire. An Austrian gentleman—Dr. Gintl —was the first to solve this problem; the manner in which he effected this object is well known to electricians, and the details would be uninteresting to a popular assembly like the present. Frischen, Siemens, and Halske followed with improvements. This advance was followed in 1855 by another Austrian gentleman named Stark, who invented and carried out a method of sending two messages along a single wire in the same direction at the same time. In estimating and describing the force of electric currents, I think that electricians have made a great mistake, and the sooner it is remedied the better. I refer to such words as ampères, ohms, volts, and other terms taken from men's names, as descriptive of the amount of electric force. Surely some better names and methods of calculation may be found. It is bad enough to put Greek letters into algebra in order to mystify any practical man who may wish to learn it; but to call the amount of electric force so many eminent men is, to my mind, simply absurd. Suppose, in describing a steam-engine, we were to say, the steam pressure in the boiler is 140 "trevithicks," instead of pounds; the vacuum is 27 "watts," instead of inches of mercury; the power is 2,000 "stephensons," instead of horse-power: could anything be more out of taste? and yet all the talented electricians follow this clumsy and illogical apology for scientific terms, like sheep over a five-barred gate. Having thus very imperfectly dotted down something like a general outline of the progress of the science, we see that at a very early period in the history of the science the idea existed of using electricity for telegraphic purposes, all the proposals for effecting it were wanting in simplicity and practical contrivance, until Messrs. Cooke and Wheatstone, having succeeded in their experiments, patented their ideas, and placed them before the world in 1837—50 years ago. Since that time the telegraph has been extended enormously, and carried to almost all parts of the world. The ocean does not bar its way. The *Agamemnon* and *President* steamers crossed the Atlantic with the first cable, the *Great Eastern* followed with another, and many cables have been laid in the Atlantic. Other seas have also been successfully conquered, and we can now "wire" to almost the whole of the habitable globe. But on land there is something immediate to be looked after. There is much to be said in favour of overhead wires; their economy and efficiency under ordinary circumstances are very great. But we are beaten by storms. This danger must be either met or avoided—it cannot be shirked. The production of the philosopher's brain is a mere idea to-day: it is a necessity tomorrow, and we must not be deprived of our necessities by snowstorms. If we have blundered into a wrong groove, the blunder must be remedied. We cannot go back, we cannot even stand still: we must go forward; and even a seeming failure must be made the means of greater progress. The recent inconveniences arising from the breaking of telegraph wires show that we have erected them on the assumption that fine weather must prevail all the year round. That the wires will bear the strain put upon them by supports a great distance apart, in fine dry weather, has been amply proved; but that they will give way during a snowstorm has been also amply proved. The remedy therefore seems likely to be found in shorter lengths of stretch, in underground wires, or in some new arrangement. Now underground wires are expensive, and when a fault occurs it is troublesome to find its position, and other objections are urged. I would therefore throw out the hint that it is possible a middle course could be found in towns, by suspending the wires at about, say, 20ft. from the ground, with ornamental supports attached to the houses. The railway companies will also have to put up more numerous supports, or adopt the underground system; and here I do not see much difficulty in the latter arrangement, as most railways have an ample margin of unoccupied banks which might be utilised for the purpose. During the last 50 years many men of talent have come to the front with their ingenious inventions relating to electricity. The telephone was invented by Reis in 1861, improved by Graham Bell in 1876, and afterwards by Edison, Dolbear, Hughes, and others. Then in 1878 the microphone was invented by Hughes, an invention which quite startled the world at the time, but which has hitherto been only used as a scientific toy. At the present time a whole army of intellectual men are working hard in order to increase the usefulness, cheapen the production, utilise by-products, and discover new sources of electricity. Long before the invention of the dynamo, making possible the lighting of incandescent and arc lamps, and the propulsion of motors by means of the electric currents, great attention was paid to primary batteries by electricians and chemists; but it was deemed impossible through these means to devise any feasible plan for sustaining sufficiently steady currents to produce and maintain incandescence in lamp filaments, or to run motors for more than a few hours; and even now it is said to be impossible, and sometimes laughed at by electricians who stand high in their practical knowledge of other systems of light production; and thus a certain amount of prejudice may have arisen, and, in consequence, a promising, if not the most promising, scope for the development of the electric current has been neglected and comparatively undeveloped; but, at least, one gentleman with whom I am acquainted has been following a different course, and I believe that his system of producing electricity by his improved primary batteries will prove an important step in the forward march of the science. If this inventor had joined the majority I should be at liberty to mention his name, and perhaps even propose the erection of a stone monument; but as he happens to be living, his name must not be mentioned in a lecture. His first patent was taken out in February, 1885, and although the invention is not of a startling character, yet, the inventor having fully understood what is necessary, the result will be a simple, cheap, effective, powerful, and complete primary battery, and I think it will take its place as one of the "things of the age." I will only just say of this battery, that by means of very careful calculations and experiments carried on for weeks by capable men, the electric light can be produced at a farthing per hour per lamp. Now, I think, I must have exhausted your patience, if I have not the subject. We have been considering *one* of the mighty forces of nature: one of the invisible things of the Creator. We have, as it were, just touched the "fringe" of this force. We have glanced at the last 50 years of its practical application. What will the next 50 years bring forth in the further development of this power? Who would have dreamed 2,400 years ago, when the first piece of amber was rubbed, that that would lead to what we see to-day? Who can say that there are not other forces in the world, as yet undreamed of, the existence of which will be discovered in the next 50 years, and become absolute necessities to mankind. I think it will some day be discovered that gravitation is closely allied to electricity and magnetism: if I may venture to put the idea before you, it may be that the revolutions of the planets are analogous to the action of dynamos, and that the various fields and currents in which the planets revolve, and by which they are interlaced, may possibly produce that mysterious force which we call gravitation. When I contemplate the great forces of nature, their invisibility, their grandeur, their resistless and ceaseless operations, their harmony, our tiny knowledge of them and utter ignorance of what they consist, our pursuit of knowledge for a few years, and then our inevitable departure without attaining a deeper knowledge of even our common surroundings, I not only think of Sir Isaac Newton's celebrated saying already quoted, but I go farther than that and ask myself: "Are three score and ten years to be the limit of man's existence, and is there to be no future development of our powers, our knowledge, our investigations, our appreciation of real good?" And the inevitable answer comes, trumpet-tongued: No!—a thousand things contradict the possibility of such a result; for, to quote again from another author: "God hath set eternity in man's heart," and nothing less can satisfy his reasonable aspirations.

ACCURATE LATHE WORK: WHAT IT IS, AND HOW TO DO IT.*

THE process of turning and then "filing up to size" has been abandoned in nearly all progressive machine shops. Instead of that ancient "hit-or-miss" method, the latheman is now expected to turn up short, stiff pieces of iron and steel to within the ·00025th part of an inch, or, as usually called in the shops, "one-quarter-thousandth of an inch." It is just as easy to turn up work which will be a "good fit" within the above measurement as it is to turn up by guess and a pair of rickety calipers, and then file and try, and try and file, until the work goes together an approximation only of the poorest kind of a "fit." It is usual in ordinary turning to grind the tool up sharp. See that the tail stock is set accurately by the marks thereon, then gauge the cut by the calipers and let it run half-way across the work, testing the size meanwhile by frequent use of the calipers. When the middle of the work is reached the carriage is run back to the tail stock, the work turned end for end, and the turning process repeated until the two cuts meet at the centre of the shaft, perhaps coming together in an eccentric fashion, leaving two shoulders diametrically opposite each other as a result of slipshod turning. To do a nice job, the lathe must be accurate. The bed must be straight, and without worn places therein. There must not be the least trace of lost motion. The tail stock must fit tight, every part of the lathe in first-class condition, and, above all, perfectly clean. The best workman in the shop cannot do nice turning with a slovenly lathe, and the least dust or dirt in bearings or on the V's will defeat the purpose, so far as accuracy is concerned. See that the centres are perfect and clean, both in work and in the lathe. Make a special tool for taking finishing cuts, and keep it for that exclusively. Make the tool stiff enough to practically eliminate springing tendency. Grind said tool so that it will cut upon its side, close to the point, and cut twice the width of the feed used at least. A diamond-point tool, set to cut with the side parallel to the work, instead of with the side usually used, will give a fair idea of the tool, but is not the exact shape. A tool is often used for working into corners which is almost exactly the shape intended to be described. Do not pick up an old tool and remodel it. Get a piece of nice new steel, forge it carefully, and harden in a bath of cool, clean water. Now heat the tool slowly until it is at a temperature of about 300°F. This point will be reached when water will flash off into steam, and is just about as hot as a laundry iron when it will "hiss" loudly as Ah Sing touches the iron with his wet finger. This degree of heat should not start the colour in the slightest degree, but it changes the structure of the steel to an extent that wonderfully toughens the steel, without decreasing its hardness in a measure anyway appreciable. Steel thus treated will stand nearly as great strain as that having its temper drawn down to a straw colour.

After making a tool to your satisfaction, grind it nicely, and then whet it sharp on an oil-stone or a slip. A tool for a finishing cut on iron needs as keen an edge as for cutting wood, and for our pur-

* By JAMES F. HOBART, in *Manufacturers' Gazette.*

pose the tool must be sharp. Place the tool in the tool-post, and adjust it precisely as high as the live centre, and this adjustment must be exact; make sure that the two lathe centres are exactly of a height. Any variation in this adjustment is also fatal to exact work. Put the work between centres and adjust tail centre nicely. See that it is well oiled and tightened up. Set the micrometer caliper to the exact size of the desired finished work, and turn a spot at tail stock end of work sufficiently large to measure. Adjust tool by cross-feed screw until the tool cuts exactly, as near as can be determined by human touch, the desired size, then change work end for end, run the tool to head stock end of work, and see if it is in position to cut to required size when in that place; and if so, you may be assured that the lathe will turn a piece of metal with both ends exactly of the same diameter. If the tool is found to cut too large or too small when at head end of work, adjust it to required size there by means of the cross-feed screw; then reverse work once more, run tool back to tail stock, and adjust it to the place already turned by means of the tail stock off setscrews. Move the tail stock until the tool is in exactly the same position relative to diameter of work that it was in after adjustment was made at head end of work. Now start the cut, and set up to size if necessary by testing by the micrometer calipers. After getting the right size, run the tool the entire length of cut, if possible, without a stop. Do not even oil the lathe spindle while making the cut, or you will change the size of cut. Don't oil the ways on the tail spindle, or shorten the belt, or put resin on it. Don't let any heavy weight be placed near or removed from the floor near your lathe, and do not try to keep up to size by calipering the work and making necessary adjustment of tool by moving it back or forth, up or down. Let the tool alone until it has cut as far as desired, then remove the tool and measure the work as much as you wish. There will be some variations in size in different parts of the work, according to truth of the lathe and uniform density of stock; but both ends will be so near one diameter that it is hard to measure the difference. A piece turned in this manner will need little, if any, filing to fit into a collar. A lap and a little grinding therewith will readily reduce the large places, and a dead smooth file will reduce them without appreciable loss of cylindrical truth. For a finishing cut by this method, leave only one-half the stock usually left by the average workmen to "file up" on. Just ·001 of an inch is enough to do good work in with fast speed.

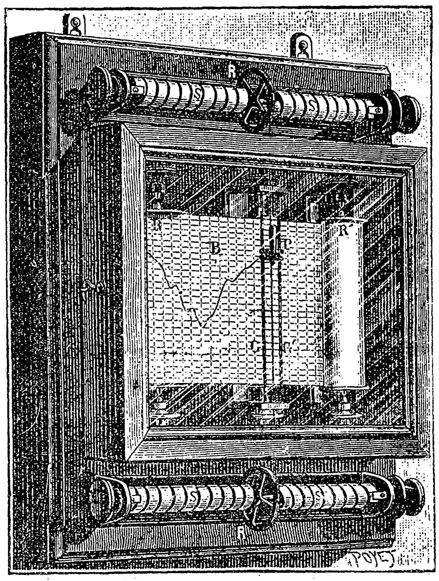
NODON'S GELATINE HYGROMETER.

METEOROLOGY already owes a great part of its present progress to registering apparatus that permit of following the phenomena of the atmosphere step by step, so to speak. Among all such instruments, hygrometers alone have been uncertain in their operation, and their indications subject to numerous causes of error. It will be understood, then, how profitable it would prove to have a registering hygrometer that should be accurate in its indications, sensitive, and prompt in its action. This is a desideratum that appears to have been supplied by Mr. Albert Nodon, as it seems from a note recently presented to the Academy of Sciences by Mr. Lippmann. There are, as well known, two very distinct kinds of hygrometers. In the first place, we have condensation ones, such as those of Daniell, Regnault, Alluard, Bourbouge, and others, which furnish very accurate indications, but which, unfortunately, necessitate quite a delicate manipulation, and which are scarcely utilisable as registering apparatus. The second are absorption hygrometers, the action of which is based upon the property possessed by certain substances (such as hairs, horn, wood, ivory, &c.) of becoming more or less distorted in an atmosphere of varying humidity. These devices are easily used, and can be readily employed in the construction of a registering apparatus. Unfortunately, the distortions that they undergo are in most cases variable with the temperature, and the material of which they are formed undergoes an alteration in time that falsifies the instrument's indications. It became a question, then, to find a hygroscopic substance that should permit of constructing a hygrometer giving just as accurate and rapid indications as are furnished by condensation apparatus, and being as simple as absorption ones, and, in addition, a substance that should undergo no distortion under the influence of the temperature, and that should last as long as possible, its hygroscopic properties not being modified by time. There is one material which possesses all these properties to the highest degree, and that is gelatine. This substance, which can be rendered unchangeable by adding to it a small amount of salicylic acid, absorbs an amount of water that is proportional to the hygrometric state of the air, and increases in weight and bulk proportionally to such state. These properties are independent of the temperature between the observed limits of from 10° to 35° C.

These remarkable properties of gelatine have been applied by Mr. Nodon in the construction of a hygrometer as follows:—If we spread gelatine over a strong paper or Bristol board spiral, whose interior is protected by some hygroscopic substance, such as bitumen, we shall obtain a device which is sensitive to variations in the hygrometric state of the air, and one which is analogous, as regards operation, to the spiral of Breguet's metallic thermometer. When the hygrometric state rises, the gelatine elongates and the spiral unwinds.

It will at once be seen that we might obtain analogous results with hygroscopic substances other than gelatine—such, for example, as gum tragacanth, gum arabic, dextrine, &c., spread in thin coats upon some support other than paper, such as celluloid, ebonite, glass, and the like. But, among all the substances that are applicable, gelatine and paper have given the best results, and so Mr. Nodon has elected them to the exclusion of all others.

His registering apparatus consists of four gelatine paper spirals, S S S S, mounted in pairs upon the same base. One of the extremities of each is held in a clamp, while the other and free extremity acts directly upon a pulley, R. These four spirals, with their combined action, constitute, as a whole, a device that operates with greater regularity than would one with a single spiral. Over



the two pulleys, R R, which are arranged in the same vertical line, runs a silk thread, to which is attached a small and very light slider, P, that moves between two guides, G G'. It is upon this slider that is arranged the inscribing style. The whole is balanced by a small counterpoise on that portion of the thread that is in the rear.

We thus have a contrivance that is movable in a vertical direction, and capable of obeying the least rotary motion of the spirals. The style bears against a band of ruled paper, B, which unwinds from the roller R', and winds upon the roller R, which latter is slowly moved by a clockwork that causes the paper to advance ⅜in. per hour. By selecting a sufficiently thin paper, a great enough length can be wound upon the cylinder to allow the apparatus to operate for ten consecutive days. As the thickness of the paper wound around R increases very slightly with respect to the latter's diameter, we may admit with sufficient approximation that the lengths of paper unwound during an hour's time remain constantly equal to one another. The clockwork is inclosed in the base of the apparatus. The paper, roller, and pen are protected by a glass plate that can be removed at will. The four spirals operate in the atmosphere; but may, however, be protected by means of wire gauze or a jacket perforated so as to allow the air to circulate freely within.

After plans by the inventor, Mr. Ducretet has constructed a model provided with a dial, which is very convenient for use, and the simplicity of which permits of its being offered to the trade at so low a price as to put it within the reach of all. The external extremity of a sheet-gelatine spiral is fixed in a small metallic box, while the inner extremity of the same causes a needle to move over a dial. This apparatus, which reminds one, externally, of aneroid barometers, is remarkably sensitive and accurate. An analogous model, constructed by the inventor in April, 1885, was left till June, 1886, in a laboratory, and was, during this epoch, frequently compared with an Alluard hygrometer. The indications were found to be exactly the same, and the spiral had, therefore, during this space of time undergone no change in its hygroscopic properties. In another model, provided with a spiral of very numerous revolutions, the sensitiveness so increased that the least variations in the hygroscopic state of the surrounding air, which had absolutely no influence upon other hygrometers, even the most sensitive ones, caused a motion of the needle. From numerous observations, it had been concluded that the indications furnished by the hygrometer are in most cases more certain than those given by the barometer. This important fact has led Mr. Ducretet to inscribe the probable state of the weather opposite the graduations on the dial of his hygrometer, thus allowing of the apparatus being used as a weather indicator.—*La Nature.*

FIXTURES FOR MAKING TWIST DRILLS ON THE UNIVERSAL MILLING MACHINE.*

VARIOUS conditions may arise in most shops which render it desirable to make small twist drills in moderate quantities with, at least, some approximation to the prices at which similar drills may be purchased. Any shop having a universal milling machine can undoubtedly do this by taking the little trouble necessary to "rig up" so as to make the best possible use of the machine. If drills are to be made at an economical rate, the milling of the spiral grooves must be done rapidly enough to make it necessary to support the drill at all times directly under the cutter, so as to prevent all springing of the drill blank; and things must be so arranged that there will be no tendency for the cutter to lift the drill from the rest, either at starting the cut or at any other time; for if there is any such tendency it will be found rather an arduous undertaking to counteract it by pressing the blank down with the handle of a brush, as has been suggested. Then, too, a chuck will be needed which will hold the blanks much more securely than most chucks can be made to hold. For this purpose the one shown in Fig. 1 can be recommended; the spring collets for which, shown by Fig. 2, should be made with a hole through them just the size of the drill to be held. They should be given a spring temper, and the lower end of the nut, and also the end of the body of the chuck where the collet comes against it, should be tempered. This chuck, when well made, is excellent, not only for the purpose for which it is here shown, but for use in the drill press as well, and may be provided with a collet long enough, so that no more of the drill may project from the chuck than is necessary for the depth of hole to be drilled. The next thing is to provide a rest which will always support the drill blank directly under the cutter, and allow no yielding of the blank, no matter how heavy the cut, nor how fast the feed may be. A rest which seems to fulfil these conditions perfectly is shown by Fig. 3, in which a is a casting fitted and bolted to the platen of the machine in the same manner as the regular rest; b is a piece of steel having its upper face provided with a V-groove in which the drill blank rests. It is fitted into a, and is slotted where the screws c and d pass through it, so that it is free to move vertically at either end, except where the screws c and d are tightened. It will be seen that the piece b may be set at any angle within certain limits, as well as adjusted for height, which makes the rest useful for many purposes. The facility with which it may be adjusted to support any slender piece of work for a considerable portion, if not all of its length, and inclined either way to support taper work held between the centres, or anything held in the chuck at an angle, either above or below the line of centres, makes it, though simple and strong, almost a universal rest. Its base should be arranged, as shown, so as to form a basin for the reception and disposal of oil and chips. This feature should always be looked after in the designing of milling machine fixtures, because when milling steel such an abundance of lard oil should be used upon the cutter as to make it necessary to catch and use it repeatedly.

The way things look when rigged up is shown by Fig. 4, the spiral head being elevated about one-half degree, to make the centre of the drill the thinnest at the point, and the grooved piece b of the rest adjusted so as to support the drill its entire length. Now, if the motion of the machine be reversed, and the cutting commenced at the upper end of the groove, and feeding out to the end, it will be found that there is no tendency to lift the drill from the rest, and things may be crowded up to the limit of the capacity of the cutter.

When milling work having only two grooves, a considerable portion of the time is consumed in indexing, since the index pin must be turned

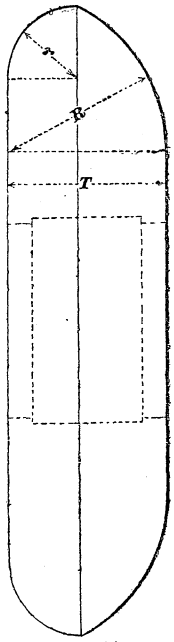

Fig. 7

twenty revolutions to turn the work from one groove to the other. Most of this time is saved by the use of the collar marked *c* in Fig. 4. It is made to turn freely upon the collar which screws on the spiral head spindle, and is held in proper position by the milled head-screw, as shown. It is provided with four numbered lines or graduations, 90° apart, which, when the spindle is revolved, successively come opposite a mark placed upon the spiral head, and thus indicate when the spindle has been turned one-fourth, one-half, or a complete revolution. If, in starting the first cut, one of these lines upon the collar be brought fair with the line upon the head, then in starting the second cut it is only necessary to bring the opposite line into the same position, so, in running back after taking the first cut, the index pin is left in the plate until the desired line comes into position, when the pin is pulled out from the plate, and held in the right hand, while the backward motion of the slide is continued, until it is arrested by the stop. The pin can then be put into the proper hole, and the work is indexed without loss of time, and without liability of mistakes made in counting.

When the motion of the machine is reversed, something is needed for throwing out the feed at the end of the cut. For this purpose the device Fig. 5 is presented. The piece of polished drill rod *a* is flatted and drilled at one end, and is fastened by a screw to the underside of the lever by which the feed is manipulated, the other end sliding freely through the stud *b*. The clamp collar *c* may be tightened upon the rod at any point by the thumb screw, and when, by the backward motion of the slide, it comes in contact with the stud *b*, the lever is drawn forward, and the feed thrown out. When fixed up for work in this way, the machine will be found very effective, since the cutter can be sunk into the blank the full depth at once, and only one cut taken in each groove, and that one at a rapid rate. In this way drills ·225in. diameter, and with grooves 3⅝in. long have been milled at the rate of 170 per day. The advantage of having things fixed up solidly for such work was plainly shown when a lot of ⅜ drills were wanted, and two machines, one small and the other the large back-geared machine, were rigged up for the job. The small machine ran at a speed of 60 revolutions per minute, and the large one at 68. The arbors were the same size, and yet, notwithstanding the higher rate of speed at which the cutters ran in the large machine, they invariably ran longer and did considerably more work at one grinding than when used in the small machine, and the cutters were frequently interchanged without altering the result. This can only be attributed to the fact that the outer end of the arbor is supported in the large machine, and that the entire machine is much heavier and better able to absorb vibrations. This would almost seem to indicate that no matter how rigidly we may seem to have things fixed, there is an advantage to be gained by having them still more so.

Fig. 6 shows a device by which the drills may be backed off very rapidly, and in good shape. It consists simply of a flat piece of steel provided with a hole *a* just large enough for the drill to slide through easily. As the drill is pushed through this hole, the edge of the spiral groove comes in contact with the end of the screw *b*, which causes the drill to rotate, then an emery wheel is so adjusted as to come in contact with the drill through the square opening shown.

The device may be fastened to the ordinary flat rest of a grinder by the screw shown, and upon which it swings against a stop pin.

Though many twist drills are seen having curved cutting lips, it is not generally considered a desirable form, and the "straight lip" drill is usually much preferred.

If the angle of the spiral be 20° and of the lip of the drill 30°, and the thickness of the drill at the centre one-tenth of its diameter, all of which are probably pretty near what they should be, then the form of cutter shown by Fig. 7 will produce a straight lip drill. Referring to Fig. 7 and letting D represent the diameter of the drill, then

$$r = {\cdot}375\ D.$$
$$R = {\cdot}338\ D.$$
$$T = R = \text{thickness of cutter.}$$

A convenient method of obtaining this form is shown by Fig. 8. A square is drawn one side of which equals three-quarters of the drill, then divide the square into four equal parts. The point *a* is where the arcs which form the shape of the cutter unite; *b* and *d* are the centres from which the arcs *a e* and *a c c* respectively are described. These arcs are the nearest approximations to the true curves, which were developed by Mr. Chas. A. Bauer, to whom the craft is indebted for this presentation of them. I infer from his remarks that the development of these curves will prove quite an interesting study for those who are fond of such things, and that it is not nearly so simple as it seems at the first glance.

With this cutter and the other devices which I have shown, twist drills, admirable in every respect, may be made at a rate which will often be surprising.

THE HOUSEKEEPER AS A CHEMIST.

THE substances used as food belong mainly to the class of organic bodies. They are composed principally of carbon, hydrogen, oxygen, and nitrogen, and are of a very complex constitution. The action of heat upon them is often to change their character very decidedly, and yet in many cases the chemist cannot perceive any difference in their composition. Take the case of albumen, for instance, which forms the white of an egg, and is also present in meats of all kinds. Its chemical formula is approximately $C_{72}H_{112}N_{18}O_{22}S$. Upon heating to 163°, the watery liquid becomes changed into a tough, white solid, more or less difficult of digestion; but the change appears to be only a physical one, and the chemical composition remains the same. This property of coagulation is made use of in clearing coffee from its sediment. When the liquid white of egg is stirred into the boiling coffee, it solidifies at once, inclosing in the mass all the particles held in suspension, and leaving the liquid beautifully clear. The action of fish-skin is similar, only in this case the gelatine of the skin unites with the tannin of the coffee to form a leathery substance, which acts like the coagulated albumen.

Gelatine is made from the bones and tissues of animals, and is of considerable importance in the domestic economy. In its coarser forms it is known as glue, but when properly refined forms the bright, clear, cooking gelatine. Its most characteristic property is that of gelatinisation. It is insoluble in cold water, but absorbs it, swelling up, and becoming soft. Upon heating the

water, it rapidly dissolves; and upon cooling again, after a while sets into a more or less firm mass, known as jelly. Prolonged boiling of the solution causes it to lose this property, as housewives frequently discover to their sorrow when the jelly absolutely refuses to "jell." The addition of a small quantity of strong acid, like nitric, also destroys this property, without injuring its adhesive qualities; and the familiar "prepared liquid glue" is made in this way. Fruits contain a body known as *pectine*, which also possesses the property of gelatinising, although its composition is very different from true gelatine, which is found only in animal organisms.

The stimulating effects of coffee and tea are due to an alkaloid known as caffeine or theine, according to the source from which it is obtained. Its composition is the same in both cases ($C_8H_{10}N_4O_2$), and the pure alkaloid is frequently used in medicine. The agreeable flavour of these beverages is due to various aromatic substances which are extracted by the boiling water from the leaf or berry; but the restorative and exhilarating effects must be credited to the alkaloid, which seems to bear some resemblance to the well-known cocaine.

Flour is one of the most indispensable articles used in the family. It consists principally of starch, with more or less gluten and inorganic or mineral constituents, according to its coarseness or fineness. Some of the finest bolted flours consist almost entirely of pure starch, and are inferior in nutritive value to the coarser varieties, although they make a whiter and more attractive loaf of bread. The raising of "dough" is a true process of fermentation, precisely similar to that of the brewer or whiskey-distiller. The yeast-plant, when mixed with the flour, acts in some mysterious way upon the starch, first transforming it into grape sugar, and then breaking this up into alcohol and carbonic-acid gas. The alcohol is partially driven off by the heat of the oven, though in a freshly baked loaf its odour is quite evident; and the carbonic-acid gas permeates the dough, its expansion causing it to puff up, or "rise," rendering it light and spongy.

Two molecules of starch $(C_6H_{10}O_5)_2$, with the addition of a molecule of water (H_2O), form a molecule of cane-sugar ($C_{12}H_{22}O_{11}$), another substance in universal use. Unfortunately, it is only in the wonderful laboratory of the growing plant that this combination can be effected, or the price of sugar would be even less than at present. It readily crystallises, forming either granulated sugar or rock candy according to the size of the crystals. By heating it melts, and upon boiling is changed into a pliant, uncrystallised mass, known as barley-sugar or sugar candy. At a somewhat higher temperature it becomes partially decomposed, and a dark brown substance, known as caramel, is formed, which is sometimes used for giving a rich colour to soups and gravies. Granulated sugar is seldom or never adulterated, the peculiar form of the crystals rendering any foreign admixture very easy of detection. In the cheaper forms of coffee-crushed and brown sugars much moisture, molasses, and glucose are frequently bought at a high price.

The term "salt" is a familiar one, and is applied not only to the condiment of the table, but to all combinations of an acid and base. Chemically speaking, tallow and the various greasy substances used in soap-making are true salts, consisting of palmitic, stearic, oleic, and other fatty acids, as they are called, united with glycerine as a base. Upon the addition of caustic soda or potash, the acids separate from the glycerine, setting it free, and unite with the alkali, forming soap. Hard soaps are made from soda, and soft soaps from potash. The cleansing action of soap is not well understood, but is doubtless due to the action of the alkali contained in it. Additions of soda-ash, borax, resin, &c., are often made to soap, but are of questionable advantage.

This list of the applications of science to domestic affairs might be extended indefinitely; but enough has been said to show that the great principles of nature control the most common affairs, as well as the experiments of the chemist or physicist.—*Popular Science News* (U. S. A).

ACNE.*

ACNE (the Greek original means the "bloom of anything") is the term given to a retention of the secretion of the sebaceous glands of the skin, with secondary inflammation and deposit in them and in the hair follicles. It is characterised by red conical or hemispherical elevations or nodules; some are solid, others are filled with pus; they are found everywhere except upon the palms and soles, and affect chiefly the skin of the face, chest, and back; and they occur mostly in young persons. The disease appears to be due to the occlusion of the orifice of the hair follicles or of the ducts of the sebaceous glands opening into them. The retained secretion then becomes a source of irritation and inflammation, and suppuration follows in and around the hair sac and its appendages. This, expressed in the fewest words, is the pathological anatomy of simple or uncomplicated acne.

Omitting for the sake of brevity and clearness all the intermediate forms, we may go at once to a type of disease at the other end of the scale, and speak of the so-called acne rosacea. This attacks the face and scalp alone, and is characterised by an intense reddening of the skin, due to an injection of the blood vessels, without much swelling or tension. The serpentine vascular lines, the blood in which may be momentarily driven out by pressure, are most abundant on the sides and the bridge of the nose. This is an obstinate disease, occurring chiefly in advanced age, though not unknown in youth. However great may be the hypertrophy of the skin the disease never extends deeper than the skin, nor does it lead to ulceration. Between the extreme phases of local disease thus delineated there are countless grades and shades which ought to be recognised; for they are so many tokens of constitutional power or inertness, as the case may be.

My notes of treatment profess, then, to deal only with acne punctata, acne vulgaris or indurata, and the acne rosacea, which betrays a grave alteration in the nutritive function of the skin.

The object of the practitioner should be to prevent acne punctata from passing on to acne vulgaris by getting rid of obstruction in the glands and checking the hyperæmia condition; in acne indurata, to lessen hyperæmia and promote the absorption of inflammatory products; and in acne rosacea to destroy the new growth of connective tissue.

The therapeutic points may be expressed thus:—Quiet dormant acne requires stimulation and a spur to more healthy action, while those species of acne which are marked by heat and tension call for soothing local measures. In the one case the medicinal and dietetic plan should be tonic and supporting; in the other we should advise a combination of tonic and aperient remedies and a cooling abstemious regimen.

In order to promote a healthy action of the sebaceous glands, and to prevent the formation of what are called "comedones," the following plan should be adopted, as originally described by Dr. Liveing. The steps of his method are as follows: (*a*) Steam the face every night by holding it over a basin of hot water for a few minutes. (*b*) Rub the skin for five or ten minutes with soap (I prefer terebene soap) and flannel, or with a soft nail-brush; then sponge off the soap with warm water. (*c*) When the face has been dried, a lotion should be thoroughly applied, composed as follows: half an ounce of precipitated sulphur, two drachms of glycerine, one ounce of spirits of wine, with three ounces each of rose-water and lime-water. This is allowed to dry on the skin and to remain on all night. In the morning the face is cleansed with warm oatmeal and water or weak gruel. If, for any reason, an ointment seems preferable to a lotion, a combination of precipitated sulphur and vaseline is very useful. The treatment must be modified or suspended for two or three nights if the skin becomes sensitive and somewhat tender. Dr. Liveing contends that the most common cause of failure is want of perseverance or timidity on the part of the patient or of the doctor; and that we ought not to be frightened from continuing efficacious remedies by a temporary increase in the redness and irritability of the skin. If, by any chance, this plan be unsuccessful, nothing is so effective as the application of potash soap in the form of a lotion. The lotion is composed of one ounce of soft soap, one ounce of rectified spirits of wine, and seven ounces of rose (or distilled) water. This should be rubbed in vigorously with a piece of flannel for a short time, taking care not to make the skin sore. According to Dr. Liveing, the worst cases of acne will yield to the soft soap treatment if practised with necessary caution.

For eight years and more I have followed in its main outlines Dr. Liveing's plan, and with great success. But, the experience which only actual work brings has led me to make modifications to suit the various susceptibilities and irritabilities of human nerves and skin. Some of these modifications I will now relate in the fewest words. In the first place, something is often required to be done during the daytime to pacify the heat and throbbing, which are part of the usual history of acne. An excellent lotion, the heritage of nearly every dermatologist, is made by combining oxide of zinc, calamine, prepared chalk, lead lotion, and lime water, to which may be added a small quantity of glycerine. Let the bottle containing this be gently waved about so as to diffuse the materials, which are only held in suspension; then pour a little into a saucer, and with a sponge (reserved for the purpose) sprinkle the face from time to time. Wipe off, when necessary, with a bit of fine muslin the powder which remains on the skin after the evaporation of the fluid, and the face may be washed occasionally with a little starch gruel. In the second place, the cases are not a few in which it is better not to use any kind of soap as part of the evening ceremonial. After the face has been steamed, we may put on a medicated jelly composed of oxide of zinc, gelatine, and glycerine. It must be liquefied by putting the vessel that holds it into hot water, and then applied with a brush. Then, thirdly, there are some sensitive skins intolerant of sulphur in any guise. When this is so, we should think of combinations of lead and chalk and zinc, blended as a quasi-ointment with the finest vaseline. There are several pharmaceutists in London and the provinces who prepare oleate of lead and oleate of bismuth; and Dr. McCall Anderson's formula of oleate of bismuth with vaseline and white wax has beeu aptly described as "one of the most healing of salves." Sometimes nothing agrees better than the old-fashioned but capital substance called Kirkland's "neutral cerate," which is composed essentially of lead plaster and olive oil.

* Extracted from a paper by Dr. JOHN KENT SPENDER in the *Lancet*.

SCIENTIFIC SOCIETIES.

WESTERN MICROSCOPICAL CLUB.

ON Monday week this club met at the house of Mr. E. E. Halford, of 18, Leinster-square. The subject of the evening was the "Radula of Cephalophorous Molluscs," that is the apparatus by which such creatures as the snail break up their food. In the mouth of these is found a muscular mass, stiffened by two so-called "cartilages"; to this mass Mr. B. B. Woodward, who officiated as demonstrator, would restrict the name of "odontophore." Over this is stretched a horny membrane, bearing on its upper surface numerous horny teeth disposed in rows. The inner end of this membrane, known as the "radula," is encased in a sac, arising beneath the œsophagus. The teeth are hook-shaped, their points curving back towards the throat. They are secreted by certain cells at the posterior extremity of the radula-sac. As those in front are worn away by use, the whole radula moves forward, just as the human finger-nail, secreted in the fold of the skin enveloping its base, grows forward to replace the waste at its tip. The radula is found in Cephalopods, Pteropods, and Gastropods. It is so distinctive of these, that those strange, worm-like animals, Neomenia and Chætoderma, are relegated to this last group, mainly because they possess a radula. The diversity in number, shape, and arrangement of the teeth gives rise to an almost endless variety of patterns, hence their popularity as microscopic objects. Mr. B. B. Woodward pointed out the system by which the various patterns of these are expressed by sets of numbers. The length of the radula varies greatly, though not at all in proportion to the size of its possessor. It attains its greatest length in the common periwinkles and limpets, being found in the latter sometimes nearly 3in. long. In the edible snail (Helix pomatia) it is very little longer than its breadth, about ¼in. But here what it needs in size is made up by the number of minute teeth, amounting to 21,000. In the slightly larger radula of the big slug (Limax max.) there are 27,000 teeth.

A classification of the Mollusca, according to the arrangement of these teeth, has been attempted. It is, however, now acknowledged that they cannot be depended upon for such a purpose, though they are still an aid to the relationships and derivations of the Mollusca.

After reference to the literature of the subject dating from the time of Aristotle downwards, Mr. Woodward concluded an exposition listened to with great interest by the members. A discussion ensued, in which Prof. Stewart gave a number of interesting facts and theories to account for the extraordinary boring powers of some of the molluscs. Dr. Thudichum took exception to the statement that the teeth contained chitin; in his experience, this substance was not found in any creatures above the Arthropoda. Numerous beautiful sections of whole molluscs were shown by Mr. M. F. Woodward. Microscopes and illustrative objects were contributed by Messrs. Bartlett, B. F. and E. E. Halford, Moore, Nelson, Snow, E. Swain, Stokes, B. B. and M. F. Woodward.

The next meeting of the club will take place on Feb. 7, when Mr. F. Crisp, LL.B., Secretary to the Royal Microscopical Society, will open to the club his unrivalled Museum of Microscopes and Microscopical Apparatus.

A RUSSIAN engineer claims to have discovered a process of reducing petroleum to the form of crystals, which may be easily and safely transported to any distance and then reconverted into liquid form.

SCIENTIFIC NEWS.

THE death is announced of Mr. John Arthur Phillips, F.R.S., F.G.S., the well-known mining engineer, chemist, geologist, and metallurgist. Born in Cornwall sixty-four years ago, he was destined for the profession of a mining engineer; but as no mining school then existed in this country, he received his technical education at the Ecole des Mines at Paris. It was here that Mr. Philips imbibed that taste for original research which never deserted him, and which led to his numerous investigations, bearing, for the most part, upon the application of chemistry to mineralogical and petrological questions. His works on mining and metallurgy have long been regarded as standard textbooks, and at the time of his death he was engaged with Mr. Bauermann on a new edition of his well-known "Elements of Metallurgy."

Col. Sir Francis Bolton, founder of the Society of Telegraph Engineers and Electricians, inventor of the system of telegraphic and visual signalling introduced into the Army and Navy, and well-known in connection with the illuminated fountains at the series of exhibitions at South Kensington, died last week, in his 55th year. The deceased had filled the office of Water Examiner under the Metropolis Water Act since 1871.

Mr. John Roach, the well-known American shipbuilder, is dead, at the age of 73 years.

Father Denza, of Moncalieri, gives in *Cosmos* the results of the watch kept in the Italian observatories on Nov. 27 for meteors. He concludes that the majority radiated from Perseus and Taurus, very few from the radiant of the Andromedes. The stream is therefore probably of small extent but very dense, and also has its origin in the disintegration of Biela's comet.

The *Journal* of the Liverpool Astronomical Society for January, 1887, contains, as usual, a number of interesting papers, with a variety of notes, &c.

A meeting was held last week in Glasgow with the view of forming a Scottish Astronomical Society, but acting on the suggestion of the chairman those present decided to seek connection with the Liverpool Astronomical Society, leaving the formation of a special society in Scotland until such time as a sufficient number of members could be got together. It appears, however, that an effort will be made to form a Scottish Society at once; and all interested in the movement or willing to become members are requested to communicate with Mr. William Peck, F.R.A.S., 6, Hanover-street, Edinburgh.

The lectures founded by Sir Thomas Gresham will be read to the public gratuitously on the following days at Gresham College, Basinghall-street, in the subjoined order, beginning each evening at six o'clock:—Rhetoric (Mr. J. E. Nixon), Jan. 18, 19, 20, and 21; law (Dr. Abdy), Jan. 25, 26, 27, and 28; geometry (Dean Cowie), Feb. 1, 2, 3, and 4; physic (Dr. Symes-Thompson), Feb. 8, 9, 10, and 11; divinity (Dean Burgon), Feb. 15, 16, 17, and 18; astronomy (the Rev. E. Ledger), Feb. 21, 22, 23, 24, and 25; and music (Dr. H. Wylde), March 1, 2, 3, and 4.

In reference to the new storage battery, which we referred to on p. 367, brought out by the Union Electrical Power and Storage Company, of 127, Cannon-street, it may be as well to say, in answer to numerous inquiries, that all the available particulars concerning it will be found in No. 1107, p. 316, and No. 1128, "Lithanode," p. 208. It is stated that the new storage cell gives 50 per cent. more work for its weight than other batteries.

An improved battery, which is said to be capable of maintaining a constant current, has been patented here by Dr. Lugo, of New York —9403, 1886. The carbon element is in a porous cup containing a solution of chloride of copper. The zinc element is immersed in an alkaline solution in the outer jar. The carbon element is made in the form of a cup containing free hydrochloric acid, which immediately dissolves the precipitated copper, and prevents it from being deposited upon the carbon. A new supply of chloride of copper is thus constantly formed, chlorine is supplied to the zinc, and the action of the battery is kept up.

With reference to the placing of the telegraph wires underground some experiments have been recently made at the Borough-road works of the Anglo-American Brush Co. with a system devised by Mr. T. O. Callender and Major-Gen. Webber. The wires in this system are laid in cases of bitumen concrete made in 6ft. lengths, and jointed with molten bitumen. At intervals of about 100ft. "flush-boxes" are provided for examination and repair. Each cable has a separate "way," and is completely separated from others by the bitumen concrete, which is an insulator, and very strong, so that it may be laid near the surface, while it can be moulded of any required shape.

Mr. R. S. Culley, the author of "A Practical Handbook of Telegraphy," says that more than thirty years ago underground wires were tried in this country—one system running along the London and North-Western Railway from London to Manchester, Liverpool, and Leeds; another along the high road from London to Carlisle. Neither worked more than five years, although constructed with the greatest care, and at much expense. The method adopted in Germany is to form a complete cable, just as for submarine work, with a sheath of galvanised steel wire, and to coat it with bitumen while laying it in a deep trench. The cost is great, but so is that of the annually recurring break-down of overhead lines, not only on account of repairs, but also because of the loss of business.

The subject chosen by the Paris Academy of Sciences for their "grand prix des sciences mathématiques" (3,000fr.), was "the perfecting in some important point of the theory of the application of electricity to the transmission of energy"; but only one memoir was sent in, and the committee of adjudication (MM. Levy, Becquerel, Bertrand, Fizeau, and Cornu), have, without prejudice to the author of the paper received, determined to leave the competition open for the present.

Prof. Perry, F.R.S., will commence at Finsbury Technical College, on Jan. 20th, a series of six special evening lectures on the "Steam-engine Indicator Diagram," to be continued on Thursdays, the laboratory demonstrations being given in alternate weeks. A number of special pieces of apparatus have been devised by Prof. Perry on purpose for this course.

Explosions of gas and of kitchen-boilers have been rather frequent of late, and have, as usual, been caused by a want of care. Mr. L. E. Fletcher writes once again to urge the necessity of fitting all such boilers with a safety-valve, for it is not only when the water freezes there is risk. An instance occurred on July 21st last at Stoneleigh Abbey owing to the stop-taps on the flow and return-pipes being shut.

At a late meeting of the Vienna Chemico-Physical Society, Dr. Hans Molisch described two distinct tests for sugar in liquids. Half a cubic centimétre of the liquid is mixed with two drops of a 15 to 20 per cent. alcoholic solution of alpha-naphthol, and concentrated sulphuric acid is added in excess. If the liquid is then shaken, a deep violet colour appears when sugar is present, and on the addition of water a blue-violet precipitate is formed. The other test is similar, but with thymol instead of naphthol, and the colour assumed by the liquid is carmine-red.

The "Year-Book of Photography" for 1887 is, as usual, full of interesting matter, and contains, amongst other illustrations, an example of "pin-hole photography," or photography without a lens—a subject of discussion in our last volume, pp. 289, 307, 330, 354. The subject is the façade and dome of the Invalides at Paris. Pinhole, 1-80th of an inch; distance of plate from hole, 5in.; exposure, 20secs.

It has been resolved to erect a monument to James Watt in his native town of Greenock.

SOCIETIES for the advancement of dress reform for women have been established in Sweden, Norway, Denmark, and Finland. They intend to work on the same lines as the English Rational Dress Society, and, as far as possible, in connection with it.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, *332, Strand, W.C.*

All Cheques and Post-office Orders to be made payable to J. PASSMORE EDWARDS.

*** *In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks, a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

SATURN'S RING—DARK TRANSITS OF JUPITER'S IVth SATELLITE — A VERY NOVEL FORM OF OBJECT-GLASS — A MARE'S-NEST IN THE CAMERA—POPULAR SCIENCE—THE OCCULTATION OF ALDEBARAN — STOPPING A FOOTPATH—KEEPING TRUE TIME—M. FOLIE "NODDING."— OF A VERY INFERIOR STAMP—ROAD REFORM — NAVIGATION — LENGTH OF CHORD—ASTRONOMICAL PHOTOGRAPHY—DECREASE OF SUN'S HEAT WHEN HE IS NEAR THE HORIZON.

[26685.]—I DO not know whether any public institutions in England receive the *Bulletin* of the California Academy of Sciences; but, if so, I may commend its perusal to such astronomers as may be able to obtain access to it, containing, as it does, much that is interesting in connection with the study of the Heavens. A notable contributor to its pages is Professor George Davidson, of the United States Coast and Geodetic Survey, whose descriptions of planetary detail, &c., as observed with a 6·4in. equatoreal, form really valuable contributions to our knowledge of the physical structure of the members of our Solar System. Going back to the year 1883, I find that this practised observer speaks so definitely of the existence of Encke's division in Ring A. as to predicate pretty definitely the distance to which it extends on the ring. Now, as I have before remarked, it is of no use for any one to oppose to an observation of this kind (made under a combination of peculiarly favourable circumstances) the allegation that he has scrutinised Saturn with a bigger instrument and has *not* seen the division! No one can read Professor Davidson's papers and doubt that at all events it existed at the date of his observation. Can this anomalous mark be variable? Another matter of considerable interest is the dark transits of Jupiter's IVth satellite in 1884, which was observed by Mr. Charles Burckhalter, of the Chabot Observatory, Oakland, Cal., employing a $10\frac{1}{2}$in. Brashear reflector; by Mr. C. B. Hill, at the Davidson Observatory, and by Professor Davidson himself. An observation of Mr. Burckhalter's which seems eminently worthy of attention would appear to indicate that the IVth satellite of Jupiter is divided into bright and dark areas, the south pole being the dark one. As was remarked by the President of the Academy, a careful watching of a satellite thus marked right across the planet's disc might even lead to the determination of its rotation period. This would, of course, apply equally to Satellite III., which also presents a partly bright and partly dark disc to us. (See, too, p. 168 of "Celestial Objects for Common Telescopes.")

A description appears on p. 126 of certain microscopic objectives manufactured from a new glass discovered or invented by Prof. Abbe. Judging from a passage in a letter received recently from a friend of mine, this remarkable material would seem to have been applied to the construction of at least one object-glass for a telescope; and the details are to me so curious and inexplicable that I propose to quote *verbatim* from the letter in question, and ask Mr. Penny, for one, what his idea of the matter is:—"C'est," said my friend, "le nouvel objectif fait avec le verre d'Abbe. Dans ce système l'objectif ne le compose plus que du crown seul; le flint est supprimée; la correction est obtenue par une lentille placée devant l'oculaire et les deux corrections seraient realisées d'une manière *absolue*. Enfin à diamètre egal, l'objectif donne quatre fois plus de lumière. Il existe un six pouces ainsi construit à Potsdam. Le cout en est formidable sans doute. . . . . N'en a-t-il donc pas encore été question en Angleterre?" Have any of my brother readers heard previously of this remarkable object-glass at Potsdam, which, consisting simply of a disc of Abbe's peculiar crown-glass, is rendered abso-

lutely aplanatic by means of a small lens in front of the eyepiece? The whole thing seems so entirely opposed to all one's preconceived ideas of the optics of the refracting telescope, that details cannot fail to be of the highest interest. Pending an attempt I shall make to get them from the Continent, any information on this subject cannot fail to be valuable. For aught I know, such information may already exist in accessible form in this country; but if so, I unfortunately do not know where to lay my hand upon it.

From time to time astronomical *canards* are started, which take in a limited public for a short period, and then die a natural death. Visible inhabitants of our own Satellite; lights moving about on the surface of Mars, as an obvious attempt on the part of its population to signal to and communicate with their fellows in other members of the Solar System; and Wiggins's "Dark Moon" afford illustrations of what I mean. As a cock-and-bull story of the first magnitude, however, it is long since I have come across anything to surpass the announcement, reproduced in your "Scientific News" on p. 387, that Mr. Roberts had photographed 20 planetoids in the neighbourhood of θ Orionis! Mr. Roberts is a persevering man with an ample fortune, and doubtless possesses everything in the shape of apparatus that money can buy: but to ask astronomers to believe that he has succeeded in photographing twenty asteroids at once is a demand upon their credulity which will, I fear, be but feebly met indeed. The mere fact that the mass of star discs upon his negative are elongated in a north and south direction, shows that apparently the driving clock of his equatoreal is far from perfect. That it should have stopped altogether during a short temporary accidental exposure, that the plate should have slipped (the most probable supposition), or even that a shower of meteorites should have left short traces on the plate;—one and all of these explanations are infinitely more credible than the one put forth. I do not wonder half so much, however, at Mr. Roberts, with his imperfect astronomical experience, fancying that he had lit upon a new planetary system, as I do at the Astronomer Royal for Ireland giving this wild idea the sanction derivable from his ridiculously flattering speech. Whether Sir Robert Ball made it with his tongue in his cheek, the reporter wholly omits to mention. If this sort of thing is to go on, we shall be able to shorten the term "mare's nests," as applied to quasi-miraculous discoveries in the sky, into "Roberts's." (Since this was written, I have seen an engraving from part of Mr. R.'s plate in the *Journal* of the Liverpool Astronomical Society, whence it appears that all the lines are close to bright stars, exactly at the same distance apart, and of the same relative brightness as the stars they accompany. This settles the question.)

The paragraph on "Popular Science," extracted from *Engineering*, on p. 388, reminds me that a few days ago one of the leading morning papers came out with an account of the utilisation of the sun's rays by their concentration on a steam-boiler as a bran-new scientific invention! I thought at the time that it was a great pity that the writer was so indolent a student of his ENGLISH MECHANIC as to have forgotten (or never known) that this device was described and illustrated on p. 444 of your XXIInd volume.

The occultation of Aldebaran by the moon last Friday night (concerning which "A. W." put query 61307, on p. 399) might have been observed with a first-class hand telescope quite within 1 second, at the star's disappearance at the dark limb of the moon. As for getting "the correct time" from this, though, it would involve a great mass of very complicated calculation, obviously quite beyond the power of your correspondent. A few elementary considerations may serve to show him why. The moon is so comparatively close to the earth, that, as viewed from stations separated by a very few hundred miles, she is sensibly displaced in the sky. At Bridlington Quay, for example, she would appear quite perceptibly to the south of that point of the celestial vault upon which she would be centrally superposed as seen from Greenwich. Hence Aldebaran disappeared at a different (and more northerly) part of her limb to that by which she was occulted as viewed from the Royal Observatory. The small difference of longitude, too, between Bridlington and Greenwich would involve another, though comparatively trivial, correction. What "A. W." will have to do, in fact, should he observe either of the occultations of α Tauri in the evening of March 2nd or the early mornings of July 17th and October 7th, will be to compute the phases of the occultation *de novo* for his own locality—a work, as I have previously hinted, of a very elaborate and operose character. Of course, if the moon were so far off that a star was covered by her advancing limb at the same absolute instant as viewed from every part of the earth whence it was visible, then, knowing his longitude, your querist could find his time with the utmost ease and simplicity; but as this is, as I have tried to explain, very far indeed from being the case, he can only do so approximately at the cost of a very great deal of real hard work.

In reply to query 61314, p. 399, if the footpath concerning which "G. F. O." inquires is a public right of way, he clearly can *not* plough it up; or, if he does and sows it, with the rest of the field, the public, to whom it has been dedicated, are clearly within their right in trampling down so much of his crop as covers the ancient pathway. The law is righteously jealous of right of way, and the closing of a road or pathway is a very elaborate process, as "G. F. O." may discover from the perusal of the Act 27 and 28 Vict. c. 101, secs. 84—93.

Among the many gratifying proofs of the silent but rapid spread of a taste for applied astronomy, may, I think, be reckoned the fact that Mr. Latimer Clark's little book of *Transit Tables* has become "a hardy annual." Obviously it must address a sufficiently numerous public to render it remunerative; and, as surely, that public must purchase the work for *use*, and by no means for amusement, or for reading in railway trains. I am very glad, indeed, to find that people are becoming more anxious to obtain and keep accurate time; and are no longer content to trust to a station clock, to which the time is "brought" once a week, as well as a £3 watch (as probably as not itself wrong) will carry it. If we consider how much may hinge upon the correctness of a public timekeeper such as the clock of a parish church, I almost wonder that, in these days of grandmotherly legislation, a short Act has never been passed to render it compulsory for the custodians of such clocks to possess some independent means of deriving true time from the heavens. I have myself known the church clock in a large country parish, after being sometimes five minutes slow and sometimes five minutes fast, to stand at 10h. 55m. for nine days consecutively. If I had my way, I would compel the churchwardens in every parish in the kingdom to provide one of Mr. Clark's excellent and economical transit instruments, and the small book of tables which have formed the text of my remarks, for the use of the clerk, verger, or sexton, whichever has control of the church clock. It would really, though, almost seem as though voluntary action will before long abrogate any necessity for compulsion—a consummation most devoutly to be wished.

Following up the remarks I made in letter 26389, p. 171, in connection with the theories of the Belgian Astronomer Royal, I may say that I was highly amused at a little paragraph in the current number of *The Observatory*, in which it is pointed out that in a communication to the *Comptes Rendus* for Dec. 13th, M. Folie gives practical illustrations of results obtained by adopting his theory of the diurnal nutation of the earth's axis. "So far," says the author of the notice in *The Observatory*, "as we can gather, his method is to obtain from a series of observations of a star a certain constant of diurnal nutation, then, by substituting in his formulæ this value, he obtains a correction to each observation"! I call this delicious. Probably as an example of the circulus in probando, it is unsurpassed. Where ignorance is bliss 'tis Folie to be wise.

What a golden opportunity has been lost in the new issue of postage stamps of rendering them of some historical value. I have, so far, only seen the threepenny one, which is as mean and vulgar a production, with its staring black and yellow, as could well have been devised; but what I most especially refer to is this—and if it appears in one stamp of course it has been repeated in all—the ridiculous head of the Queen, which is represented as that of a girl of 19! If this is meant by some snob for flattery, it is flattery of the very poorest description. From every almanac that is published, from *Whitaker* down to the penny *Moore*, we may learn that Her Majesty is in her 68th year; and to represent a rather stout elderly lady of that age as a slight girl not out of her teens is too coarse and gross a piece of sycophancy to delude anybody. On the half-crown of George III., of which so many are still in circulation, we may still discern the honest likeness of that monarch as an old gentleman. I cannot and will not believe that it is by the desire of the Queen herself that this twopenny-halfpenny piece of flunkeyism has been perpetrated. If on each fresh coinage or issue of stamps the head of the Sovereign were accurately represented from a strictly contemporary likeness, a valuable contribution would be made to the history of the future; as it is, the supposititious profile of the Queen possesses about the same amount of historical value and interest as the Roman toga on the idiotic image of George IV. in Trafalgar-square.

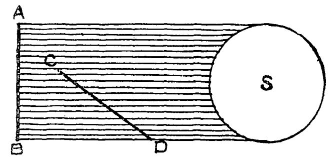
I wonder what "Norfolk" (letter 26677, p. 414) is prepared to pay annually in Highway Rate towards the attainment of his charming little scheme of road reform? To cut bodily through a hill of any magnitude would entail enormous expenditure; while to divert a road through people's parks, farms, and pleasure-grounds would probably involve an even heavier cost still. No doubt roads have been laid out, in the dim and distant past, in defiance of any scientific principles; but there they are, and unless we submit to an impossibly overwhelming amount of local taxation, the only thing we can do is to make them hard, firm, and sound. The jobbery incident on our existing system of appointing parochial highway surveyors has much more to do with the unsatisfactory character of many country roads than the existence here and there of an awkward gradient. I should really like to see "Norfolk's" estimate of the cost of reducing the roads of (say) Devonshire to anything approaching a series of gentle slopes.

In connection with reply 60092 (p. 415), it may not be out of place to inform Mr. Shearer that in the very rough-and-ready formula I gave I treated the earth as a plane: or, perhaps it would be more correct to say, gave the distance between the observer's eye and the base of the mountain through the intervening convexity.

The most simple way for "J. F." (query 61348, p. 420) to find the length of the chord of any given arc is by the formula: Chord of arc = 2 sin. of $\frac{1}{2}$ arc. This really requires no knowledge of trigonometry, although a table of natural sines must be used. For example, What is the length of the chord of an arc of 13° 30′ in a circle of 4ft. 6in. radius? Half this arc is evidently 6° 45′. Now, the natural sine of 6° 45′ is 0·117537, and if we multiply this by 4·5 we get 0·5289165ft., the length of the sine to this radius. Doubling this, we finally obtain 1·0578330ft. as the length of the chord we require.

In reply to query 61355 (p. 420), astronomical photographs are taken in a camera fixed in the focus of the object-glass or mirror of a telescope. Sometimes (as in Mr. Robert's photographs) the sensitive plate is placed directly in the primary focus of the mirror; in other cases an enlarging lens is interposed. The length of exposure varies from a fraction of a second to an hour and a half, or longer: the longer the exposure the larger, more blurred, and indistinct do the discs of bright stars become, but the greater the number of previously invisible stars which impress their images on the plate. Instantaneous exposure then would only avail in the case of bright stars. The concluding part of the query I fail to understand, "Zenith arrangement" being a wholly novel idea to me. "Southings," if used in connection with photographic plates, can only mean fixing the north and south points, or direction of meridians upon it.

In connection with query 61363, p. 420, it may suffice to remark that obliquity of the sun's rays does make a very material difference in the number of them which fall upon any given area, as "J. C. O." may see from the subjoined simple sketch:—



where S represents the sun from which rays are falling square on to the surface A B. If now we tilt that surface as at C D, it will be seen at once how considerably the numbers of incident rays is decreased. In short, they form nearly a tangent to that part of the earth's surface where he is rising or setting. Of course, atmospheric absorption does come in too to diminish the sun's heat when he is close to the horizon.

A Fellow of the Royal Astronomical Society.

A NEW SPECTROSCOPE, AND SOME ACCOUNT OF WORK DONE WITH IT —U CYGNI.

[26686.]—DURING my search for new red stars I frequently wished that I had a spectroscope to examine the spectra. I purchased a McLean star spectroscope, and found it showed the spectra of the bright stars very beautifully; but as the majority of the new red stars detected were faint ones, this spectroscope was quite incapable of doing the work which I had hoped for. For some time I was much puzzled what to do, till I happened to find in a note at the end of Dr. Huggins's address on "Spectrum Analysis applied to the Heavenly Bodies," delivered at Nottingham before the British Association, August 24th, 1866, the following passage:—

"In order to see the spectrum of a star, it is not necessary to do more than to place a prism behind the ordinary Huyghenian eyepiece, and to give a little breadth to the spectrum by placing the star a little out of focus. For such an apparatus, a small compound prism which gives direct vision is convenient. The prism may be placed within the converging pencils of the object glass immediately before they fall upon the field lens of the eyepiece." Happening to have two

compound prisms of five prisms cemented in the ordinary manner made by Elliot and Co., I proceeded to devise a spectroscope after the manner above described. I tried various eyepieces, and found that a medium-powered one gave the best results.

The accompanying figure will enable any brother reader to make one for himself. A is the ordinary adapter for the telescope into which the eyepiece E, magnifying 200 times, screws; B is a second adapter, fitting inside the first. It is prolonged at each end so as to protect the prisms, which are shown by P.

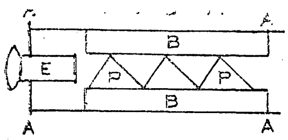
As soon as a red star is swept over, the sweeping power can be changed for the spectroscope as easily as one eyepiece is changed for another. With this instrument attached to the 17¼in. reflector the spectra of stars down to the 9th magnitude can be observed. Some idea of the ease with which it is managed, and the work it is capable of doing, will be best obtained by tabulating the work done on the nights of Nov. 24th, 25th, 29th, and 30th—four in all.

New stars of IV. type	15
New stars of III. type	31
Type doubtful.....................	7
	53

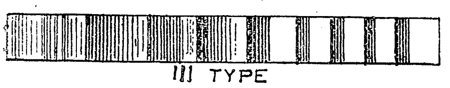
The greater part of these were not set for, but were actually swept for, so that the number of stars actually examined on these nights would be probably three times as many at least. Dr. Dunér, in the *Memoir* "Sur les E'toiles a Spectres de la Troisième Classe," gives only 55 stars of the IV. class discovered up to the present time. During November seventeen new ones were added. Perhaps the best testimony to the excellency of the instrument will be given by showing the number of stars of the IV. class detected by those who searched for them:

Dunér	27
Espin....................................	17
Secchi	14
D'Arrest	7
Pickering	4
Vogel....................................	3
	72

Of course, we must not forget the large light-grasping power of the telescope. I have headed this letter a "New Spectroscope"; but this must be understood as referring to the making up of it, as it is clear Dr. Huggins has already used something of the kind, as has also, I believe, Professor Pickering. I have tried in Fig. 2 to give some



F I G. 2.



III TYPE

IV TYPE

idea of the appearance of the stars of the III. and IV. type. The figures are freely copied from those of Dr. Dunér; but his do not give the columnar effect in the III. type stars, which I have tried to represent.

As regards U Cygni and the colour of the 8-mag. companion, I have never seen the blue colour mentioned by your correspondents. With a small aperture it had certainly a bluish look, due mainly to contrast with the beautiful red star; but with the larger aperture, the star has invariably been found to be yellowish. The blue companion to β Cygni loses nothing of its colour in the 17¼, showing that it is not the increase of aperture which diminishes the colour of the companion to U Cygni. This red star shows a weak IV. type spectrum. The neighbouring variable star, B 535, which is now approaching a minimum, shows a much more strongly marked IV. Your readers must not suppose that Fig. 2 represents the spectrum of all III. or IV. type stars. Very few stars have the whole of the bands there shown.

T. E. Espin.

The Liverpool Astron. Society's Observatory, Wolsingham, Darlington, Jan. 4th.

THE LUNAR RAY SYSTEMS.

[26687.]—ON p. 368 of the "E. M.," Mr. Gemmill has an interesting letter on the vast ray systems which form so striking a feature in the full-moon aspect of our satellite. It is remarkable how these features should have been so neglected as they have been, in common with all full-moon markings, especially by those selenographers devoted to the idea of real changes being still in progress upon the moon's surface; since there is every reason to believe them to be amongst the most recent of lunar objects, and therefore one would be more likely to find changes still going on in them than in the older formations. It is a fact, however, that not a single one of the great ray systems has ever been more than very superficially studied, and we do not yet possess a map or chart of one sufficiently exact or detailed to be of much practical use. The best maps of the ray systems, and the full moon markings in general, which we have are undoubtedly photographic; but the best photographs hitherto produced give but a very poor and incomplete idea of the real objects, and are often difficult to interpret, even as far as they go.

With regard to classifying the different ray systems into Tychonic, Copernican, and the Messier rays, I think our present knowledge is scarcely sufficient yet to authorise us in doing this. The Proclus rays are clearly not all "Tychonic," as Mr. Gemmill points out; nor are the Tycho rays themselves all "Tychonic." There are undoubtedly other rays of a similar character to the two bright streaks starting from Messier A. One will be found issuing from Pico, and forming part of one of the Tycho rays, is almost a facsimile of the Messier system.

A *complete* list of ray systems, however desirable, will, I think, in practice be unattainable, for it will be found that nearly every walled-plain, crater, craterlet, mountain, and bright spot, are centres, more or less complex or important, of a system or systems of light rays; and that there is no visible line of demarcation between the bright rays and the ordinary bright streaks which cover the surface of the moon. Still, a catalogue of the more prominent systems, embodying in it a short description of the principal characteristics of each one, would be of much use. It would not necessarily require also great instrumental power for its formation. Some of the best lunar photographs would here no doubt be of much assistance, since it is chiefly in the minuter details that these break down.

Mr. Gemmill does not say whereabouts he thought he saw portions of several great systems curving round from the invisible hemisphere. More information upon this subject would be interesting, as throwing some light upon the condition of the invisible side of the moon, though there can be little real doubt but that it resembles the visible one. **A. Stanley Williams.**

COMET F, 1886.

[26688.]—NO doubt both you and your correspondent, B. J. Hopkins, will have thought it strange of me not writing before now to explain the mistake I made in my letter of December 9th, 1886 (26572, page 322) in my description of the position of the small tail of this comet; but the reason is I have been so very busy during the last few weeks with removal to a new house, and other matters, that I have had very little leisure for letter writing, so I desire to take this, my first, opportunity of expressing my regret for having accused Mr. Hopkins of error when I was in error myself.

My previous letter was written in a great hurry, and in the hurry I thoughtlessly described the position of the small tail with reference to the actual direction of the comet's movement across the sky, instead of with reference to its apparent movement across the field of view of my telescope, therefore, I was both right and wrong in saying it was on the following side: right, because it was on the following side with reference to the comet's real motion, but wrong because it was on the preceding side with reference to the comet's apparent motion across the field of the telescope, and as the latter is the very motion which is ordinarily referred to in using the terms "preceding" and "following," I frankly admit the mistake was mine, and not Mr. Hopkins's.

I have made several evening observations of this comet since writing my previous letter, and found its general form remains much the same as there described, the only appreciable change being the gradual diminution of its brightness.

I have also swept several times for "Finlay's" comet (*e*, 1886) but without success, and as I have been previously very successful in picking up faint comets, &c., I suppose it must be beyond the reach of my 3in. glass. Is it so?

Huddersfield, January 7. **Excelsior.**

VACCINATION AS A PREVENTIVE OF SMALL-POX.

[26689.]—THE Vaccination Acts were passed in England through the instrumentality of the Epidemiological Society, whose report (since shown to be full of fallacies) was accepted by Parliament unexamined and unchallenged in the year 1853. It is rather singular that this period should have been chosen for rendering the Jennerian prescription obligatory, as there was no epidemic of small-pox, and the mortality was greatly below the average. In London for that year there were only 211 deaths from small-pox, and the indifference to vaccination was increasing all over the country; in some districts the practice had been virtually abandoned without any increase of small-pox. Immediately after the passing of the Act of 1853 small-pox began rapidly to increase in the Metropolis, as will be seen by the following annual summary of the Registrar-General for the last 30 years:—

Decades.	Estimated Mean Population.	Small-pox Deaths.
1851—1860 ...	2,570,489 ...	7,150
1861—1870 ...	3,018,193 ...	8,347
1871—1880 ...	3,466,486 ...	15,551

the lowest decade averaging 200 per cent. more than the year this law was passed by Parliament. This increase is attributed by some medical authorities to be in part due to the contamination of the blood by vaccination and variolation; but it is alleged that the mortality amongst the small-pox patients registered in hospital as unvaccinated is eight times as great as amongst the vaccinated; but this, allow me to say, is not a fair way of drawing conclusions. The prime factors of vaccinated and unvaccinated are, it should be known, a variety as well as a quantity. The unvaccinated are: Firstly, the neglected classes, whom Mr. Bright once called the "residuum"; secondly, the unhealthy, whom the vaccinators dare not operate upon. The *British Medical Journal* for Oct. 23, 1881, says:—"It is probable that a large proportion of unvaccinated persons is to be found among the ignorant, dirty, and wretched inhabitants of the slums in London, and very few among the educated and better-fed members of society. The disease (small-pox) is much influenced by overcrowding." In short, the unvaccinated in the metropolis are a class more amenable to disease generally, and are the first to succumb to all zymotics, not because of non-vaccination, but by reason of non-sanitation. This is not the case with the children in unvaccinated countries, as in the cantons of Garus, Appenzell, Basle, Lucerne, Zurich, and Schaffhausen, Switzerland; in some of the provinces of Spain where vaccination is not enforced, and amongst the sect of the Lippovians in the Baltic provinces of Russia, whose religion forbids the operation, and where all are unvaccinated. These are found to be not more, but less liable to disease (small-pox included) than vaccinated children generally, and the same may be said of the now large unvaccinated populations in Dewsbury, Bingley, Keighley, Leicester, and other districts of England. **William Tebb.**

7, Albert-road, Regent's-park, London, Jan. 4.

VACCINATION.

[26690.]—I SHALL be obliged by your giving me space for a few lines in answer to "W. H.'s" letter.

I had at first intended to leave it unanswered, as there is not much use in replying to anyone whose line of argument seems to be—We differ, therefore you are wrong. The doctors' reports confirm what you say, therefore doctors are interested parties, and their reports not to be trusted.

However, as I may not have made the matter as clear as it might be made, I will endeavour to make it clearer.

I may mention here that there is an error in my former letter which I should have written to correct had I not thought the meaning was obvious. The 6th paragraph should have been as follows:—

"The last year's return for London was as follows:—

Deaths from small-pox		899	
Of which	unvaccinated	330	
	vaccinated	218	569."
	not stated:................	351	

No one, that I know of, ever stated that every person vaccinated is exempt from small-pox, as "W. H." would have seen if he had read my letter with care before answering it, as I pointed out that the protection afforded by vaccination decreased after a lapse of some years. What I asserted, and repeat, is that the proportion of vaccinated persons who die of small-pox is very greatly less than amongst the unvaccinated.

There are in London, within the Registrar-General's tables of mortality, in round numbers, 3,800,000 persons. Of these, $\frac{19}{20}$, or 3,610,000, are vaccinated, and $\frac{1}{20}$, or 190,000, are not.

Now, if we divide these numbers respectively by 576 and 330 (the number of deaths amongst the vaccinated and unvaccinated) we find that one person in 6,344 died amongst the vaccinated, and one in 576 amongst the unvaccinated.

Again, if we divide 3,610,000 by 576, we get the number of persons who would have died amongst the vaccinated if the same rate of mortality had prevailed amongst them as amongst the unvac-

cinated. This gives 6,267, and, deducting 569, the actual deaths, we find that 5,698 persons owe their lives to vaccination, for if vaccination were no protection there could be no reason why the vaccinated should not have suffered in the same ratio as the unvaccinated.

The worst epidemic in London of late years was in 1871, when the deaths from small-pox amounted to $2\frac{1}{2}$ per 1,000; this is probably the worst "W. H." has ever seen, and is trifling to some of the epidemics which have occurred in countries in which vaccination is not practised, the deaths being from 10 to 15 per thousand.

I add an extract from the tables for 1882, to show that there is nothing exceptional in the returns for 1885.

It is to be regretted that in so many cases it was not possible to ascertain whether the case was one which had, or had not, been vaccinated. I have in every case considered the doubtful cases as vaccinated, only calculating those deaths unvaccinated about which no doubt existed. The deaths registered since 1882 were as follows:—

Deaths.	1882.	1883.	1884.
Unvaccinated	184	55	319
Vaccinated	108	42	250
Not stated...........	139	37	344

I would have wished some abler writer had taken this matter in hand; but in default I have used my very best endeavours to show the real state of the case, and as I hope very few of your readers share "W. H.'s" opinion regarding medical men, I hope I may be successful.

Mr. Young refers to an increase in the number of deaths from small-pox during the 15 years from 1869 to 1883; this would be in part accounted for by the increase in population, and in part by the year 1871 having been one in which small-pox was unusually prevalent, the number of the deaths reported as unvaccinated being unusually large.

I have just been referring to an account of the statistics of small-pox towards the end of the last century in the "Encyclopædia Britannica," Vol. II. page 95, previous to the discovery of vaccination. The report states that the deaths from small-pox in Great Britain and Ireland were annually from 40,000 to 45,000; whilst in London, with a population of over 1,000,000, the deaths for a period of 75 years averaged 2,020 yearly, and that one in ten of all the deaths in London was from small-pox. It was also stated that in Chester, Liverpool, and Manchester one person in 205 died of it yearly.

I think this record of the past, compared with Mr. Young's statistics of the present, is a sufficient proof of the fallacy of his argument against the value of vaccination as a preventive of small-pox.

Lavant.

ANTI-VACCINATION.

[26691.]—IN 1819 I and an older brother and sister were vaccinated with vaccine taken from a cow in the parish. Eight years afterwards we were each of us inoculated for the small-pox, and slept with younger brothers (who had also been inoculated) while they had the small-pox, without acquiring the disease. I have several times since been with persons suffering from small-pox, but have never caught it. Only one puncture was made in my arm, and that was the custom during the early years of my life; but as vaccine became more and more diluted by transmission more punctures were deemed necessary. Next, the seven years' limit was instituted. It is nearly seventy years since I was vaccinated, and I am safe from small-pox now.

"W. H.'s" wholesale condemnation of the honesty and veracity of medical men reminds me of the sore-backed horse, who, when turned into a field where there were other horses, would not believe, until he had examined each one of them, but that all horses were, like himself, sore-backed. How is it that the anti-vaccination maniacs so utterly failed in Paris? Because, in my opinion, in France all the vaccine is used immediately after being taken from the cow.

I have heard much from mothers who had marriageable daughters of what has followed vaccination; but in every instance I have ascertained that the so-called consequences of vaccination have been hereditary, and generally proceeded from inherited syphilis or scrofula (parent and child, in my opinion); but many mothers will not hesitate to be untruthful rather than that a fact should be known which would militate against their daughters' chance of getting married.

I recollect the time when scarcely a year passed that there was not one or more towns within a few miles of my home "shut up," as it was then called—that is, the markets, fairs, schools, &c., were closed on account of small-pox being there. Is there anything of the kind now? Where are the men and women with their faces a mass of pits, or blind of one or both eyes, from the small-pox, that were so numerous sixty or seventy years ago? If vaccination propagates diseases so frequently now, how was it that inoculation for small-pox did not do the same?

I hope our Government will never be such cowards on the vaccination question as they were in reference to the Contagious Diseases Act.

Jan. 4. **Abergwili.**

A QUESTION IN COAL ECONOMY.

[26692.]—I AM obliged to "Chemical" (p. 415) for his notice of my remarks on this subject; but I hoped that some of your West Ham readers would have replied, for it is not unlikely that a few of the coals may be used in the manner suggested by your correspondent, as, indeed, I hinted. But if all the coals which Mr. Cook mentioned are used in one street in West Ham, I ask what business such "factories" have in that locality? I answer the question at the same time, by supposing that the manufacturers find it advantageous to be near a market, and that what they lose in paying extra for coal is more than recouped by the saving on the carriage of the manufactured products. Unfortunately, that does not touch the real pith of the question, which is, Why are so many coals used to produce such results? I can quite believe that as many as 170,000 tons of coal are used at the works in which your correspondent is engaged, for I know that steam-engines are not the only wasters of coal. As a matter of fact, several million tons of coal are annually wasted in this country, more especially in districts where coal is cheap, although the fact is staring us in the face that as soon as coals become scarce and dear, our manufacturing industries will stop, and England will progress on the downward gradient. The late Sir C. Siemens did what he could to hammer these facts into the minds of the leading men of this country; but still the waste goes on, and there are many steam-engines, furnaces, &c., using even as much as ten tons to do the work of one—there are thousands of instances where 50 per cent. more coal is consumed than need be. It is only the other day that the secretary of some league (the title of which I forget) drew a dreadful picture of a former sugar-refiner in London who paid £2,000 annually to the coal dues. Here evidently was a "hampered industry"; but it is quite clear that if it did not pay to remain in London that sugar-refinery would have been shifted. Two thousand pounds a year in coal dues represents 37,000 tons of coal, or over 100 tons a day; but since the original statement another has been forthcoming—viz., that the sugar-refiner used 900 tons of coal per week to refine 1,800 tons of sugar, and I appeal to all who know what can be done towards economising coal to say whether it is not swallowing a very large camel and straining at a gnat to talk of a "hampered industry," when a ton of coal is used to refine two tons of sugar. To take steam-engines alone, there are plenty of firms in this country who will make engines of 40 horse-power and upwards, and guarantee them to give an economy of 3lb. of coal per I.H.P., so that a ton of coal would yield 700 horse-power, say, for an hour; but it is well known that there are thousands of engines which consume 7lb., 10lb., ay, even 20lb. of coal per horse-power. Is not that a deplorable waste? And yet those who permit that waste to go on are the first to cry out about foreign competition, and howl for "fair" trade as they call it—meaning protection for their special industry. My contention is, then, that if Mr. Cook's statement is a fact (and there is some doubt) it is so much the worse for the fact, and the manufacturers who are using coals so wastefully should be improved out of West Ham.

Nun. Dor.

PHOTOGRAPHS ON GLASS, POTTERY, &c.

[26693.]—AN improved process of producing photographs on pottery-ware, glass, &c., known as a photo-ceramic process has been patented by the Hon. Denis Lawless, of the Barracks, Aldershot, and a few notes concerning it may be of interest to your readers. The patentee says (I quote from his specification which is No. 358, 1886):—

"My invention relates to a photo-ceramic process for producing pictures, photographs, or other designs on tiles, plaques, or other objects of pottery-ware, or on plates or other objects of glass, metal, or other similar substances, by impressing on them a raised and depressed surface corresponding to the lights and shades of the picture, photograph, or other design, by means of a die or mould into which, or with which, the clay, glass, metal, or other material used for making the object is pressed or moulded. The die or mould is made by casting in metal, or by electrotyping from a reverse mould, or it may be made in plaster, wax, guttapercha, or other material, the mould being taken from a 'gelatine relief,' or from a reverse mould thereof, or the 'gelatine relief' itself may be used direct for impressing the object with the raised and depressed surfaces. After the object has been moulded or impressed it is glazed or enamelled with a coloured glaze, enamel, or other vitreous substance which is more or less transparent, and is then 'fired' or heated to a temperature sufficient to melt the enamel, which then runs into the depressed parts of the object, which correspond to the darker or shaded parts of the picture or design, leaving the raised parts, corresponding to the lighter parts, thus producing the original picture or design, with all its graduations of shade, in whatever colour the glaze or enamel may be, if the body of the object is white, or modified if it is coloured according to the colour of the glaze or enamel. By the use of various coloured enamels the picture or design on the object may be produced in colours. The 'gelatine relief' may be made according to Poitevin's process by allowing the light to act through a negative or positive transparency of the picture, photograph, or other design, or in some cases the picture or photographic print may itself be used as a transparency, on to a surface of bichromated gelatine of such a thickness as will be necessary for the amount of relief required. The bichromated gelatine is made by adding bichromate of potassium or ammonium to a warm solution of gelatine and afterwards allowing it to set and dry on a level surface, such as a glass plate, or the gelatine mass may be bichromated after it is set by soaking it in a solution of bichromate of potassium or ammonium. After the dried surface or film of bichromated gelatine has been sufficiently exposed to the light under the transparency of the picture or design, it is placed to soak in water, which causes those parts which have been protected from the light to swell up by absorbing the water, while those exposed to the light remain unswollen in a greater or less degree, according to the transparency or opaqueness of the various parts of the negative or positive transparency. The mould is then taken from the 'gelatine relief' while the mass remains in a swollen condition. The 'gelatine relief' may also be produced according to the 'Stannotype' process by washing away in hot water those parts which have not been rendered unsoluble by the action of light. In this case some pigment such as Indian ink should be added to the bichromated gelatine forming the surface or film. In making the bichromated gelatine mass I find a suitable proportion of quantities to be ten grains of potassium or ammonium to 1oz. of gelatine; or, instead of using only gelatine, I sometimes use a mixture of sugar and gelatine in the proportion of one part of sugar and eight parts of gelatine. In the application of the process to metals or other substances that can only be moulded in a molten condition or stamped or impressed under great pressure, I prefer to take an electrotype of the cast or mould from the 'first' or gelatine mould, and then proceed as hereinbefore set forth."

The patentee says that "he is aware that it is not new to produce 'first moulds' by the bichromatised gelatine process; neither is it new to glaze articles by dipping them in, or coating them with, glaze or enamel, and then firing them. But by the combination of these known processes, carried out in the manner described, he produces artistic results never before attained by a purely physical process. **J. T. N.**

HOW TO MAKE GOOD BLUE PRINTS.

[26694.]—ALTHOUGH directions how to produce good blue prints have been given from time to time, I often find men expressing a difficulty, which may probably vanish if they will try the plan I have found successful. The solutions are made with filtered rainwater, or preferably with distilled, but boiled water will do. They consist of one part red prussiate of potash (ferricyanide of potassium) in six parts water; one part citrate of iron and ammonia in four parts water. The proportions are by weight. Mix equal parts of these solutions before applying; keep the mixture away from sunlight; apply with soft brush, and use as soon as dry. The sensitised paper will be nearly useless if kept for twenty-four hours even in the dark. When freshly prepared it is yellow, with greenish tinge, but gradually becomes grey, and is then of no use. The best paper to print from is parchment tracing paper. Drawings can be made in pencil on white paper; the parchment tracing paper is then damped and stretched over the pencil drawing, and the tracing preserved as original. This paper will stand one erasure of ink, but not more. To get a clear white line, the ink used must be very opaque. Time of exposure, from $4\frac{1}{2}$ to 6 minutes to clear sunlight; more if somewhat overcast, and remember it is no use trying on a very cloudy day. Begin with $4\frac{1}{2}$ minutes' exposure. If print is too light a colour, leave exposed longer next time; if lines are not clear white, the ink used is not opaque enough, or the papers have not been pressed together sufficiently—i.e., you need more blanket backing. A little experience will show the proper colour of print when it has been exposed long enough. Wash prints immediately on removal from printing frame, and wash thoroughly, or else the white lines will not remain white. A porcelain-lined sink is best for washing, but the important thing is to use plenty of water. Any white paper of sufficient weight to stand the washing is good. For small sheets paper such as that

which this is printed on will do well. A lighter blue will be produced by anything which partially intercepts the light—a double thickness of tracing paper or a flat tint, for instance. Perhaps if any of your readers try this method, they will report results. M. I. M. E.

ESTIMATION OF DIABETIC SUGAR—PREPARATION OF FEHLING'S SOLUTION—VALUE OF FEHLING'S SOLUTION—CONSTITUENTS OF BEET-JUICE—IRON COMPOUNDS IN TEA—ARROWROOT AS FOOD.

[26695.]—THE letters of Mr. Stokes and "M. O. H." (pages 347 and 389) on the subject of the estimation of diabetic sugar by Pavy's ammoniacal cupric solution deserved a more prompt reply from me; but I hope the writers will accept my excuse of "Christmasing" as a sufficient one.

Any description of his experience in the employment of Pavy's solution which Mr. Stokes may be disposed to communicate will be read with pleasure by myself as well as others; but I must protest against being supposed to be aware of the private experience of any chemist before he has published his results. My book is necessarily a compilation of published facts, supplemented with the results of my own experience in certain directions, and if Mr. Stokes has hitherto preferred to keep his special knowledge to himself, instead of placing it before chemists in the ordinary manner, surely I am not to blame.

In my last letter (p. 302), I stated that "Pavy's solution may be used for the determination of the glucose in diabetic urine, though it cannot be used for the detection of small quantities of the sugar." This Mr. Stokes interprets as, "Mr. Allen states that in the case of diabetic urine containing but little glucose the Pavy blue liquid cannot be employed." Mr. Stokes goes on to show that Pavy's solution can be employed for the determination of very small quantities of sugar; but "is too delicate for qualitative use, for it shows the minute proportion of glucose normal to all urines." Just so. I said it could not be used for the detection of small quantities of sugar, and after traversing this statement Mr. Stokes ends by exactly endorsing it. As to the determination of small quantities of sugar in urine by Pavy's solution, Mr. Stokes is well aware that it is one thing to determine the true sugar in urine, and another to ascertain the reducing power of the urine on Pavy's solution, and express the results in terms of sugar. There are other constituents of urine, such as creatine and creatinine, which are credited with the power of reducing alkaline cupric solutions, and as the amount of these non-glucose reducing bodies is variable, and even their nature to some extent uncertain, it is evident that the accurate determination of small quantities of diabetic sugar by its reducing power is impossible. That Pavy's solution possesses some practical advantages over Fehling's solution in *comparative* estimations of diabetic sugar, I am prepared to admit on the authority of Mr. Stokes; but the influence on the results produced by varying quantities of salt and other conditions, must militate against the absolute accuracy of its indications. As a rule, however, it is practically far more important to watch the increase or diminution of the diabetic sugar from day to day, than to ascertain rigidly the amount present, and for such purposes Pavy's solution is well suited. Short of the tedious purification by basic acetate of lead, evaporation, and re-solution in alcohol, I am not aware of any method by which the non-glucose reducing bodies of urine can be eliminated so as to allow of a rigidly accurate determination of the sugar.

It is a matter of indifference chemically whether the alkali metals in Fehling's solution be potassium, sodium, or a mixture of the two. Practically, the use of a tartrate at all may be considered a "dodge" for keeping the copper in solution in presence of caustic alkali. Tartrate of sodium is made by neutralising tartaric acid with sodium carbonate. Potassio-tartrate of sodium (Rochelle salt) is made by neutralising cream of tartar with sodium carbonate and filtering from the precipitated calcium carbonate. Hence it is cheaper than the sodium tartrate, to produce which tartaric acid must be previously isolated.

I presume the reason why "Knapp's" process of determining reducing sugars has not come into general use is that given me by the chemist of a leading firm of Burton brewers for not employing it. "I know Fehling's solution, its faults and advantages, and I understand its indications; but I have no time to learn the use of a new tool, the results obtained by which might not be directly comparable with those hitherto obtained." This reasoning may not be very logical or scientific, but there is a good deal of human nature in it.

If I understand "M. O. H." rightly, he proposes to destroy grape sugar by boiling with caustic soda, and then estimate the residual non-glucose reducing bodies by a cupric solution. But he here assumes that the products of the action of alkalies or glucose are not themselves incapable of reducing such a solution—an assumption which I think he will find quite unjustified by the fact. It seems to me that the weak point in all determinations of reducing sugars by alkaline cupric solutions is that two distinct actions are going on simultaneously—namely, the destruction of the glucose by the alkali, and its oxidation by the copper. The error due to this cause is to a great extent avoided by Soxhlet, who by a series of approximating experiments arrives at the exact amount of cupric solution capable of reacting with the sugar. My impression is that, while very constant results are obtainable by employing alkaline cupric solutions under constant conditions, the accuracy of the indications when these conditions are modified, as constantly happens in practice, is by no means so great as could be wished.

"M. O. H.," in his last letter, travels from the non-glucose reducing substances present in urine to those existing in beet-juice. This is a very large subject. Asparagine is notably present, and by treatment with alkali this yields aspartic acid, which reduces cupric solutions, as does, doubtless, its homologue glutaminic acid, which is also present in beetroot molasses. Raffinose, the sugar of high rotatory power present in beet juice, also reduces Fehling's solution after being heated, and there are doubtless other bodies capable of reducing cupric solutions.

In reply to "A Grocer" (letter 26652, p. 393), I have found a sample of commercial tea adulterated with a soluble salt of iron; but that was many years ago, and I believe the legislation against adulteration has put an end for ever to such practices. Such a sophisticant as sulphate of iron would have to be used very sparingly, or the inky appearance of the infusion would certainly attract attention. To detect it, the powdered tea-leaves were treated in the cold with dilute acetic acid, and potassium ferrocyanide was added to the filtered solution, which also contained sulphates. By operating in this manner there is no chance of error from the solution of ferric phosphate existing as a natural constituent of the leaves. Of course, magnetic iron ore (often titaniferous) was formerly frequently used for weighting caper and lie-tea, sometimes in considerable proportion.

Of course the statement on p. 342, that starch is not nutritious, is erroneous, unless the term "nutrition" is applied in the very limited sense of something which will support life unaided. It is quite true that starvation may ensue on an exclusive diet of arrowroot or other pure form of starch; but, on the same ground, we might describe sugar and fat as non-nutritious. Butter might be described as "simply salted fat and water." Although a certain amount of nitrogen in the food is necessary for the support of life, it is ridiculous to class all non-nitrogenous foods as non-nutritious. If albuminous foods were solely used, such as lean meat, much more would be required to be eaten, and a large proportion would be used in keeping up the animal heat, which can be done equally well and better by the non-nitrogenised proximate food constituents.

Sheffield, Jan. 8th. Alfred H. Allen.

THE PATENTS ACT, 1883.

[26696.]—I LEARN from an article in the *Times* that the Patents Act of 1883 is still "upon its trial," and from one of your contemporaries that if a patent is worth anything it is worth £25—the old price. It has always seemed to me that the correct policy for any Government in connection with patent law, is to make the preliminary fees as low as possible—just sufficient to cover the expenses of the office; for if nothing comes of a patent, no one is injured except the patentee, and he only loses then a small sum, whereas it is notorious that many inventors had a grievance because they could not pay the fee demanded a few years ago. The number of applications for patents during the past year has, I see, reached the "record" of 17,162—that is, it is a larger number than in any previous year; but I learn from the *Times* that a large proportion of the inventions are valueless. That has always been the case. What the *Times* should show, to make the argument worth anything, is that the proportion of valueless patents is greater now than it was when the fees were higher. After all, what is the reduction? It is £4, instead of £25, for the preliminary stage—that is four years, which is a "preliminary" stage for the majority of inventions, most of which, no matter how useful, have to be thrust, as it were, down the throats of those who will derive most benefit from them. It seems that with all that has been written on the subject, old ideas still prevail, and there are some writers who still contend that the old fees were not exorbitant.

But there is this to be looked at. If an invention is of no use, the mere fact of its being patented is of no interest to the public: the patentee loses what money he has paid. If it is of use, the public will pay for it, and not a farthing more than it is worth; but if it is of use and not patented the public knows nothing about it, and is probably deprived of the advantage which a patent gives—after 14 years. I have never been able to comprehend the justice of the patent and copyright laws when compared with those which relate to the ownership of land. For instance, a man might be the owner of land which, from no labour of his, becomes worth a hundred times its previous value in the course of a few years, and he derives all the benefit in perpetuity. Another man discovers something, or invents something, or writes, say, a book, and his ownership of that terminates in the case of a patent after 14 years, and in the case of a book after 40; but the patent has been taxed in the mean time and then becomes public property, while the land remains private property for all time, although the owner has done nothing whatever to enhance its value. This, however, has nothing to do with the effects of the Patents Act, 1883. It is asserted that a large number of the patents taken out since the reform are of no use whatever. Suppose that is so, Who is injured? Considering the small protection you give the inventor, it is no loss to the State if the whole of the patents granted in any year are useless, for the fees charged cover the expenses of the office; while if any invention is useful the public benefits after 14 years, because the patentee has been compelled to disclose "how he does it," and his invention then becomes public property. No doubt it is very annoying to people who were just about to discover this or that, to find that someone else has obtained a patent, and that they cannot use it without making terms; but who suffers? No one uses a patented invention, and presumably pays a royalty, unless it enables him to do what he wanted to do more cheaply than he could by other means; and surely if a patented invention is worth using, the patentee should have a share in the profits. It seems to me that a Patents Act should be very useful to the Chancellor of the Exchequer. It should put the fees as low as possible for securing a patent: it should secure that patent to the inventor as his property, to be disposed of by will in perpetuity on payment of an annual tax, which need not be very heavy. That, however, should hold good only while the present laws referring to other kinds of property are recognised. It is satisfactory to learn that under the present system the Patent Office will "pay its way" and have a respectable surplus every year. It would be as well, however, in the interests of future patentees, if the money now expended on a scheme of examination which is of no benefit to anyone were utilised in completing the "Abstracts," and in bringing the indices up to date. The only information a would-be patentee needs from the office is an intimation when a similar invention is in the office, for under any conditions he cannot otherwise know that until some time after he has taken out his own patent. Every facility is offered to the searcher in the library, the officials of which are deservedly noted amongst Government servants for their courtesy, and it will be a pity if the legitimate work of the office is hampered by the expenditure of its funds on a more or less useless system of examination. As an instance of how "slow" everything connected with our Patent Office is, the committee appointed to inquire into the working of the new Act has not yet made its report. Saml. Ray.

THE ELECTRIC LIGHT ON BOARD A SALVAGE SHIP.

[26697.]—SEEING a notice in your paper of the salvage ss. *Hyæna* being fitted with electric light, I venture, with your permission, to send you short description of the installation, which may prove of interest to your readers. The boat belongs to the Liverpool Salvage Association, and is employed for the purpose of salving wrecked goods and all the multifarious duties that such a vessel may be called upon at any time to assist in. Recognising the enormous utility of the electric light for such purposes, the committee of the association were pleased to order an installation of arc lamps, incandescent lamps, and submarine lamps of the latter type for divers' use. The work was intrusted to the firm of Perry and Cox, Liverpool, and they put down a Gwynne Invincible type vertical steam-engine and a Phœnix compound dynamo, driven by an endless rope and grooved pulleys. The dynamo develops 94 ampères with 65 volts, runs at 900 revolutions, and the engine at 330 revolutions.

The two masts of the vessel are each fitted with wrought-iron arms, and carry one Pilsen arc lamp, taking 26 to 30 ampères each, and developing nearly 4,000c.p. Spare cable is also supplied, so that either or both the lamps can be disconnected and hung in the rigging of another vessel if necessary. The submarine lamps are Edison-Swan 100c.p., inclosed in Delta metal watertight holders, which are permanently attached to a cable composed of two strands, each of 130 No. 26 wires, insulated and made specially waterproof by the London Electrical Wire Co.

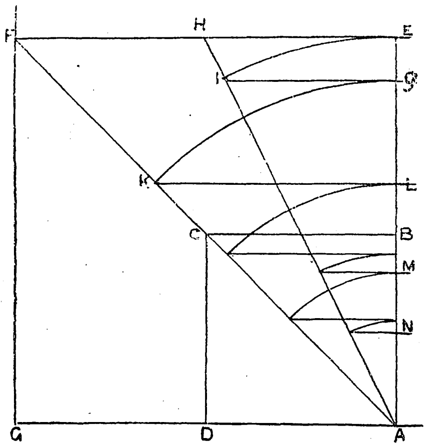
I need scarcely point out the great flexibility of such a cable. There are from 100yds. to 200yds. of cable to each lamp, and the ends are fitted with a straight, round terminal, so that by simply pushing them into the switch-boxes arranged around the ship they are connected. Twenty-candle lamps are fixed throughout the cabins and different compartments, and the whole are regulated from one switch board by side of engine. The engine governs so well, and the compounding of the dynamo is so effective, that whether one lamp, or any part of the installation, is turned off or on, their burning leaves nothing to be desired. The arc lamps are simply perfection, and the engineers to the association have expressed themselves more than satisfied with their working. The divers report on the submarine lamps that, at night, in tolerably clear water, they must prove of immense service, enabling them to examine and properly inspect any part of a ship's keel, besides their great use in a vessel's hold or deck. The varied uses and application of such installations as the above must naturally draw attention to the vast field that exists for their practical use, especially when it can be adopted so simply and so effectively.

On board a steamship, where a few horse-power taken from the boiler is never missed, and where an engineer is always at hand to look after any electric plant, the cost of any installation is really nothing in comparison to the advantages bound to accrue from its use.

50, Bedford-st., Liverpool. **Chas. W. Cox.**

THE DUPLICATION OF THE CUBE.

[26698.]—I WISH to submit a method of duplicating the cube, which I believe to be absolutely correct, for the investigation of some of your numerous correspondents. It is thus: First form a square to represent a 3in. cube, as in the accompanying figure, A, B, C, D; prolong the line A B



and A D to twice their length, and form a 6in. square, A, E, F, G, representing a 6in. cube, it being equal in bulk to eight of the former. Draw a line from point A to point F. On larger square another line is drawn from point A, cutting line E F at point H, in direct line with C D. Then, with compass, from point A to E, draw an arc cutting line A H at point I. Then draw a line from I parallel with line E H, cutting line A E at point J. Then again, with compass, from A to J, form another arc, cutting line A F at point K. From point K another line is drawn parallel with line E H, cutting line A E at point L. Line K L gives the base of duplication of cube A, B, C, D. The further lines and arcs are intended as a way of proving the accuracy of the above method, inasmuch as line A E gives the quadrupling base of A L, and A L gives the quadrupling of base of A M, and A M the quadrupling of A N. A N should be (to be correct) in length one half the length of base A B. Points being indefinitely fine, it is impossible to apply to them correctly. Figures will give the duplicate much finer. I, therefore, give the duplicate of 3in. in figures as far as necessary, which is 3·77976315, being in proportion of 1·25992105 to 1. The same theory will duplicate globes. **Williams.**

MOISTURE IN COAL.

[26699.]—FROM time to time letters have appeared in "Our" journal dealing with the economic value of various substances in common demand. I do not, however, remember that coal has been dealt with, so far as its value is affected by moisture or absorbed water. As next month (February) is, I believe, generally admitted to be the worst in which to raise water-absorbing minerals, may I suggest that some of our readers make some determinations of moisture and report? The method usually adopted is so simple as to be undertaken by many who are not in the strict sense of the word chemists.

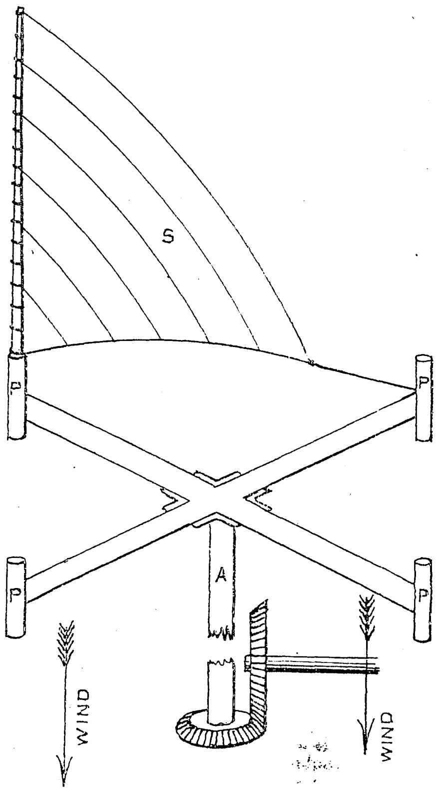
For those who may be of the latter class the following will suffice:—Finely-powder, say, 30 or 50 grains of coal picked from the heap, and dry between watch glasses at 105°, 110° for one hour, allow to cool, and again weigh; loss = moisture.

In years gone by, I remember being struck with the amount of water some coal taken from exposed situations contained, and I venture to think that, with your kind permission and the help of your readers, data collected over a wide area would be valuable. **Francis M. Rogers.**

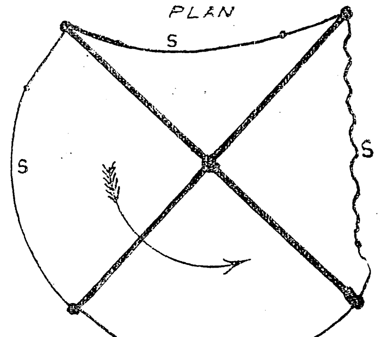
21, Finsbury Pavement, E.C.

HORIZONTAL WINDMILL POWER.

[26700.]—THE greatest amount of power to be got out of a horizontal windmill is, I believe, obtained by means of four sails, set as shown on sketch S. From experience, I fear it will hardly



PLAN



give satisfactory results; but as the question is again before the readers of the "E.M.," I roughly sketch a design, which can be easily tried by any one interested. The weak point is, securing the pieces of pipe, P P P P, to ends of crossbeams strong enough. This done, the light spars with sails of sailcloth lashed to masts, may be placed in their steps, the sheets (or ropes holding sails) made fast to the following beam, or arm; but not taut, leave slack. The support A, of any required length, strongly fastened to crossbeams, having a bearing at bottom (say, a steel cone), and a slack bearing or support near the crossbeams, concludes explanations. Now, observe the plan, and you will see that three out of four sails are always pressing towards the direction required. Square-headed sails, as sprit sails, would have more power, and take stronger gear. **Wm. Hosken.**

[26701.]—BEFORE this discussion drops into limbo I should like to make a few remarks on some of the points raised.

It seems generally acknowledged nowadays that no motive power is worth a moment's consideration but steam power, as though those "Wooden Walls" that contributed so largely to make the British Empire each burnt 200 tons a day of that precious stuff that is too often "human creature's lives."

By all means use coal legitimately, but not waste a 1,000 tons to enable a vessel to cross the "Pond" in three or four days' less time, nor shut up so many water-mills and windmills merely because it is the fashion to live in close quarters, where a steam or a gas-engine is the only motive power that can be crowded in.

I suppose this waste of coal will be only checked by its becoming scarcer and dearer, and then wind power will be commonly used. There is no reason why wind power should not be more often used now but fashion and prejudice.

There is a windmill in sight of where I write that is working at least one pair of stones nearly every working day in the year, for in good positions the power is more available than generally stated.

Now, a horizontal motor has many advantages over the vertical: First, it is cheaper in construction, the tower has not to be so high, and has no fan-tail or gear to bring it up to the wind. Secondly, being on top of the mill it takes up less room, for the swing of the whips of the vertical curtails the space inside while preventing any adjoining buildings. And, again, it takes better advantage of the wind, as being blown away from the wind at half the speed of it, the sails take half of the pressure; whereas, the vertical only takes one fifth, and (*pace* Mr. Browne) it comes up to the wind at *less* resistance than the vertical, for, as I bevelled the forward edges of all my sails they only took the *same* pressure as the wind was travelling at, and that on only *two* of the sails at the time, as the four others were doing useful work. And, please notice the tips of the vertical whips travel at more than twice the speed of the wind, continually cutting their way with four arms, on an average 8in. thick, with the addition of 12in. caused by the angle of the sail 15° (average) with the plane of revolution.

In answer to Mr. Browne (p. 413), first "where is it to be seen at work?" At present I have not any mill erected, but hope to have one before long. But why make a point of that? I never saw one before I made it, and anyone interested can experiment for himself, for he will reap the profit. Mr. Browne's second stumbling-block is, "It is difficult to understand Mr. C.'s excuse for not increasing the power of his windmill." Is it? Well, if Mr. Browne is good at persuading landowners that commerce and trade benefit by sacrificing park-like appearance, and cut down some old elms 75ft. high, I can with pleasure give him a job.

Mr. Browne says, "In my mind the weight is the greatest barrier of all." Not so. Mr. B. will find that the wind blows in gusts, never steadily, and weight *is* necessary to act as a flywheel, to keep the motor going when the trough of the wave comes, and yet not allow it to start off in the crest of the wave; and when in work, a part of the weight is taken off the step brass by centrifugal tendency.

One word more: canvas sails will not do; how can you regulate the speed without automatic shutters, the same as the vertical mill?

Albert Collingridge.

ORGAN WINDCHESTS.

[26702.]—IN reply to "W. H. H." (letter 26537), there can be no question that the "patent windchest" of Mr. Roosevelt is the most perfect thing of its class ever invented; but I should hesitate in recommending its adoption for a Chamber Organ of the ordinary size. The windchest has to be made of a much larger size than an ordinary slider windchest planted for the same number of pipes, and it is almost invariably a matter of great difficulty to get space enough for the ordinary windchests in a Chamber Organ. Beyond this one matter of size there is no objection to the Roosevelt windchest; indeed, in every other respect it is immeasurably superior to the slider form. I do not think the invention is protected in this country in any way. It has been adopted by Mr. T. Casson, of Denbigh, in his new organs.

I am asked to give "the size of the feeders" for an "organ of ten stops"; but it must be obvious that the mere statement of the number of stops conveys but little notion of the wind required. Had the names and scales of the stops been given, I could readily have furnished exact dimensions for a suitable bellows. Taking an imaginary specification, such a one as should be prepared for a Chamber Organ of ten stops, as a guide, the bellows receiver should measure about 7ft. by 3ft. 6in., and each of the three feeders about 3ft. 6in. by 2ft. I can assure "W. H. H." that he cannot have too large a bellows. The larger it is, the steadier the wind will be, and the easier the supply will be kept up.

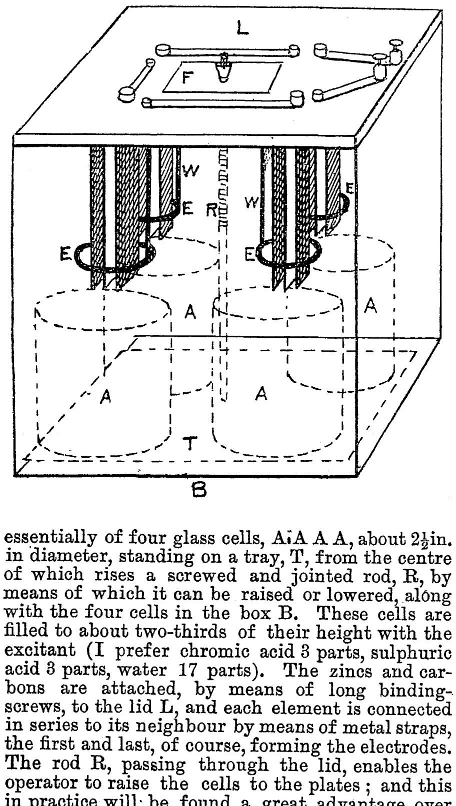
If the crank-shaft and all its accessories are properly made, and fitted with a flywheel of

moderate weight, about 4ft. in diameter, the blowing should be quite easy. It is advisable to let the shaft (for hand-blowing) have its bearings on friction-wheels. I am pleased to learn that my "Notes on the Chamber Organ" have proved interesting to "W. H. H." and others, and that there is a prospect of a practical book on the organ being well received, for such a treatise I have long been preparing for press. **G. A. Audsley.**

ON A SIMPLE MEANS OF INCREASING THE EFFICIENCY OF THE CHROMIC CELL.

[26703.]—IT is a well-known fact that the remarkable fall in current strength which takes place in the single-fluid batteries of this class depends to a great extent on the absolute immobility of the exciting fluid. This is due to the fact that as the hydrogen is absorbed by the oxidant (chromic acid, bichromate of potash) as fast as it is generated, no mechanical movement is produced in the mass of the liquid, so that the liquid near the zinc plate becomes quickly charged with sulphate of zinc, thus protecting the plate from the farther action of the acid. Many schemes have been proposed to avoid this, such as setting up circulatory currents in the fluid by the external application of heat (Sprague), or by means of an aspirator (Courtenay), &c., &c. These methods are excellent in their way, but are rather inconvenient of application by the amateur, who has only to deal with a few cells—and fewer shillings.

A very simple mode, which is quite effective, which gives no more trouble than snuffing a candle, and which could be made automatic if desired, is one which I have adopted in my own 4-cell batteries for temporary lighting purposes, &c. The battery (which is figured below) consists



essentially of four glass cells, A A A A, about $2\frac{1}{2}$in. in diameter, standing on a tray, T, from the centre of which rises a screwed and jointed rod, R, by means of which it can be raised or lowered, along with the four cells in the box B. These cells are filled to about two-thirds of their height with the excitant (I prefer chromic acid 3 parts, sulphuric acid 3 parts, water 17 parts). The zincs and carbons are attached, by means of long binding-screws, to the lid L, and each element is connected in series to its neighbour by means of metal straps, the first and last, of course, forming the electrodes. The rod R, passing through the lid, enables the operator to raise the cells to the plates; and this in practice will be found a great advantage over lowering the plates into the cells. The arrangement for setting up movement in the fluid consists simply in ebonite rings, E E E E, which encircle the plates, and which are attached to the ends of guttapercha-covered wires, W W W W, the upper extremities of which pass through the lid of the box, and are soldered to the four corners of a flat square of wire, F, which, on being raised and depressed, agitates the fluid in the cells, and thus prevents the accumulation of zinc sulphate round the plates. For the convenience of carriage, &c., the lid L is fastened to the box by means of two rings and catches, and is furnished with a central handle, not shown in the sketch.

S. Bottone.

LATHE MATTERS.

[26704.]—I FEAR our lathe correspondents are taking a holiday in the middle of the lathe season: we generally have some interesting matter to discuss about this time.

I have been reading over some of the late Mr. Hartley's letters, and particularly the one on page 315 of Vol. XXV., in which he speaks of his book I have also a letter from him on the subject, and it appears that the book was only waiting for more subscribers. It would be a great pity if that book were lost to the world. Can nothing be done to prevent this? Will Mr. Hartley's executors tell us how many more subscribers are required to justify publication, and will any who wish for the book to appear send in their names?

On page 416 of the same volume Mr. Jesse Lowe concludes a letter by promising to "communicate further." May I venture to remind him of his promise? We have never had in the "E. M." any detailed account of the medallion machine of which he is the inventor, nor has there yet appeared any complete working drawing of a geometric chuck.

"Tuebor" sent us two good things last winter, and could, no doubt, send more; so did "W. R. W." Where, too, are our old friends "O. J. L.", Dr. Edmunds, "Vulcan," and others? **F. A. M.**

ROAD REFORM—PYROLOGICAL FOOT-BLOWER.

[26705.]—IT is a pleasure to see the subject of road reform brought into the pages of the "E.M.," for it is a matter that can well bear a little intelligent discussion.

My knowledge of the subject is confined to that arising from my travels as a cyclist, which teach me that, though there is little hope as yet of getting the short-sighted local authorities to lay out capital in easing gradients which are a continual tax on the community at large, yet it is possible to induce them to improve the surface—which is so frequently villainous — by representing that the present system of repair (so-called) is not only inefficient, but also uneconomical. I inclose a tract on the subject for the Editor's perusal, which is excellently lucid, and I cannot do better than quote a few extracts from it.

"The causes of roads being bad and yet ruinously expensive may be any or all of the following:—

"(1) The material is unsuitable, local material, of whatever kind, being used to save carriage.

"(2) It is excessive and irregular in size; McAdam's rule that every stone that exceeds 1in. in its largest diameter should be rejected, being ruthlessly disregarded.

"(3) The road is of bad transverse section, hollow in the middle, or possibly inconveniently convex.

"(4) The surveyor is ignorant or indifferent, being appointed without consideration of his fitness for the office.

"(5) It is repaired at the wrong time of year, in too wholesale a manner, and by the aid of "binding material" which is worse than useless.

"(6) Too much is spent on materials.

"(7) Too little is spent on skilled labour."

As regards the last two the following may be given as an example:—

"As an instance of the saving which may be effected by proper supervision, I might quote a case from Lincolnshire, where the Donnington turnpike roads were, during the last seven years of the trust, placed in the hands of Mr. Wheeler, a civil engineer. From 1868 to 1874 he effected an annual saving of £276 over only 26 miles of road, while at the same time these roads were so much improved that a horse could draw along them nearly double his former load." The Roads Improvement Association, of 57, Basinghall-street, E.C., issue the little work from which the above matter has been condensed at a nominal price for distribution, and invite inquiry and co-operation from those interested.

With regard to the second part of my heading, I strove to construct such an apparatus as was described in the Reply column some time back. The plan was to use three bellows; two to blow—each taking alternate strokes—and a third having its upper board weighted to serve as a receiver, and deliver the air under a constant pressure. I failed to get this third sufficiently air-tight, and suspect that it would be necessary to make a pair with special care in constructing the joint by the nozzle if the ordinary form of bellows was adhered to; but I also found an omission in the design of far greater moment. It is that each of the blowing bellows sends the greater part of its wind, not into the weighted receiver, but into the collapsed pair, which is its colleague. A valve at the nozzle of each of the blowers is necessary to prevent this, and with this addition the result is excellent.

B. B.

MICROSCOPICAL NUMERICAL APERTURE.

[26706.]—WILL Mr. E. M. Nelson, and any other microscopical reader of "Ours" accustomed to testing glasses, kindly inform us whether they observe any difference in the performance of objectives of the same N.A., but the one a water and the other an oil immersion.

Theoretically, they should be alike; but in practice, both from what has been written and from my own experience, I should say there is a difference.

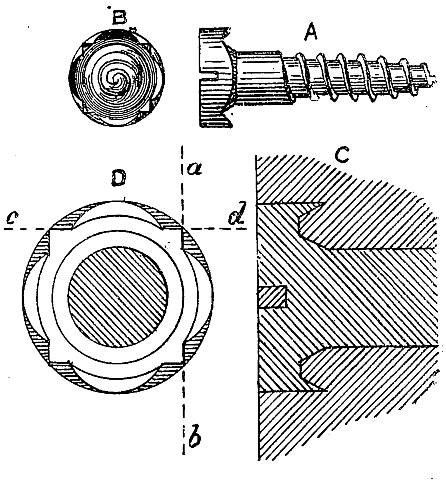
Thus, Dr. Dallinger, in his last address to the Royal Microscopical Society on the cell nucleus, says: "The highest and latest class of water immersions, as made by Powell and Lealand, proved a large gain over all their predecessors in searching into minute living structure; and then followed the early homogeneous lenses of Abbe and Carl Zeiss, which showed great advance in the direction needed" (N.A.).

Now, it happens that the N.A. of these two sets of lenses is almost exactly alike—Powell and Lealand's water immersion being 1·26 and Zeiss's 1·27. Consequently, if the performance of one is superior, it must be from other causes than N.A., and should be due to the medium oil instead of water.

My own experience confirms this, as I find that my Swift's last new oil immersion, $\frac{1}{12}$in., will pick up much finer detail with central light than my Powell and Lealand's water immersion $\frac{1}{8}$in., although the N.A. of the oil immersion is a little less of the two. Of course, there is the question of workmanship; but it cannot apply here, as the latter's name is sufficient guarantee that it is not inferior to any other maker. **T. F. S.**

A SCREW THAT WILL DRIVE IN FLUSH WITHOUT A COUNTERSINK.

[26707.]—I SEND drawings of a screw that will drive in flush (in pine and deal) without a countersink, making a neat job with less work than an



ordinary screw. The shaded portions in D represent the flat facets on the outer ring formed by cutting four nicks across as indicated by *a b*, *c d*.

Silke.

TRICYCLES.

[26708.]—WHILE thanking R. G. Bennett for his remarks (26635, p. 390, No. 1136) relative to the alleged greater ease in propelling small geared-up driving-wheels of bicycles as compared with large wheels geared even, I fear the theory propounded will not stand the test of examination. Mr. Bennett says that "the larger the front steering wheel is, *compared to its driver* (the italics are mine) the less it strikes and jumps." Now, had he omitted the words I have italicised, I should have "been with him"; but I submit that the relative sizes of the steering and driving wheels have nothing to do with the question. There is no downward thrust, as is evidently intended to be inferred by the diagram.

Suppose the axle of the driving wheels is supported, so that the rims are not in contact with anything, and suppose that force is applied to the pedals as usual, the wheels will then simply spin round without communicating any progressive motion to the axle, and this will occur all the same, whether the axle of the pedals is above or below the axle of the driving-wheels; but let the rims of the wheels be put into contact with a plane or other surface, and immediately the axle is propelled in a line *exactly parallel with the surface*, no matter in what direction the surface lies. The same holds good with the steering-wheel, whether larger or smaller than the driving-wheels: its axis moves in a line *parallel with the surface* on which it rolls, and also *parallel* with the lines of motion of the axle of driving-wheels.

Of course, a small driving-wheel strikes and jumps over the irregularities of the surface more than a larger one; but I am perfectly satisfied that anything like the digging action supposed by Mr. Bennett is not produced by large driving-wheels, and that consequently smaller ones cannot cure an imaginary defect.

I now begin to think that the explanation of the

alleged facility of working the machines with small geared-up wheels will be found in the fact of these machines having as a rule *larger steering* wheels than has been customary with the older type of tricycle, and that it is to this fact alone, or chiefly, that the greater ease of propulsion is due. This would tell with especial force in those machines in which a considerable proportion of the weight of the rider is placed on the steering-wheel whether front or back. I can well imagine that much of the freedom from concussion provided for by the use of large driving-wheels may be neutralised by a small front-steering wheel, and that in reducing the size of the former, while at same time increasing the diameter of the latter, an amelioration as regards vibration may be the result; but the cause would be the increased size of the steering-wheel, not the gearing up of smaller drivers. It may be, indeed, that facility of propulsion with any given power may be governed, *cœteris paribus*, by the diameter of the smallest wheel, and if so, that would be a sound reason for reducing the superfluous diameter of the driving-wheel without this in any way conducing to the greater ease of propulsion.

Gamma Sigma.

GOODS TRAINS PARTING COUPLINGS.

[26709.]—"NUN. DOR." (26662) seems to consider my last letter to be so curious as only fitted for a daily newspaper. How odd it is that I hold precisely the same opinion concerning his. I will not stay, however, to wrangle upon a side issue of this kind, but would state that my twenty years' experience of practical railway working through tunnels and over hills and down holes, and the study which I have all along given to questions affecting the safety of railway working, enables me to judge of the practical utility or otherwise of a system which will merely acquaint a driver of the fact of his train breaking loose. I did not, in my former letter, approve of the suggestion which was made. I admit it to be very good, so far as it goes, but it does not go nearly far enough; and I repeat that the engine driver of a parted train is powerless in preventing the hindmost portion running back, and in no case can he prevent a following train from running into the detached portion. "Nun. Dor." seems to imagine that the sounding of the whistle would be heard in the rear signal-box; but if he has had any experience of tunnels or signal cabins, he should know that the chances are 50 to 1 against such.

In regard to Mr. Stretton's proposals, they certainly would be the most effective; but I am afraid that the whole of us and the rising generation will be laid beneath the sod before the companies even begin to consider the fitting of their goods stock with automatic brakes.

I might, however, be allowed to mention the matter of runaway switches. They are used on a great many inclines throughout the kingdom, where in case of a train running back, it is turned off the line on to a rising bank, with effective stop-blocks, sometimes composed of earth, into which the vehicles bury themselves without doing much damage, and entirely clear of the opposite set of rails. As my work lies beyond the radius of the Underground Railway, I cannot speak of its adaptability for an arrangement of this kind. Perhaps some Underground Railway man will enlighten us.

It will be understood that it is only goods trains that I refer to, for I consider the automatic brake should be fitted to all passenger trains.

W. F.

ELECTRIC LOCKING FOR RAILWAY SIGNALS.

[26710.]—IN a reply which appears on p. 416, No. 61171, your correspondent "Electric" gives a brief account of the Spagnoletti system of signalling used on the Severn Tunnel section of the Great Western Railway; but there is one most important and vital point which requires to be made clear.

The object of electric locking is to prevent mistakes of signalmen, and to establish an absolute mechanical block system which cannot fail in its object or break down by the mistake of one man. "Electric" states that *after* the signal lever is put back to danger it is locked. I have examined the system, and I have also pointed out the important and serious defect which exists. Suppose that the signalman has his attention directed to the signalling of another train, or to the telegraph instrument, or that perhaps in consequence of a long term of duty he makes a mistake and omits to put the lever back again, or does not do so until the man at the next box in advance has sent the electric current intended to lock the lever in its normal position of "on," what is the result? The lock would be actuated by the electric current; but the lever not having been put back to danger would not be "locked," as, in fact, it would be on the wrong side of the lock, therefore the arrangement would fail in its object. Mr. Spagnoletti, writing to *Iron* upon the subject, admits this fact; but contends that signalmen do not omit to put the lever to danger; but I know from my own experience that such omissions or mistakes *do occur* in practice, therefore some appliance is required which renders it necessary for the lever to be put back to danger after the first train, before the "be ready" or "is line clear" signal can be accepted for the following train; or, perhaps even a better arrangement is to place the starting "signal" electrically under the control of the signalman at each end of the block section, so that no train can enter such section without the consent of two men, and in case one fails to place the signal to danger, the other can do so. It will at once be seen that it is not sufficient to lock a signal when it is "on"; but power or control is necessary to be able to put it on, if by error it has not been so placed after the passing of every train. The defect having been pointed out, I trust the inventor will take steps to improve and perfect his system. For many years I have urged the adoption of the system of electric interlocking in order to prevent the very serious accidents which result from the mistakes of signalmen.

Clement E. Stretton, C.E.
Consulting Engineer Amalgamated Society of Railway Servants.
40, Saxe Coburg-street, Leicester, Jan. 7th.

DOUBLE ENGINE RUNNING.

[26711.]—"M. R. SHAREOLDER" records a reduction of 30 tons in the dead weight of the Midland Scotch day trains, and on the 3rd January another reduction of 10 tons occurred as the small third-class coach to Glasgow was taken out of the train; but there is yet plenty of room for reduction. There is a large heavy "bogie" from London to Leeds, and another from Normanton to Carlisle: these should be replaced by small carriages, as they are not necessary for the traffic.

I agree with all Mr. Stretton and others have said against drawing a lot of empty rolling stock about the country for no purpose, and at great expense.

Locomotive.

PASSENGER TRAINS AND PARTING COUPLINGS.

[26712.]—UPON reading the remarks made by Mr. Stretton and "W. F." in the ENGLISH MECHANIC of Dec. 31, I was at first tempted to reply; but as "Nun. Dor." has disposed of them, it only remains for me to add that I endorse his remarks in the main. Those of our readers who have had to do with heavy mineral traffic will be able to judge how far any existing automatic brake system, depending mainly upon well-made joints, would stand under the severe handling a railway waggon is exposed to; and since a fair proportion of the waggons composing every goods train belong to private owners, the augmentation of maintenance charges, to say nothing of capital expended in outlay, would handicap most trades in a time of unwonted prosperity, and in these depressed times is out of the question. If, however, a system can be introduced which will, without entailing unreasonable first cost, apprise both driver and rear guard, first, that all couplings are properly made, and also when by accident or in ordinary shunting operations the waggons are disconnected, it would not be too much to expect the Board of Trade to interfere, and insist upon its introduction for the protection of the public. Apart from this, coal-owners and others employing large numbers of waggons would soon take a personal interest in its adoption, on account of the saving of time effected in making up their trains. Personally, I regard a railway whistle as an instrument of extreme torture; but since it exists, and probably will for many a year yet to come, nothing can be easier than to operate it by a modified electrical arrangement such as I have described, if the disc and bell arrangement is objected to. The public have no notion of the wholesale manner in which couplings part, and draw-bar hooks are wrenched off; and this does not arise from bad workmanship, or poor material, but from the excessive and sudden strains to which both are exposed. The powerful coupled engines now employed are more than a match for the couplings and drawhooks in use, and yet these former are about as heavy as it would be safe to make them unless manual labour be assisted in some way in coupling up. If those of our readers who have the opportunity will refer to their waggon-books, and selecting a new 10-ton waggon doing heavy mineral work, will, over 12 months note how many times it is stopped with "coupling broken," "draw-bar snapped," they will find the analysis is very instructive, and will hail the good time coming when "goods traffic" is removed from passenger lines.

We live in exceptionally high-pressure times, and those of us who have to do with constructive work are beginning to look for stronger materials than we possess to meet the heavy demand made upon them. A good brake is certainly a desideratum, and its design affords an open field for any of our readers who may have time and opportunity to experiment in this direction. It is too much to expect owners and railway companies to adopt the automatic continuous system, even were it feasible. But cannot the old side-lever brake be improved upon? I venture to think it can.

Francis M. Rogers, F.C.S.

JOY'S VALVE-GEAR—N.E. LOCOS.

[26713.]—A REPORT has gained considerable ground here in the North that Mr. Wordsell's successor on the Great Eastern has taken Joy's valve-gear out of several engines and put in the ordinary link motion. Can any of your Great Eastern readers give any reliable information regarding this?

I should like to know what other railways have adopted Joy's valve-gear, and with what result, satisfactory or otherwise.

Mr. Wordsell has lately turned out a considerable number of passenger and goods engines, all fitted with this gear; but a great amount of groundless prejudice exists against him, and this is often visited on his work, so that it is extremely difficult to get to know from the men whether they really like them or not, though for style and finish they outshine anything the North-Eastern ever turned out before.

G. S.

APOCRYPHAL LONG RAILWAY RUNS.

[26714.]—I SEE in *Whitaker's Almanack* for 1887 a rather remarkable statement under the heading "Longest Runs of Trains in Great Britain"—viz., that a train runs from Dublin to Cork, 165 miles, without stopping. I can hardly credit this, seeing that the long run from Newcastle to Edinburgh (124 miles) by the North-Eastern night down Scotch express is hardly ever done without stopping for water. Can any reader say under what conditions this remarkable run is performed?

Mr. Rous-Marten's letter on "Speed Myths" is exceedingly interesting; it shows, I think, that for great speed nothing can touch a single wheel engine. He says, "I had the opportunity of testing the swiftest and most powerful engine in the Kingdom." Could he not inform us which engine this was?

There are, I believe, two compounds on trial on the Great Western: A broad-gauge convertible, with four cylinders, and a narrow-gauge with two cylinders, both having 7ft. coupled wheels, and *no* working parts outside the framing, thus making very neat-looking engines. Details as to dimensions and performances are at present kept secret. No. 10 is, I believe, fairly satisfactory, though there is a difficulty in turning sharp corners both with No. 9 and 10.

The L. and N. Western seems to be reaping the results of fitting its stock with the vacuum brake; the number of times this brake has failed them recently ought surely to open their eyes to the folly of their proceedings. We shall see one of Mr. Webb's *splendid* locomotives landed comfortably into Euston-square one of these days; whether the company will then think about altering their brake depends upon the amount of damages they have to pay.

I should be very grateful if some reader would help me in the following difficulty:—I went to pump *hot* water from an open copper to a room upstairs; the pipe runs first about 15ft. horizontally from the boiler, and then 12ft. vertically. I find the pump I have put up (an ordinary suction pump) pumps *cold* water quite well; but when I try to pump the hot water, the steam from the boiler keeps the suction valve open, instead of letting it close, as it should do. At least, this is the only explanation I can think of to account for its inability to pump the hot water.

Zulu.

RAILWAY SPEEDS.

[26715.]—THE amount of repetition that occurs in your columns on railway matters, on account of new subscribers requiring information already given in back numbers, is unfortunately almost a necessity; but it is rather too bad when a correspondent asks the same question twice over, when answered the first time. In letter 26288, p. 86, Mr. Grey asks for details of the 10 a.m. express from London to Grantham. If he will take the trouble to refer to letter 23306, p. 66 of Vol. XL., he will find that the information has been supplied to him before, and that he worked out and published various interesting calculations from it.

The question of maximum speed attained on railways is one concerning which very little really accurate information is available. Mr. Marten fixes it at 75 miles per hour. No doubt his 81·8 record on the G.W.R. was a mistake; but I should like to call his attention to a run given by himself some two years ago in a contemporary (since defunct), in which he states that the distance from Stoke to Tallington, on the G.N.R., 15½ miles, was covered in 12½ minutes. Now, comparing this

with other observations which I have made myself between the same places, I calculate that the maximum speed on that occasion must have just touched 80 miles per hour towards the bottom of the gradient. I believe that between the two points mentioned higher speeds are attained than anywhere else in the world, and I have on one occasion travelled at a speed of 78 miles per hour on that section.

Those who make the matter of railway speed a study will find Kapteyn's chronograph a very convenient instrument for timing, as the speed taken between quarter-mile posts can be read off direct; but when great accuracy is required, if the speed is over 50 miles per hour, it is necessary to take the time for a whole mile and calculate the speed from it, because in timing a quarter of a mile at high speed a very small error in the time introduces a large one in the result. When timing between posts the head should not be moved, otherwise the second post will not be taken in the same relative position to the observer as the first.

Lincoln.

"OURS" FOR HOSPITALS.

[26716.]—I THINK Mr. Bower (letter 26667, page 412) has hit on an excellent way of beginning the Jubilee year, and hope that as many of "ours" as possible will send their mite for such a good purpose. Eleven shillings will provide a copy of the "E.M." post free for a whole year, and each number may afford pleasure and profit during many a weary hour. Might I suggest that, while country subscribers would, no doubt, specify the institutions they wished to benefit, we in London had better leave the choice to you, Sir (if you will consent), as unless we act unitedly, the resulting good might be much diminished. If you, Sir, will notify that you are prepared to receive amounts to be applied in this way, I shall be happy to send a year's subscription for two copies.

D. G.

[We will willingly receive such subscriptions, and distribute them equally, as far as they go, among the London hospitals.—ED. "E.M."]

USEFUL AND SCIENTIFIC NOTES.

Tooth Powders.—Prophylactic medicine is of greater value to the public than curative, although they are slow to give it its due; hence the subject of tooth powders may be of some interest. The necessity of keeping the teeth clean, with a view to the prevention of future trouble, is overlooked by toomany, even in the higher classes, sometimes from carelessness, sometimes from ignorance. Now, cannot the medical attendant do a great deal to combat theis state of things? The dental surgeon is often asked, "How soon should the first tooth brush be used?" "As soon as there are teeth to use it upon" should be the reply. An ideal tooth-powder should be alkaline, since acids dissolve the tooth substance; finely pulverised, that it may not mechanically abrade; antiseptic, to prevent decomposition of food lodged between the teeth, and perhaps to destroy the microbes which are always found choking the tubules of carious dentine; it should contain nothing irritating to the gums; and, lastly, it should be pleasant to the taste, or it will not be used. Fluid dentifrices do not, as a rule, clean the teeth effectually, unless they contain some ingredient which acts upon the enamel itself; and those preparations which are eulogised as making teeth white or preventing deposit of tartar, should be avoided. Charcoal was at one time a very popular form of dentifrice, and is even now largely used, but from the amount of silica it contains it will rapidly wear away teeth that are not of exceptional hardness; and, moreover, the gums in some instances become tattooed in a curious manner from absorption of minute particles. Pumice-powder, again, is too gritty; and camphorated chalk is said to make the gums spongy. Precipitated chalk forms the best basis for a tooth powder, to the base of which may be added pulv. saponis and ol. eucalypt., a drachm of each; and, if there is no objection to the taste, half a drachm of carbolic acid.—*Lancet.*

THE Dudley Chamber of Commerce have just had before them a communication from their secretary on the working of the Boilers Explosions Act, 1882. The communication stated that it was likely that the Government would soon proceed to further legislation in the direction of compulsory supervision of boilers. The workmen were constantly clamouring for an extension of official supervision, forgetting that all increase of working expenses operated vigorously as to wages and trade. It was doubtful if such inspection would prevent many accidents, for the causes which led to explosion developed suddenly. There would be no inspection between the periods of official inspection. The secretary was of opinion that there was no need for further legislation, and the Chamber agreed in these remarks.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[60739.]—**Continued Fractions.**—As this query has got into the U.Q. column, I think it well to offer a solution of it. "R. E. F." has asked for a method of computing logarithms by means of continued fractions, and he stated his belief that such a method is given in the second volume of Francœur's "Mathematics." Having that volume (French edition, 1809) in my possession, I may here say that it contains nothing whatever on the subject. The following method of performing the operation I take from a work on "Trigonometry," by T. Luby, T.C.D., 1825:—The problem to be solved in this case is to find the value of x in a continued fraction from the equation $a^x = y$. The two consecutive numbers between which x is comprised can easily be seen by inspection. Let these numbers be n and $n + 1$, and let $x = n + \frac{1}{x'}$; substituting this value in the equation we find $a^{n + \frac{1}{x'}} = y$, and, therefore, $\left(\frac{y}{a^n}\right)^{x'} = a$, or, as we may put it, $c^{x'} = a$. Proceeding again in this manner, we shall see that the value of x' lies between two numbers n' and $n' + 1$, and so assume $x' = n' + \frac{1}{x''}$. Repeating this operation continually, we shall find—

$$x = n + \cfrac{1}{n' + \cfrac{1}{n'' + \cfrac{1}{n''' + \&c.}}}$$

By applying the ordinary process of converting a series into a continued fraction, any one of the logarithmic series may be exhibited in this form.—VLADIMIR.

[60744.]—**Question in Dynamics.**—Perhaps "M.I.C.E., Bath," may like to know—at any rate I owe it to him to tell him—I have come round to his and "Nephesh's" view of this question, and am quite willing to return his compliment by admitting that he was right and I wrong.—W. A. S.

[60881.]—**Pitch Pine Stopping.**—To "NUN. DOR."—What I want is a stopping for shakes, so that when polished or varnished it shall present the same appearance as the wood.—G. H. H.

[60925.]—**Locomotive Engines.**—Your correspondent, "Loco.," p. 415, states as a fact that engines having a small leading-wheel run better than those coupled in front. May I ask if he will be good enough to favour us with any facts or figures upon this important subject? I have ridden many hundreds of miles upon various engines and on different lines; but I may say that I have found several engines coupled in front run quite as steadily as those with bogies or small leading-wheels. Recently, after the Railway Congress at Brighton, through the courtesy of that company, I rode from Brighton to Victoria on one of the Gladstone class, "Northcote, No. 217," and certainly, I have never found an engine to run more steadily at high speed, or to perform its work in a better manner.—CLEMENT E. STRETTON, Consulting Engineer Amalgamated Society of Railway Servants, Leicester, Jan. 8th.

[61049.]—**Electric Lighting.**—This query is addressed to Mr. Striffler; but like many others in which one writer is appealed to, remains up to the present writing unanswered. I write this to point out that if your correspondents would but endeavour to comprehend the principles upon which all schemes of electric lighting are based—as they may by studying carefully Mr. Sprague's work—they could answer all such questions themselves, and save both money and time. The very notion of charging accumulators by means of primary batteries is economically absurd.—NUN. DOR.

[61063.]—**Wheat Straw.**—As the brittleness of wheat straw is due to its silica, anything that would remove the silica would perhaps render the straw permanently flexible. The querist might try the result of soaking in weak hydrochloric acid or in solutions of the alkalis.—NUN. DOR.

[61064.]—**Vertical Engine.**—It appears "J. W. R." is desirous of increasing power with present engine. I should advise, in the first place, to set your valve right—the travel is not equal; that done, you will gain more pressure on your bottom card. Then as to changing your governor. Put on a Fremper cut-off governor, which will increase your initial pressure on your piston, by having the full boiler pressure waiting for the opening of the valve; said governor must be placed as close to the steam-chest as possible, because expansion takes place in the pipe from the governor and steam-chest as well as the cylinder, until the slide-valve cuts-off. By using a good cut-off governor, you could speed up your engine, which is sadly too slow. By doing so, your governor cut-off would be very early, and you would derive more benefit from expansion; your terminal pressure would be lower, consequently, less steam to condense at each stroke, with the higher speed to your air-pump—result would be a better vacuum. I could make many more suggestions; but I presume you wish to make the change as cheaply as possible. There is lots of room for improvement on those cards.—JAS. D. ROSTRON.

[61071.]—**Planing Machine Tools.**—Is it possible that there may be something wrong with the tool-box itself, as it will lift well enough when planing with right-hand tools, but binds hard with left-hand ones? My tools are not cranked, as there is no one here that I can trust to crank them.—A. F. SHAKESPEAR, Lüttichaustrasse 14 III., Dresden.

[61072.]—**Motor for Bottle Brush.**—The water motor will be cheaper than the electric motor, if the querist has a good fall of water. He surely knows how high his cistern is, or can measure with a gauge the pressure at point of delivery. Probably he would find it cheaper to employ a strong lad to turn a flywheel.—NUN. DOR.

[61074.]—**Organ Tremulant.**—The tremulant is a doubtful advantage to a pipe organ, and there are not many illustrations in back volumes. See No. 528, p. 204; No. 348, p. 258; or No. 349, p. 284. A simple tremulant is made by putting a little bellows on the wind trunk with a bit of wire carrying a weight extending from the upper board of the bellows, and a spring to keep the bellows shut, or, rather, to tend to do so. When wind is admitted to the bellows by opening the valve, the bellows opens, but is immediately returned by the spring, a little wind escaping by a small leather-covered hole. This arrangement sets up a sort of vibration in the wind current, which is imparted to all the pipe sounds which the "wind" controls. Perhaps the best tremulant is that which is placed in an enlargement in the wind trunk—a sort of box with a valve or diaphragm, which can be shifted so as to close or open the wind trunk passage as may be desired. The diaphragm carries a valve kept to its seat by a spring which the wind can force; but the spring causes the valve to endeavour to return to its seat, and accordingly the "wind" is put into vibration. A lever lifts the diaphragm out of the way when the "tremulant" is not required. Considering how much we have about organ-building in these columns, it is rather singular that this query has been passed over apparently; but perhaps your correspondents think that a tremulant is of little value in an organ. Be that as it may, the querist will find all he wants at the places cited above.—ORGANON.

[61080.]—**Small Organ.**—"J. C." must settle for himself what reeds he requires. How many tunes does he wish to play? Let him set them all out in the key of C, and see how many accidentals occur, then take a balance and choose reeds accordingly. I explained the system on p. 490, No. 1010, and gave a scale, which may suit "J. C.," on p. 439, No. 1008. It is an easy matter to determine which reeds to use when you know what tunes are to be played: it is difficult and unprofitable to guess at a scale which may or may not suit a querist.—GRAY'S INN.

[61094.]—**Æolian Harp.**—There must be two bridges, one at each end. Use what strings you like, and tune them to anything so long as they are all the same. See No. 1048, p. 163.—ORGANON.

[61094.]—**Æolian Harp.**—There should be two bridges, one at each end, about 1½in. from the pegs; this is not necessarily an exact distance, a little variation does not matter much; the bridges, ⅜in. high, are not fastened, so they can be adjusted at will. The strings are of gut—violin first strings answer best. You can tune the strings to any note; but I find the lower notes C, D, or E of the treble clef very satisfactory. All the strings *must* be tuned to the same note; any departure from this is a mistake—unison is necessary for the best results. It is best to tune with the ordinary tuning-hammer, such as piano-tuners use. In tuning do not be satisfied until all the strings sound exactly alike. When the weather is suitable and there is sufficient wind, which, of course, is a *sine quâ non*, the instrument is put into the window and the sash drawn down close to the strings, but not touching them. The harmonic sounds are then produced in endless variety, but always in the regular order well known to students of acoustics, the combinations at times being extremely weird and beautiful.—D. GRIMSHAW, Burley-in-Wharfedale, near Leeds.

[61101.]—**Stars Visible from Bottom of Well.**—Will "B. A." add to my obligations by fixing a time within which his answer to this question applies. I ask, because the question he has so readily answered has been passed by not a

few professional astronomers, and our own "F.R.A.S." (p. 345) was careful not to make quite so definite an assertion as "B. A." does. Perhaps "B. A." can give a definite answer to the original query: it appeared on page 313.—E. D.

[61103.]—**Bath Chair.**—This is rather a peculiar query. A sketch is to be made and space occupied in order that Mr. Stevens may make a Bath chair to double up. As he understands the principle, why cannot he set the work out on paper to some definite scale, and then see how the parts fit?—J. T. M.

[61104.]—**Steel Band.** — I presume "32in. thick" means a 32nd of an inch thick; but as to the smallest size pulley, that is a matter for experiment with different kinds of steel. All bands of the kind wear longer and work better on pulleys of good size; but 4in. would not be too small if the steel is good.—SAML. RAY.

[61107.]—**Small Coils.**—How can anyone say what is the smallest section-wound coil that can be made? Full directions for making coils have been given many times in back volumes, and it is purely a matter for experiment how small one can be made.—L. P.

[61112.] — **Fletcher's Muffle and Air Furnaces.**—What is the question in this query? All I can find is "Do quartz crystals grow?" although the query occupies 22 lines. I suppose quartz crystals may be said to grow out of the mother liquor.—F. C. S.

[61131.]—**Electric Cautery.**—It is very evident, from A. D. Stewart's reply, Dec. 31st, that he has very little idea as to what his requirements are. Surely, when he could so easily give the R. of his cautery to ·01 ohm, he might have been able to give the diameter of the wire, or at least the weight of same in grains per foot, and from either of these the current could have been found. Having to depend upon others, he says he has, in consequence, suffered much; but I am certain the parties favoured with his orders would suffer in a much larger degree, as it is the exception to find a surgeon who has the least idea what his requirements really are. Happily, there are a few who use electricity every day, and who use it most successfully; but as a rule, surgeons want the (as yet) impossible. They want current to work cauteries, say, 4 to 20 ampères, current to work incandescent lamps, electro-magnets, constant current up to 40 volts, induction currents, &c., &c.; and yet all this should be of such dimensions that they could easily carry it either in their hat or coat-pocket. Mr. Conry appears to have had very little experience in the heating of wires, and his elaborate formulæ I am sure will give "A. D. S." very little assistance. If he had given us the current in the experiment with the No. 30 wire, it would have been of greater service. He does not say anything about the effect of radiation and convection from the surface of heated wires; yet, if he will study this question, he will find that these alone determine the final temperature which a wire carrying a current may attain, specific heat and weight of wire having nothing to do with the question before us. I have made some experiments which may assist the doctor. I find that 14·5 ampères would just raise a platinum wire ·026in. diameter to a white heat, and, using the following formulæ, we can find the current required in Mr. Conry's experiment thus, $c' = c\left(\frac{d'}{d}\right)^{\frac{3}{2}}$ When c = current in a wire with diameter d, then c' gives the current required to heat d' to same temperature, and assuming No. 30 as ·0124in. diameter, then we find the current to heat same = 4·75 ampères. I may add that it would give me much pleasure indeed to see the Leclanché cells which could maintain such a current even a few seconds. If "A. D. S." will get or make three large bichromate cells, he will have no trouble in doing all he wants, and these will also work a 5-volt incandescent lamp of, say, 10 candle-power. The cells should be fitted in a close case, and arranged with rack to raise them immediately you are done using; in fact, if this arrangement is automatic, then all the better. Am-meters are regularly offered in "Sale Column" of "E.M." at 5s. each. I have no knowledge what their value as instruments of precision may be; but their price places them within easy reach. "A. D. S." should have "Sprague's Electricity" on his book-shelf, and a few hours spent in perusing this would be well repaid.—OHM.

[61145.]—**Does it Boil?**—TO "SIGMA."—Thanks; read on after your own on p. 416, and take to yourself all I said to Mr. S. B. Please dwell on this, too. Why is it that water cannot be heated beyond boiling temp. for each selected pressure? It hardly looks as if additional heat was then expended solely in vaporising because nature directly forbade the water to grow hotter, but rather as if the given external pressure were then no longer sufficient to restrain the evolution of (displacing) vapour, and that this process acted as a waste-pipe in preventing further rise of temp. in the liquid. In the nearly-boiling stage, my feeling is that no vapour is formed so as to drive back the atmo. or "displace" it. Surely the vapour then formed only gets between and among the particles of air? And if so, what forbids me to regard such evaporation as a merely passive process by which a liquid is dissolved in a gas, with analogy to solution of sugar in water?—WEALD.

[61145.]—**Does it Boil?**—I meant no offence to "Weald," and am sorry he has taken it, the more so as it hinders his seeing my points. My complaint was that if he had maintained his solution hypothesis at first, no one would have been put to the pains to give him elementary definitions of boiling; and certainly there would have been no opening for purely verbal definitions. The phenomena of vaporisation are exceedingly interesting and important, and numbers of keen-witted men have investigated them and recorded the results of their observations and experiments in books. If "Weald" chooses to despise these records, the loss is his: he simply puts himself at an incalculable disadvantage in his search after physical truth. He does full justice (no more than justice, I must add) to the printed words of Mr. Bottone. Why reject the printed words of other men of science merely because it is bound up into a volume? In this special case he has started an hypothesis which helps to bring home the nature of vaporisation to his mind; but a yes or no answer to his queries will take him but a little way—if he brings mind to a good book, he will assuredly find answering mind therein. The analogy suggested is certainly not complete: the sugar does not dissolve in the absence of the water; the water vapour is given off in the absence of air, to the same amount and with much greater rapidity than when air or other gas is present. Once more, if he wants to understand the subject, why not study it by mastering what the great experimentalists have recorded concerning it? Then he will stand on their shoulders, it may be, to attain further truths. Many thanks to Mr. Fletcher. I ought to have puzzled it out for myself; but somehow missed the explanation.—W. A. S. B.

[61156]—**Battery for Lamps.**—This querist should consult "Sprague's Electricity," new edition, p. 168, Table IV., and Tables V. and VI.; in the latter the cost per unit for various cells is given. —OHM.

[61203.]—**Porous Pots.**—You must burn them over a clear coke fire, as anything else deposits a sort of soot over them and in the pores. If coke is scarce up your way, I shall be pleased to send you some.—W. HOLDEN, Newport, Mon.

[61299.]—**Capricious Dynamo.**—Many thanks for both replies; both, however, are wrong. To "Sigma," I will say no one touched the connections in either case. To "Miller," that the dynamo was specially built for plating, and will not work nicely without the series coils, as the bath is of very low resistance indeed. I have since repaired the dynamo by "soaking" the pole pieces in a forge fire for a couple of hours, and allowing it to cool down gradually; but I am not sure that this remedy will be permanent.—SELIM.

[61234.]—**Bursting Pressure.**—I am much obliged to "T. C., Bristol," for his kind assistance; nevertheless, I think if he will kindly review his calculations, he will find out his error.—NONCONFIDENT.

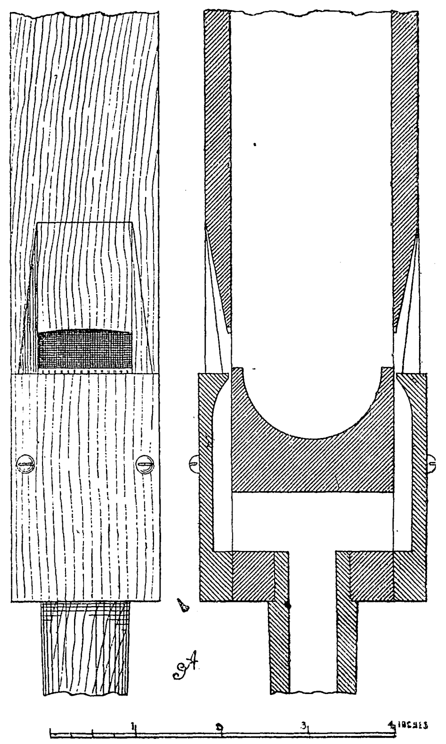
[61257.]—**A New File.**—The file I referred to in my query was not Mr. Kirkwood's, as he seems to imagine, but a German patent, and was for cutting steel, iron, and brass, a special form being made for softer metals and wood. I thought that a reader of the "E. M." might have had some experience with the same or a similar file, and could give his opinion. Cannot "R. S. T." communicate with me, if interested, as out here I have no way of paying for advertisement?—A. F. SHAKESPEAR, Dresden, Lüttichaustrasse 14 III.

[61274.]—**Portable Cell.**—There is no trouble in arranging this. Take an ordinary Leclanché cell, and make up a saturated solution of salammoniac, soak cotton wad thoroughly in this, and then pack the cotton inside the cell. This arrangement works well for testing, especially if used with one of the cells without porous pot.—OHM.

[61290.]—**Mediæval Outlines.**—If "Draughtsman" happens to be friendly with the head of some printing establishment, he might obtain a loan of typefounder's catalogues, which are sure to contain an assortment of interesting and beautiful designs.—ARTHUR MEE.

[61295.]—**Turning Slate.**—Use cast-iron, which is cheap. Some use bits of soft wood which hold grains of emery. Carbonado too dear for such work.—J. K. L.

[61278.]—**Hot-Air Motor for Organ, &c.**—In reply to "C. C.," I may direct his attention to the hot-air engines made by the Britannia Company, Colchester. Personally I have had no opportunity of observing the operation of a hot-air motor as an organ blower; but these engines are good, and will no doubt answer the purpose. They are made up to 2-man power, and heated by gas or ordinary fuel. "C. C." may obtain particulars by writing to the company. I have much pleasure in giving particulars of my Doppel-flöte; and as the stop is practically unknown in England, for there is not another example in any English organ, to my knowledge, I have prepared a scaled drawing of the

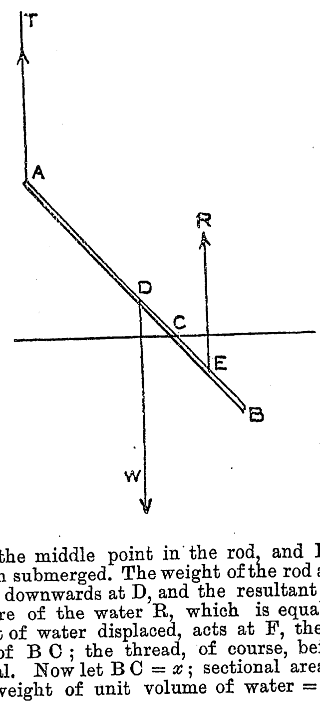


middle C¹ pipe, showing the proportions of mouths, the sunk block, windways, caps, &c. The internal dimensions of the several C pipes are as follows:—

	Ten. C	C^1	C^2	C^3
Width, internally	$1\frac{3}{4}$in.	$1\frac{1}{8}$in.	$\frac{3}{4}$in.	$\frac{1}{2}$in.
Depth, internally	$2\frac{15}{16}$in.	$1\frac{3}{4}$in.	$1\frac{5}{16}$in.	$\frac{7}{8}$in.
Length, from mouth...	$25\frac{1}{2}$in.	$13\frac{1}{4}$in.	$6\frac{1}{2}$in.	3in.

The pipes, of course, are stopped; they are of mahogany on the mouth sides, their caps have plain edges, and the blocks are slightly nicked. The windage required is small, while the tones produced are singularly round, full, and of good mixing quality. The bass octave is added in stopped pipes with single mouths, voiced very full, to carry down, as nearly as possible, the tone of the double-mouthed portion of the stop.—G. A. AUDSLEY.

[61306.]—**Question in Mechanics.**—In subjoined diagram A B is the rod, A T the thread, D



being the middle point in the rod, and B C the portion submerged. The weight of the rod acts vertically downwards at D, and the resultant vertical pressure of the water R, which is equal to the weight of water displaced, acts at F, the middle point of B C; the thread, of course, being also vertical. Now let B C = x; sectional area of rod = a; weight of unit volume of water = ρ; and

weight of rod = W. Taking moments about the point A, we have—

$$W \times AD = R \times AE;$$

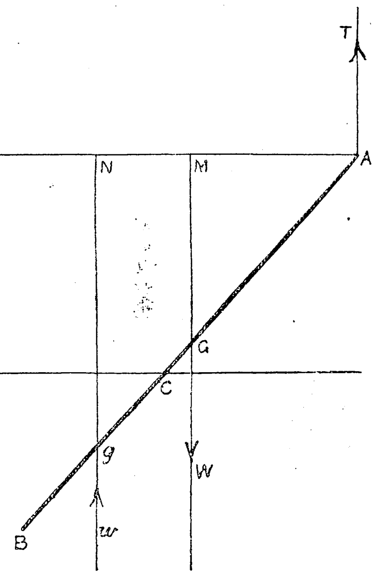
or—

$$(12 \times \cdot 7 \times a \times \rho) 6 = (x \times 1 \times a \times \rho) \times \left\{ 6 + \frac{x}{2} + (6 - x) \right\}$$

$$\therefore \quad 50 \cdot 4 = x\left(12 - \frac{x}{2}\right)$$

On solving the quadratic equation we get $x = 5 \cdot 43$.—A. J. J.

[61306.]—**Question in Mechanics.**—When the rod is at rest, it is kept in equilibrium under the action of three forces—the weight W, the reaction of the fluid on the part immersed, which is equal to the weight w, of the fluid displaced, and the tension of the thread T; but the two forces W and w are vertical forces, therefore their resultant T is also a vertical force. If now in the figure,



G and g be the centres of gravity of the rod and of the fluid displaced, and AMN be a horizontal line through A, meeting the verticals through G and g in M and N; then, taking moments about the point A, we have the equation—

$$W . AM = w . AN,$$

or $$\frac{W}{w} = \frac{AN}{AM} = \frac{Ag}{AG} \quad \text{.........................} \quad (1)$$

If we take BC the length of the part immersed equal to x; then Bg will be equal to $\frac{x}{2}$, and Ag will be $12 - \frac{x}{2}$; also AG = 6.

$$\therefore \frac{Ag}{AG} = \frac{12 - \frac{x}{2}}{6} = \frac{24 - x}{12} \quad \text{.........................} \quad (2)$$

Again, if the weight of the unit of length of the fluid displaced be taken as the unit of weight, we shall have $w = x$ and $W = \cdot 7 \times 12$—

$$\therefore \quad \frac{W}{w} = \frac{8 \cdot 4}{x} \quad \text{.............................} \quad (3)$$

and from (1), (2), and (3) we have—

$$\frac{24 - x}{12} = \frac{8 \cdot 4}{x}$$

or— $$x^2 - 24x + 100 \cdot 8 = 0.$$

A quadratic eqn. from which we have—

$$x - 12 = \pm 6 \cdot 57$$

or— $$x = 5 \cdot 43\text{ft. and } 18 \cdot 57\text{ft.}$$

The second value supposes the point g to be in the line BA produced.—MILVERTON.

[61310.]—**Electricity for Killing Dogs.**—Although I heartily disapprove of cruelty to animals, especially for so-called "sport," yet sometimes I cannot help thinking that some of the energy spent in preventing cruelty might be more usefully applied. We work our signalmen twelve hours a day, we work our tram-men sixteen hours a day, and our engine-drivers often longer; we compel young girls to stand the whole day in shops for the sake of seeming busy, and we tax the resources of science in order to provide a painless death for homeless dogs, and prosecute farmers for not milking their cows at market by Greenwich time! Is not a tram-man better than a dog, and is not an English girl of more account than a cow?—WM. JOHN GREY, F.C.S., Newcastle-on-Tyne.

[61322.]—**Induction Coil.**—TO MESSRS. BOTTONE OR CONRY.—These are all the same in principle. Both medical coils and intensity coils depend on induction for their manifestations. The current given by the former is not required to be very great or of high tension, so no great care is taken in insulation. The latter are made with the greatest care as to insulation, and with an immense quantity of very fine wire, so as to insure very high tension. Yes, a tube regulator can be used with an intensity coil. I should advise you to spend a shilling on "Intensity Coils: How Made," by Dyer.—S. BOTTONE.

[61323.]—**Back Shaft for Sliding and Surfacing.**—I should not attempt to apply a back shaft to a 4in. lathe, such as I described. A 5in. or 6in. lathe is small enough, I think, to put a back shaft to, because it means so much extra work about the slide-rest saddle—too much for one of small size. But if you will give me the sectional dimensions of the bed of the 6in. lathe which you mention, and say on which side the rack is placed, whether back or front, I will draw out the necessary gear.—J. H.

[61325.]—**Fitting Glass Stoppers.**—Wet the stopper, dip it in fine sand, insert it in the neck of the bottle, and grind away. If you are blessed with patience and elbow-grease, you cannot fail to get a good fit.—S. BOTTONE.

[61325.]—**Fitting Glass Stoppers.**—Chuck the stopper in the lathe, put on some fine emery mixed in oil, and while revolving press the bottle on with a gentle hand. The stoppers are roughed off to a near fit with sand and water on a revolving iron plate, and a few touches between bottle and stopper, as described above, make as close a fit as can be desired.—SAML. RAY.

[61325.]—**Cocks.**—I have never taken particular note of the proportions of the various sized plug-cocks, but they should be tight for water or steam to 100lb. at least. I consider lead washers an abomination. Have the thread to fit well, and screw up tight with a little red lead.—T. C., Bristol.

[61328.] — **Electrical Measurement.** — TO "SIGMA."—This question is rather wide, as it involves a good many principles if it is to be answered correctly, and I should have to refer the querist to the information to be found in my "Electricity." It appears he wishes to make experiments similar to those which I made when writing that work, and therefore I can do no better than refer him to the description of the apparatus I devised and used, which will be found p. 229 of the first edition and p. 311 of the second. A tangent galvanometer such as he mentions would answer his purpose; it would be better to make it on the plan I have described, so that each circuit would be a decimal multiple of the others; but to measure the E.M.F., the resistance, including that of the cell, would require to be made 1,000 ohms, much of which would be in the wire itself, with a variable portion to correct for temperature, cells, &c.; then the current in ampères shown by the needle would represent the E.M.F. in volts, as in my own patent instrument, the first by several years in which the actual current in ampères was shown on the dial.—SIGMA.

[61329.]—**Dynamo.**—For such small dynamos it is hardly worth while to have forgings. Nicely annealed malleable iron castings do admirably. Diameter of cores, $2\frac{1}{2}$in. The plate is of brass; to prevent fingers, &c., getting a blow from the rotating armature. The rod is the support of the brushes; but the best way is to support the brushes on a carrier, movable round the shaft and attached to one of the standards. The running resistance of 4lb. of No. 20 on the ring armature is about 4 ohms; hence on the F.M.'s there must be about 16lb. of No. 16.—S. BOTTONE.

[61330.]—**Legal.**—BAD DRY PLATES.—The agent acted as principal in the sale, and is liable.—R. S. T.

[61331.]—**Cable for Electric Light.**—I have changed title to suit index. If your 19 wires, each = ·048in. diameter, are of high conductivity copper, then the resistance of 300 yards out and 300 back will equal ·48 ohm, and the loss in volts in any conductor = C × R. Now, if we take C for your 20 lamps, as = 20 ampères, then the loss in volts = 9·6, which, unless you get your power very cheap, would be costly. Your cable could safely carry twice as much current; but, then, the loss in volts would be twice as great, and if you were not always running the full number of lamps at end of leads, the arrangement would not be good, as turning out lamps would increase the E.M.F. and destroy your lamps. The lamps you mention often break in the manner you state. Perhaps you have overrun them.—OHM.

[61332.]—**Speeding Millstones.**—Inner consciousness seems to say to me that if I want to get up a great speed I should not work off a large wheel direct on to the small one. I want to see what engineers say.—R. S. T.

[61332.] — **Speeding Millstone.** — If not wedded to the particular arrangement you name, why not take the power off the wheel direct by means of segments fixed to wheel? You could then gear up a line shaft, say, 6 to 1, and on this have the bevel gear for driving vertical spindle in a line, at a further increase of, say, 2 to 1—that is, 120 revolutions altogether. Briefly, the quicker the speed is got up, the lighter the shafting and gearing in first motions will be, and consequently less expense in repair and renewal, and less friction. T. C., Bristol.

[61334.]—**Preparation for Mixing Bronze Powder.**—None are so helpless as those who won't help themselves. However, here is the recipe, or the proportions which will answer; but others will do quite as well, and perhaps better, according to the season of the year. Procure some pale copal varnish; add about six times its bulk of turpentine, and about a 30th part of dry air-slaked lime (it won't matter much if it is quicklime). Shake well, and stand aside for several days, then decant or filter. Mix the powder with the varnish—four parts of powder to five of varnish. For the copper or deep-coloured bronzes you need not be particular about getting pale copal, the ordinary stuff will do.—NUN. DOR.

[61339.] — **Steam Boiler.** — If longitudinal seam is well riveted or brazed, and the ends have, say, three screwed stay tubes, it would be safe at 90lb. sq. in. How are you going to fire it? This will have something to do with the power.—T. C., Bristol.

[61342.] — **Problem.**—The plane B may be assumed to lie in the horizontal plane. Then the intersection of A with B will be the trace of A upon the H.P., and the intersection of C with B will be the trace of C upon the H.P. Now the angle between these traces is ω. Draw therefore two lines in the H.P., including an angle ω. Consider these lines as the horizontal traces of two planes A and C, inclined α and β respectively, and draw in the vertical traces. Then find the intersection of A with C, and determine the included angle by the ordinary method.—W. GILBERT.

[61342.]—**Problem.**—As only angles are given in this question, it is properly an example of spherical trigonometry. The three planes will intersect in a point, let this point be assumed as a centre of a sphere, then the planes will intersect the sphere in arcs of circles, forming a spherical triangle, of which one of the sides is ω; the angles adjacent to this will be α and β respectively, and θ, the inclination required, will be the angle opposite to the side ω. Hence, since we have one side of the triangle and the angles adjacent to that side given, the angle opposite that side will be found from the equation,

$$\text{Cos.}\ \theta = \cos.\ \omega \sin.\ \alpha \sin.\ \beta - \cos.\ \alpha \cos.\ \beta.$$

This equation may be adapted to logarithms by making use of an auxiliary angle; thus if we take ϕ such that—

$$\text{Cot.}\ \phi = \cos.\ \omega \tan.\ \beta$$

then— $$\text{Cos.}\ \theta = \frac{\cos.\ \beta \sin.\ (\alpha - \phi)}{\sin.\ \phi}$$

from which two equations, θ may be found by means of logarithms.—MILVERTON.

[61348.]—**Length of Chord.**—If D be the diameter of the circle and A the length of the arc then the length of the chord

$$= \left\{ 1 - \cdot 1666 \left(\frac{A}{D}\right)^2 + \cdot 00833 \left(\frac{A}{D}\right)^4 - \cdot 0002 \left(\frac{A}{D}\right)^6 + \&c. \right\}$$

If $\frac{A}{B}$ be less than unity, three terms would perhaps give a sufficiently near approximation in ordinary cases.—MILVERTON.

[61353.]—**Spiral.**—There is no general rule by which you can obtain the lengths or area of spirals, each particular spiral having a formula of its own. I should advise you to consult some work on the integral calculus, where you will find the solutions of various cases.—G. H. H.

[61353.]—**Spiral.**—As you know how to find circumference of a circle the difficulty is solved. Find the circumference of a circle inclosing the spiral and square this, and add the square of the pitch of spiral. Take the square root of the same, and then you have got the length of outside of spiral.—T. C., Bristol.

[61353.]—**Spiral.**—

h = height of spiral
θ = angle of inclination of spiral with its axis

$$\text{Length} = \sqrt{h^2 + (\pi \text{ diam.} \times \text{No. of turns})^2}$$

or— $$= h \sec.\ \theta.$$

The diam. to be measured horizontally between centres of sections of spiral.—ELAG.

[61353.] — **Spiral.** — Querist does not state whether it is a plain or conical spiral, but below are formula for both:—Let Lp and Lc be the lengths respectively of plain and conical spirals. Let C and c be circumferences of circles equal in

diameter to the diameter of the largest and smallest diameters of the spiral respectively. Let N and P be number and pitch respectively of revolutions of spiral, and let H = height if conical,

then— $\mathrm{L}p = \mathrm{N} \,.\, \frac{\mathrm{C} + c}{2}$,

and— $\mathrm{L}c = \sqrt{\mathrm{L}_p^2 + \mathrm{H}^2}$,

i.e.— $= \frac{1}{2}\sqrt{\mathrm{N}^2 (\mathrm{C} + c)^2 + 4\,\mathrm{H}^2}$.

—SEVERN TUNNEL.

[61354.]—**Photographs.**—This must be due to one of two causes—either the photographs are not sufficiently fixed, or there is something injurious in the mountant. Fix them for a quarter of an hour in hypo. solution, containing 2½oz. of hypo. to one pint of water, and mount them with dextrine. They will not turn yellow if this is done. Perhaps the paper is not good. I can strongly recommend Stanley's or Edwards'.—R. A. R. BENNETT.

[61356.]—**Force-Pump.**—An ordinary deep well pump would do this; but for driving it do not use an eccentric, as you propose, but a crank. The remainder of your proposal will suit. Put an air-vessel on suction and delivery if only one pump is used, and use 1¼in. pipe for, say, 2½in. pump.—T. C., Bristol.

[61357.]—**Shafting.**—Plumb down from the shaft that is parallel to the one to be fixed, and lay down a line on floor by which you may also set new shaft parallel by means of a bob, say a bracket as each end; you can also level along the floor, and then get correct height by means of a lath at each end. Having got the end ones correct, you can easily get a middle one up, and set by a line well strained. The others follow in the same way easily.—T. C., Bristol.

[61358.]—**Dead Point.**—There is one way in which "Another Workman" can get the dead point of his engine effectually. Take off flywheel, and admit steam. Where the piston stops is the dead point.—NOT A WORKMAN.

[61358.]—**Dead Point.**—If you must be very exact you can caliper crank at large and small end, and then scribe a centre line on crank and set it by a level; but if you have a good eye you can set it very nearly correct by sighting when the connecting-rod and crank are in line. Now make a mark on fly-wheel and some fixed part to correspond, and do same for other end; you can now pull round as often as wanted to these marks when setting valves.—T. C., Bristol.

[61362.]—**Faulty Dynamos.**—TO MR. BOTTONE OR MR. CONRY.—Almost impossible to say without examination. The following are among the many possible causes of failure:—1st, the insulation is imperfect; try this by the "sparking test." 2nd, you use too high resistance between the terminals; put on four or five 5c.p. lamps in parallel instead of one or two 10's. 3rd, the F.M. wires are coupled wrongly to the brushes. Rotate the contrary way. 4th, the brushes are too hard, and touch at the wrong points. Use a number of very thin copper strips for brushes, and let them press lightly on the commutator, just about in a line, with the space between the pole pieces. 5th, some of the armature sections are wrongly coupled; the end of one section should be the beginning of the next.—S. BOTTONE.

[61365.]—**Paraffin.**—There is no truth in the statement.—S. BOTTONE.

[61366.]—**Super-Elevation of Outer Rail on Railway Curves.**—I presume "Platelayer" requires the rule stated as plainly as possible, and I will try to do so. Super-elevation of outer rail in inches should be equal to gauge in feet multiplied twice by velocity of train in miles per hour, and divided by one and a quarter times the radius of the curve in feet. As the Irish gauge is 5¼ft., the super-elevation required would be more than on our (English) lines, really about $\frac{3}{26}$ths more. At the pace and radius he mentions, it should be barely $4\frac{5}{16}$in. (Irish gauge). "Platelayer" will find J. W. Barry's "Railway Appliances," 3s. 6d., a very interesting, readable, and valuable work to anybody interested in practical railway work; that is the source of the above rule.—SEVERN TUNNEL.

[61367.]—**Weight of Engine.**—An engine must be the same total weight, no matter if the chimney is towards Dublin or Belfast. There are some other bad faults introduced into Gen. Hutchinson's report on the Portadown accident. Instead of giving the weight in tons, cwts., qrs., he gives tons and decimal parts of tons; and also the distances are all given in miles and decimal parts of miles. It should be in chains, yards, or feet. What I want to know, Sir, is how far was it from where they got off the road to where they came to a stand in the ditch?—that we are not told. Another point is, the Government Inspector measures all his distances from an imaginary "zero" point; why not, as usual, from the first mark on the rail. If we are to get to the bottom of these cases all must be made clear—at least, that is what is required by all railway men.—A PRACTICAL RY. MAN.

[61368.]—**Newcastle and Carlisle Railway.**—The first portion of this line was opened 9th March, 1835. An engine which drew one of the first trains of passengers was named Comet, built by Messrs. R. and W. Hawthorn, and as this firm have presented to me a correct diagram of this engine, I shall be happy to give any further details of it if of interest to your readers.—CLEMENT E. STRETTON, Consulting Engineer Amalgamated Society of Railway Servants.

[61370.]—**Block Tin.**—*Blocked* tin saucepan "R. S. T." should have written; the sheet of tin-plate out of which the saucepan is made or shaped having been planished, hammered, or consolidated by blows with a highly-polished convex-faced hammer on a polished plane, steel anvil, or *block*—hence the name. During this process the tinned iron has lost much of its malleable ductility, has become more dense, and takes a higher polish. *Block* tin is a trade term applied to the pure metal with which the iron plate is coated. Lydney and its surrounding district, the Forest of Dean, is perhaps the very oldest seat of the manufacture of iron and of tin plates in the United Kingdom, the forest having been the great iron-producing centre during the Roman occupation of Great Britain on account of the richness of the easily obtained iron ore, its abundance of oak coppice for charcoal, and of limestone. The geological situation was most favourable, flanking the tidal estuary of the Channel, the ever-narrowing gorge of which concentrates the constant S.W. breezes for supplying the primitive air-blown smelting furnaces placed upon some exposed scarp, while water supplied the motive power for driving the tilt hammer of the forges. All this, alas! has recently become entirely supplanted by the steel ingots imported from the North of England and worked up into steel tinned plates, to be exported for supplying the vast "tin-canning" industry of the American and Australian Continents. In these Botanical Gardens I have often dug up specimens of smelted iron under and around one or two of these ancient hearths, remarkable for its purity and ductility; while specimens of the cinder, scoriæ, or slag, of a bright grass-green colour, high specific gravity, and containing a very large percentage of iron, abound throughout the forest, an observant visitor seeing specimens on the outer edges of the highways; while the names Cinder Hill, Cinder Tump, &c., applied to farm or field, occur in most parishes, where every ploughing turns up specimens thereof. Savants acquainted with the ancient Roman physiognomy and physique may still meet with specimens amongst the forest population (indigenous) identical therewith, and also of the Roman Causeways made by the Roman Legions during their occupation, and still intact.—THE DISPENSER AT THE FREE DISPENSARY, LYDNEY.

[61372.]—**Electro-Magnetism.**—Under the conditions stated in the query, this is an impossibility; but if a separate electro might be used, it could be done, if the electro were made of cast iron, and a strong opposing spring were attached to the armature.—S. BOTTONE.

[61373.]—**Theatre.**—Scenes roll up on the principle of an ordinary blind, only reversed—i.e., the lath end at the top, the roller at the bottom; ropes are wound round either end, which by means of a windlass are caused to unwind, making the roller ascend.—A. F. SHAKESPEAR, Lüttichaustrasse 14, Dresden.

[61374.]—**Vegeto - Alkaloids.**—Most of the treatises on organic chemistry go pretty fully into this matter. If you want a cheap book, get Roscoe's "Elementary Chemistry" (4s. 6d.) If you want to be more thorough, get a peep at Watts.—S. BOTTONE.

[61376.]—**Moss.**—This so-called golden moss is not a moss at all. It is a variety of the stonecrop, which is a Sedum, S. Acre var. It is consequently one of the Crassulaceæ, which are very closely allied to Saxifrageæ. The order is grouped under Calycifloræ. "Discipulus" can easily find out the life-history for himself, knowing the foregoing particulars. I may here point out the confusion which is always arising from the employment of popular names. A moss is at the opposite end of the botanical system to a Sedum, the former being a Cryptogam and the latter a Phanerogam. "Discipulus" should know that the mere fact of the plant bearing yellow flowers was proof positive of its not being a moss.—LEON NOBARD.

[61378.]—**Mechanics.**—You will notice that you do not give actual size of gates, so I cannot answer fully the actual pressure on hinge; but the total thrust forward on one gate is 5 × 6 × 3 × 62½lb. = 5,625lb., which might be replaced by a single force of this amount acting at ⅔ the depth—that is, 2ft. from bottom; and, as the hinges are 1ft. and 3ft. from this, the pressures on hinges will be in inverse proportion, or 4,218¾lb. at bottom and 1,406¼lb. at top. This is not the whole pressure on hinge, as the angle of gate is not here considered, neither is resistance of sill deducted. Weight of contents of globe $= a^3 \frac{\pi}{6} w$; surface of globe $= a^2 \times \pi$; pressure on surface = surface $\times \frac{1}{2} a \times w = a^3 \frac{\pi}{2} w$, which is three times the weight as you state.—T. C., Bristol.

[61378.]—**Mechanics.**—Take the general case, thus: Let b equal breadth of one door, d the total depth, δ that of top hinge, δ_1 that of bottom hinge, n any depth, P shear on top hinge, P_1 shear on bottom hinge, w weight of cubic foot of water. Then, $w\,b\,n\,d\,n$ = pressure on horizontal element of door, and the moment about top hinge is $w\,b\,n\,(n - \delta)\,d\,n$, and the sum of all these moments between $n = d$ and $n = o$ is the shearing moment on bottom hinge; but $-\mathrm{P}_1(\delta_1 - \delta)$ is the shearing moment also. Wherefore, we have—

$$w\,b\int_o^d n\,(n - \delta)\,d\,n = -\,\mathrm{P}_1\,(\delta_1 - \delta)$$

Or—

$$\frac{w\,b}{6}\,d^2\,(2d - 3\delta) = -\,\mathrm{P}_1\,(\delta_1 - \delta)$$

And, writing δ_1 for δ, we get—

$$\frac{w\,b}{6}\,d^2\,(2d - 3\delta_1) = -\,\mathrm{P}\,(\delta - \delta_1)$$

And putting $d = 6$, $\delta = 1$, $\delta_1 = 5$, $w = 62{\cdot}5$, $b = 5$, the results are: $-\mathrm{P}_1 = 4218{\cdot}75$, and $-\mathrm{P} = 1406{\cdot}25$ pounds. If it is required that the hinges shall be of equal strength, the relative position is $\delta + \delta_1 = \frac{4}{3}\,d$.—G. H. H.

[61380.]—**Engine.**—An engine with cylinders 2 by 6in. is quite useless for driving a 12in. saw. It might be possible with cylinders 12 by 8in., but not smaller, and with 30lb. pressure.—SHAKESPEAR, Lüttichaustrasse 14, Dresden.

[61380.]—**Engine Query.**—Oh! yes; it will drive it, but not at 15lb. Try 50lb., and do not force the saw too much, and then, perhaps, the band will keep on all right—that is, if the pulleys are slightly rounding and in line with each other.—T. C., Bristol.

[61381.]—**Opal Plates.**—I have always obtained excellent results by following the directions given by the Charterhouse Company. For rapid printing by contact, the most beautiful results are obtained with various gradations of tone, from very light brown and sepia to black, by a slight modification of exposure and development. Exposure to diffuse daylight 1sec. to 8sec., artificial light two to eight minutes. All subsequent operations in average light until after fixing. Stock solution for developer:—

A	Oxalate of potash	2oz.
	Chloride of ammonium	40gr.
	Water	20oz.
B	Sulphate of iron	½oz.
	Citric acid	¼oz.
	Alum	90gr.
	Water	20oz.

For correct exposure, mix equal portions of A and B. If the development should commence too rapidly, pour off developer, dilute it with water, and re-apply. This will save over-exposed plates. To produce lighter shades, double the exposure, and dilute the developer with its bulk of water. Correct exposure and strong developer for dark tones. Use clean hypo. for fixing, or you will have stains. Protect pressure frame from light entering at back or sides. Clearing solution: alum, 1oz.; sulphuric acid, 1oz.; water, 20oz.—S. BOTTONE.

[61382.]—**Instantaneous Exposures.**—What you have taken for the result of undue exposure, has been most likely caused by over-exposure and a powerful developer. Poor, thin negatives are always the consequences of over-exposure, unless the developer is restrained by means of much bromide. Try again; do not use such a large aperture, and develop with ferrous oxalate, duly restrained with potassium bromide, if needed.—S. BOTTONE.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

QUERIES.

[61383.]—**Inertia of the Reciprocating Parts of Steam Engines.**—In a paper by Mr. Imray, the following formula was given :—

$$i = 1{\cdot}23 \left\{ \cos a\,t + \frac{c^2 (\cos^2 a\,t - \sin^2 a\,t) + \sin^4 a\,t}{(c^2 - \sin^2 a\,t)^{\frac{3}{2}}} \right\}$$

Taking $c = 5$, what will be the values of i for the following values of $a\,t$: 0, 15, 30, 45, 60, 75, 90, 105, 120, 135, 150, 165, 180 degrees? Also if $c = 4$? As a check on the figures, Mr. Imray gives the values when $c = 3$ as 1·640, 1·282, 0·411, −0·435, −0·819, −0·848, −0·820 ; when $a\,t$ = 0, 30, 60, 90, 120, 150, 180. If any reader has the necessary time and knowledge, he will confer a great favour upon me, and in return I shall be very happy to put the results in a form which will be of use to other engineering readers.—O. P. Q.

[61384.]—**Steam.**—A pan, 6ft. diam., used for boiling purposes, is at the base of a building in a room 13ft. sq., the ceiling of which is 4ft. above the top of the pan. There are several holes in the wall of this room, which are used for running belts; and the problem is to draw away the steam from the pan without allowing it to escape through these holes and fill the building. To this end a funnel-shaped covering has been constructed over the pan, as well as the limited space permits, and from this a wooden shaft 10in. by 10in. has been carried to the roof of the building, 25ft. above. Unto this shaft a pipe from a powerful fan sends a strong upward current of air; but this fails to draw up the steam, and although the shaft has been altered in various ways, and the blowpipe has been placed in various positions, still we cannot make any sensible impression upon the volume of steam.—PERPLEXED.

[61385.]—**Shunt Dynamo.**—TO MR. EAVES.—I have a dynamo with cast-iron field magnets of elliptical section, something like a Bürgin machine. F.M.'s wound with about 1,500 turns of conductor, weighing 200 grains per foot; total resistance about 2 ohms. I should like to utilise these F.M.'s for a shunt-wound electro-plating machine. If I made the armature with laminated core, drum-wound with about 30 yards conductor, of resistance between collectors = ·005 ohm, 18 bars on commutator, would that be a right position? How many ampères would it produce, and at what pressure? The machine was originally series wound, eight wires on F.M.'s joined in multiple arc. It worked very well for a short time; but, owing to the low resistance in depositing bath (20 sq. ft. of work in an iron depositing bath), the armature insulation became defective from over-heating. The new machine should do 40 sq. ft., if possible. I may add that I could conquer electrical and mechanical difficulties. Pole opening, 8in. diam. by 8in. length, could be bored out to 9in.—ANGLO-DANE.

[61386.]—**Focus of Lenses.**—Will someone kindly inform me if the "actual" focus of a lens is the distance in quarter inches from the back of the lens to its burning point? Also, what is meant by "back" focus and "equivalent focus?—LENS.

[61387.]—**Ferrule Machine.**—Will some kind reader enlighten me on the following? I have a tool for making them; but it is too slow a process. They are made out of ⅜ single hoop iron, cut off long enough to reach round a piece of ⅜ round steel. I wish to make a machine, to be driven by steam, that will require no attention, only to put the iron strips in position for it to cut them off the required length, and then pass through and come out finished. I suppose there is such a machine. Can any of our readers supply me with drawings or sketch, or any information upon the subject?—E. M.

[61388.]—**Browning Barrels.**—TO "ARMOURER."—I have tried my hand on browning the barrels, first on a singled-barrelled gun, and was quite satisfied with my first try; but having occasion to brown a double one, I found, instead of a clear pattern when finished, a beautiful black polish, with a few brown streaks, about an inch apart. Not wishing to trouble, or take up a lot of valuable space, I tried again and again upon different barrels, with the result of getting a very good pattern towards the ends of the barrels, especially just where the wood plugs were. From there it seems to fade gradually towards the breech ends, where the colour is faint. I have given strict attention to the making-up of the recipe, and think that is all right. Can it be that the wood plug I put in the breech end to keep it off the bench has anything to do with it, or I give them too much scald?—J. W. B.

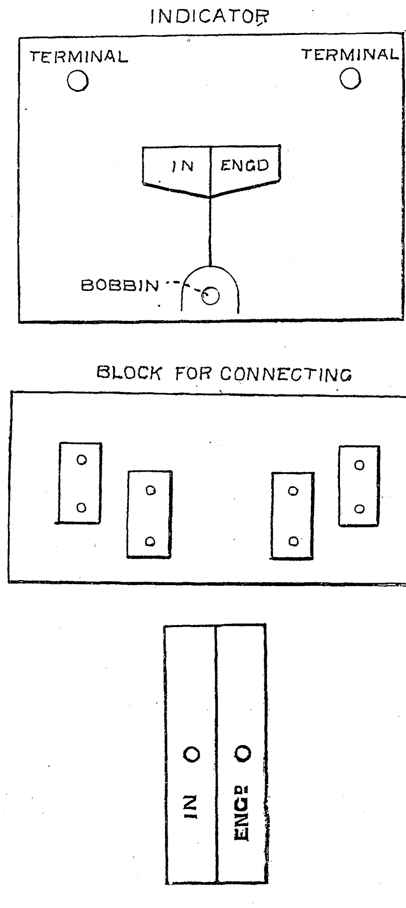
[61389.]—**Wimshurst Machine.**—I have constructed a Wimshurst machine, giving 5in. sparks without condensers; but it is not self-exciting, unless the conductors are removed. Plates are 20in., conductors 1½in. brass tube with mahogany ends. In the dark no leakage is apparent, unless it be manifested by the copious brush discharge from between the plates on one side of machine, this discharge giving a strong odour and affecting the moustaches at 9in. distance from plates. I should be pleased to know how the machine may be made self-exciting with conductors, and also to hear of any interesting experiments that may be made with the machine after one has had the trouble of constructing it. I may mention the conductors are supported by glass tubes of good insulating quality, varnished, instead of rods. I presume this would not affect the working.—HENDON.

[61390.]—**Engine Query.**—I have a small horizontal slide-valve engine, with cylinder 1⅝in. bore and 4in. stroke. What size and shape of boiler would be most suitable to drive it, and what strength should the plates be?—J. B., Leeds.

[61391.]—**Soldering.**—I notice on page 391, letter No. 26640, Dec. 31st, "Regel" kindly gives some information as to how to tin a soldering iron, and mentions chloride of zinc as the soldering fluid; but he doesn't say how the fluid should be applied, for if the copper is required to be hot, I presume the soldering fluid would cool it too much for it to melt the tin required to tin it with. I also wish to ask your readers if this soldering fluid would be a suitable flux to use when it is required to coat iron with lead, and, if so, which is the cheapest mode of obtaining or making the soldering fluid in quantities, and how it should be applied, and whether it could be used in the same way as galvanisers dip their iron sheets through their flux when passing through the spelter?—GALEN.

[61392.]—**Electric Motor.**—Would any of our readers kindly give a little information for the construction of a motor? I have a brass flywheel, weighing 1¼lb. and 4⅝in. in diam. What I should like would be an illustration showing dimensions and connections, also length and diam. of cores of magnet. What size wire, distance of armature from magnet, and the working of the contact-breaker? Also what battery-power required?—A. C. CHAMBERS.

[61393.]—**Electric Indicator.**—TO MR. CONRY, OR MR. BOTTONE.—I have got an indicator to repair, which had not been connected or working for some time. It is for telling when a person in an office is in or engaged. One tablet is placed beside the desk at which the party sits,



with a two-way push from it, with the words in and engaged, so that by pressing either it indicates on another outside the door. It is Sakes' patent, as used for electric bells, set in a small square frame, with two terminals to each. When I went to it, I found eight wires hanging derelict, and a small block with four pieces of brass screwed to it with eight screws. If you could tell me how to connect it, and wires, it would greatly assist me. I inclose sketch to explain.—J. B.

[61394.]—**Dynamo.**—TO MR. BOTTONE.—I am making a dynamo of double the dimensions given in your valuable book, and I wish to ask you a few questions respecting it: Would it be detrimental to the working of the machine to fix the field magnets and bearings on cast-iron bed instead of wood base-board? Would the dynamo do for an arc light, and what candle-power? What quantity of wire shall I require? What is a safe speed to run it?—A YOUTH.

[61395.]—**Legal.**—A. dies, leaving to his only son, B., the interest of a certain amount, which principal, after B.'s day, has to be divided between B.'s children, C., D., and E. The amount is left to be invested in Gov. stocks, or freehold mortgages. C. is desirous of drawing part of his share, and has the consent and hand of B., D., and E., but is refused by the trustees, one of whom is an attorney. Can this be done? Also, if C., D., or E. dies before B., have they not the power to make a will?—W.

[61396.]—**Stains on Horses' Coats.**—I have a horse that lies in the wet and muck every night, and I wish to show it at the horse show this summer. Could anyone recommend anything that would take out the stains without affecting the skin?—UNDER STRAPPER.

[61397.]—**Disposal of House Sewage.**—Can any reader state the best mode of disposing of this where there is water in the house but no drainage?—A. B.

[61398.]—**Electric Battery.**—I am anxious to construct a battery that will light, say, two 10-candle lamps for two or three hours occasionally, and that will at other times run a small motor, say, sufficiently powerful to drive a sewing machine for, say, two hours at a run. It must give off absolutely no fumes, be made up with one liquid only, and require as little attention as possible. I have thought of the bichromate form, with two zincs and three carbons, each 5in. by 2in., in each cell, and, say, six cells. Will anyone kindly give me their practical experience in this matter, and tell me what is the best exciting liquid and its proportions to use in such a battery, and if the one described above would meet my requirements? I may say that I have searched the ENGLISH MECHANIC through, but there are so many and varied ideas and opinions that I am absolutely confused, and therefore desire the opinion of someone who, from experience, is in a position to give practical advice, and such advice would, I am sure, be very welcome to others than—BEWILDERED.

[61399.]—**Leclanche Batteries.**—Will any of "ours" kindly say whether the bursting of the jar (inner cell) is injurious to the working of the above battery? I have several electric bells working with the above batteries, and am often troubled through the inaction or feebleness of the ringing, which is not remedied by adding fresh salammoniac to outer jar, &c. Should be much obliged for answer as to cause and remedy.—COLLIERY MANAGER.

[61400.]—**Electric Light.**—There is available within half a mile from our works about 1,500 tons of water daily, falling down an incline about 300 yards in length, giving a head of about 40ft. Will any of "ours" kindly suggest the best and most economical plan of utilising the above power for generating electricity for lighting purposes at our works, stating the necessary material and machinery, &c., required, and probable cost of same, and what would be the probable result in candle-power, and continued cost of maintenance?—COLLIERY MANAGER.

[61401.]—**Oval Chuck.**—I have just completed an oval chuck, which I made according to a sketch of one I saw in "E. M." a good while ago. I have tried to turn oval bradawl handles and handles for screw-drivers, but find it a very tough job to get them level and smooth without rings and marks of tool. I have also tried to turn flat oval pieces, such as small frames suitable for photos., &c.; but I find there is a curious twist in the work, which I cannot account for. I think keeping the tool on a certain level with the work may have something to do with the mischief. I should be glad if any of your obliging readers would give me a reliable hint as to what is wrong, and the remedy.—CHURCHILL.

[61402.]—**Electric Bath.**—Having an order to supply and fix complete an electric bath in private house, I should feel greatly obliged if some of your kind readers would assist me by giving full illustrated particulars, and best mode of fitting, and all appliances necessary to give full satisfaction.—ELECTRODE.

[61403.]—**Renovation of Violin.**—I have a violin been badly used. I am going to have it scraped and polished. Which will be most likely to improve it—French polish or linseed-oil polish?—A. C. CHAMBERS.

[61404.]—**Medallions.**—I have a number of medallions, cast by a friend many years ago, in what seems to be plaster or clay. These having been laid aside for a great many years have become very dirty, some of them a dark brown colour and others nearly black. Would anyone kindly oblige by tell me an effective way of restoring their colour? I have tried scrubbing in water with a brush; but the water seems to effect them, as they fizz and splutter, and look speckly after immersion.—P. A. S.

[61405.]—**Liquid Fuels.**—I wish a simple formula for calculating the theoretical evaporative power of petroleum and creosote oils from their constituents of carbon, hydrogen, &c., and also should be glad of an authoritative opinion as to whether petroleum or creosote gives the best results as liquid fuel?—LESS SMOKE.

[61406.]—**Glow Lamp.**—Would anyone kindly tell me how many pint bichromates are required to light a 5c.p. lamp for a couple of hours? How can I know which is the negative and which is the positive pole of a battery? How are bichromate batteries connected?—JUVENILE IGNORAMUS.

[61407.]—**Glass Spinning.**—In the old days I have seen this operation performed in the Polytechnic, and I still have in my possession some of the result. I have endeavoured to imitate what I saw done as far as my memory allows, but without success. Can any reader inform me (1) whether the wheel on which the glass is spun should revolve with a high velocity (as that which I have made is able to do), or slowly? (2) whether any particular sort of glass should be used? (3) to what sort of blowpipe flame should the glass be exposed? (4) whether the operation can be seen anywhere in London?—S. B. B.

[61408.]—**Violin Query.**—I have a valuable old violin, the tone of which has always been perfect up to a few weeks ago, when there commenced a buzzing kind of noise, similar to what would be produced by the strings being close to finger-board. I have tried all I can think of—altered the position of soundpost and bridge, and changed strings, &c., without effect. But what makes it more puzzling to me is that about a fortnight ago, after some alteration, the defect seemed to have disappeared; but was present again next day; and two days ago, after fixing the soundpost further back than usual, the tone was all that could be desired immediately on tuning up; but on trying it next day the nuisance had returned. It is a mystery to me, and I shall be glad if any reader of the "E. M.," who is able to tell me the cause, will oblige me by doing so.—A. W.

[61409.]—**Coating Springs with Copper.**—I want to coat some hardened springs with copper. Can any of "ours" help me with some suggestion? Coating must be of sufficient thickness to stand handling. I do not want to employ electricity if I can find any simpler process.—TONGE.

[61410.]—**Medicinal Action of Dynamos.**—A paper on "Insomnia," read before the British Homœopathic Society on Dec. 2nd, and reported in the monthly *Homœopathic Review* of January 1st, contains the following, and as it is a matter upon which many readers of the "E. M." have opportunities for making observations and taking notes, attention is hereby drawn to the subject:—"Dr. M. (a visitor), in reference to the action of magnetism, said that he had occasion to examine the dynamos which supplied the electric lighting to a large building. The engineer in charge of the dynamo stated that in the first week of his employment he noticed his health affected, and he felt very irritable. In the second week he found himself very sleepy, and since then he had experienced an increasing sense of this irritability. The engineer further said that all the employés experienced the same effects." Communications thereon will, no doubt, be esteemed in "Ours" generally, and especially by—THE DISPENSER AT THE FREE DISPENSARY, LYDNEY.

[61411.]—**Drilling.**—I have several hundred small irregular castings to drill. There are five holes in line,

some deeper than others. Wanted to know best method of drilling them. Each one must be counter-part of its fellow with ordinary vertical drilling machine. Twist drills will be best, I suppose.—DRILL.

[61412.]—**Twin Screw and Paddle Engines.**—To "NUN. DOR."—Many thanks for your kind attention to my query on above. Would you kindly furnish as much additional information as possible respecting the reason of the increased celerity of working a ship with twin screw or paddle engine? Also give as full a description as possible of the "disconnecting" engines—a speciality with some North of England makers. The reason my query appeared secondly was that, having failed to observe its first insertion, I thought it had become mislaid, and repeated it. I hope I am not troubling you too much.—TWIN SCREW.

[61413.]—**Irish Locos.**—Would any engineer kindly give a drawing of the new express engines on the G.S. and W.R., Ireland, and some account of the dimensions of same?—VIATOR.

[61414.]—**Electro-Motor.**—To MR. BOTTONE AND E. CONRY.—I want to make an electro-motor with H armature, 2in. by ½in. in height. Please tell me size and quantity of wire for armature and field magnets, and battery required, and will it drive sewing machine? Also, is there a book published on electro-motors?—A NEW SUBSCRIBER.

[61415.]—**Photographs by Pellet's Process.**—Can any reader kindly give me drawings and exact measurements whereby I can make a frame for the above, large enough to take paper 52in. by 31in.? Also the approximate cost?—PHOTOGRAPHER.

[61416.]—**Early Railroad History.**—I have been reading several books on railways, and they do not agree. Some say that tram roads were introduced 1602, others 1630, and one 1680. With regard to iron rails, were they used 1738 or 1767, as books do not agree upon this?—HISTORIAN.

[61417.]—**Midland Engines.**—I see the *Engineer* states that the new Midland 1738-1757 class have 250ft. more heating surface. Will any reader say if the cylinders are 18in. or 19in. diam., and if the boilers carry 160lb. of steam pressure?—ANTI-VAC.

[61418.]—**Great-Western Engines.** — Will any correspondent kindly say the size of the largest driving wheel on the Great-Western system? Are the 9ft. Bristol and Exeter engines reduced to 8ft., and also what class does No. 10 belong to, and has it an 8ft. 6in. wheel?—LOCO.

[61419.]—**Loco. Wheels.**—What is the largest driving wheel in use in England at the present day?—LOCO.

[61420.]—**Loco Firegrates.** — What is the usual size in square feet for the firegrate of a modern loco., and how much coal per hour per foot of grate can be burnt to give the best result or get the greatest heat from it? How many cubic feet of air are required to consume a pound of coal, and how much water will be turned into steam by 1lb. of coal?—LOCO.

[61421.]—**Case-Hardening.**—Could anyone inform me how to case-harden small set screws made of Bessemer steel? I have a portable forge.—W. E. GENT.

[61422.]—**To Mr. C. E. Stretton.**—Will Mr. Stretton, if he has drawings of Mr. Kirtley's 700 and Mr. Johnson's 1145 classes of engines, please give same in "E. M." at an early date?—ROVER.

[61423.]—**Strength of Materials.**—Will someone please give me the method of working questions, such as the following? A 10in. shaft has a 4in. hole run through it. What fraction of its weight is removed? To what extent is its strength in resisting torsion affected? What is the weight of a cubic inch of cast iron?—DARENTH.

[61424.]—**Model Steam Engine.**—Will some kind friend favour an amateur with the sizes for a model vertical steam engine with cylinders from about 1in. to 2in.? The sizes of crank throw, connecting-rods, length of piston, &c.?—ANGOSTURA.

[61425.]—**Oak Cantilever.** — What must be the breadth in inches of an oak cantilever, 6ft. long, 9in. deep, in order to carry a load of half a ton at its extremity? The actual stress is not to exceed quarter of the breaking stress. The breaking weight of an oak cantilever 6in. long, 1in. deep, 1in. broad, is 280lb.—DARENTH.

[61426.]—**Charcoal for Small Forge.**—Not being able to procure same in these parts, should be glad to know of some simple method of making a small quantity.—AMATEUR BLACKSMITH.

[61427.]—**Energy in Coal Gas.**—I have seen it stated that one cubic foot of South Metropolitan gas gives 622 thermal units of heat. This would mean, I suppose, 622lb. of water raised 1° Fahr., or one gallon raised 62·2° Fahr., and therefore 2·42cb.ft. of this gas should be required to raise one gallon of water from 62° Fahr. to 212° Fahr. As 1 unit = 772 foot-pounds, 1cb.ft. of this gas should give 622 × 772 = 480,184 foot-pounds = 214·3 foot-tons—that is, ten tons raised 21·43ft. Can any reader say how nearly these values have been realised in actual practice in water heaters and in gas engines, stating, if possible, the percentage efficiency obtained?—SEPHIROTH.

[61428.] — **Legal.** — A tenant, A., wished to leave the house and garden, which he rented half-yearly. The landlord permitted him to do so, on A.'s finding a suitable tenant, B. B. was found, and accepted by the landlord's agent in writing. After A. had let B. the house, A. mentioned for the first time a "small garden valuation," which proved, on examination, to consist of articles B. did not require. When the time came for A. to deliver the key, he refused to do so until B. took over the articles and paid the money. As B.'s own notice was nearly expired, and his goods packed for removal, he was forced to do so. (1) Could A. legally refuse the key on such grounds? (2) Could he let the premises to another person after B. was accepted by the landlord? (3) Could B. recover the money so obtained from him, or so much of it as was exorbitant? (4) Could B. recover any loss he incurred by reason of A. refusing him the key?—SEPHIROTH.

[61429.]—**Calculation of Chemical Analyses.** In an analysis of gas liquor published some years ago, the following particulars were given:—Specific gravity, 4½° Twaddell; free NH_3 0·9; total NH_3 1·16, equal to 5·5 per cent. Am_2SO_4, CO_2 1·33, SH_2 0·154. Equivalents of NH_3 to CO_2 and SH_2 1·45. I have been much puzzled as to how this last particular is obtained—viz., 1·45. Can Mr. Grey, or some other reader, tell me, and state a general rule for getting the number of equivalents of each constituent in any given analysis?—SEPHIROTH.

[61430.]—**Colouring Statues.**—I should be glad to know how best to go about colouring a small size "Venus Milo," made of plaster-of-Paris, in imitation of red terra-cotta. The proper pigments and proportions, and full particulars to make a successful imitation desired.—E. X. P.

[61431.]—**Dynamo.**—To MR. BOTTONE.—I wish to wind a 10c.p. Siemens dynamo for plating purposes, H armature. Would you kindly state what number and weight of wire I ought to wind on F.M.'s and armature.—R. H. H.

[61432.]—**Voyage to Australia.**—Am sending a delicate lad this month viâ Cape, and back by China route. Shall be grateful for any hints as to clothing and other requirements for the voyage.—P. C. M.

[61433.]—**Impurities in Gas.**—Please state simple test for impurities in coal gas, and what is the remedy (if any) when a company deliver gas not properly purified?—G.

[61434.]—**Snow Plough for Highways.**—Will some practical mechanic kindly give full particulars and drawing of the best form of snow plough for parish highways in the country? One that can be drawn by two horses and clear a width of about 12ft. in an average fall of from 6in. to 10in. will be desirable.—T. CHAPLIN.

[61435.]—**Storage Cell.**—To MR. CONRY.—What is the lightest form of secondary battery I could use to light a 500c.p. Swan lamp for two hours at one time, lamp to be specially made of low resistance? What would be the smallest number and weight of the cells? I have a charging current of 45 volts and 15 ampères. I should like it portable, if possible.—LIGHT.

[61436.]—**Petroleum Tank.**—What causes a 100gal. petroleum oil tank to smoke at a temperature of about 50 or 55 deg.? There is a yellow scum accumulates on the galvanised iron tanks. Would it be phosphorus? Can is not painted. Friends will greatly oblige, as it is of much importance to know.—T. WOOD.

[61437.]—**Influence Machine.**—I have two plates of vulcanite, 17in. in diam. and ¼in. thick, which I wish to make into an influence machine. Will the thickness be an objection to the construction of an effective machine?—IGNORAMUS.

[61438.]—**Measuring Cloth.**—I want a simple rule for finding the length of cloth on a roller, the circumference of which is 12in. When I have 100yds. of cloth on roller it measures 48in. circumference. How am I to find the number of yards for a larger or lesser circumference without taking off the cloth to measure? — FACTORY WORKER.

[61439.]—**Faulty Musical Box.**—I have a musical box, which, during playing, occasionally whistles. It is thoroughly cleaned and oiled, and appears free of action everywhere. Will any reader kindly inform me of probable cause?—BOX.

[61440.]—**Emery Wheel.**—I want to make a grinding and polishing machine to be driven by a 5ft. hand-wheel, and suitable for finishing and polishing rough forgings used in bicycles and sewing machines. Could any reader of the "E. M." give me any information respecting diam. and thickness of emery wheels suitable for taking off rough surface, and what speed they ought to be driven at? Also, what wheels are best for finishing, and if any kind of emery or polishing powder is used? Any other information would be exceedingly acceptable.—M. I. P.

[61441.]—**Notes on the Church Organ.**—To MR. G. A. AUDSLEY, F.R.I.B.A. — As one of the many admirers of Mr. Audsley for the masterly, comprehensive, and convincing manner in which he has dealt with the subject of chamber organ requisites, I trust he will pardon my putting a question respecting a quotation from Helmholtz, which appears at p. 402 of "Ours" of last week. It is some years now since I read Helmholtz's magnificent work on acoustics, and I have not at present the book by me for reference; but assuming that Mr. Audsley has quoted correctly, I am somewhat puzzled by the ninth and tenth upper partial tones being described as d‴ and e‴ respectively. Surely the ninth partial must lie somewhere between d‴ and d‴ flat, and the tenth partial a trifle sharper than d‴ sharp. Kindly put me right on this point.—C. R. O., Devon.

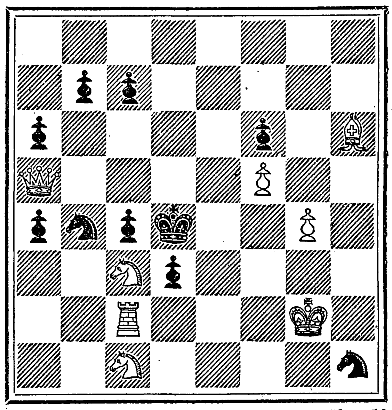
AT a recent meeting of the Chemical Society, a preliminary note was read on "The Electrolysis of Ammonic Sulphate," by Herbert McLeod, F.R.S. When a neutral solution of ammonic sulphate is electrolysed in a U-tube provided with platinum plates as electrodes, nearly pure oxygen is evolved at the positive pole and hydrogen at the negative. For one volume of gas from the positive pole, a quantity varying between 4·7 and 5·4 volumes is evolved from the negative pole. A small amount of ozone is produced. On mixing together the electrolysed liquid at the poles a strongly alkaline liquid is obtained, containing a considerable quantity of "active" oxygen. When the liquid is first neutralised with sulphuric acid, then treated with excess of baric chloride, and the baric sulphate filtered off, the liquid deposits baric sulphate on boiling, an indication of the presence of persulphuric acid in the solution. When sulphuric acid that has been electrolysed is exactly neutralised with baric hydrate, the precipitate filtered off and the liquid boiled, baric sulphate is precipitated; at the same time the liquid becomes acid and a further quantity of baric sulphate is thrown down on the addition of baric chloride.

CHESS.

ALL Communications for this department must be addressed to J. PIERCE, Langley House, Dorking.

PROBLEM MXXVI.—BY C. PLANCK.

Black.



White. [8 + 10

White to play and mate in three moves.

The receipt of solutions to the above will not be acknowledged before a fortnight. Solutions must be received before 28th Jan.

SOLUTION TO 1,024.

White.	*Black.*
1. Q-Kt 8.	1. Anything.
2. Q, R, B, or Kt mates, or P takes R, becoming Kt, mate.	

(Seven variations.)

In 1,025, the B Pawn at K R 7 should be a B Bishop.

NOTICES TO CORRESPONDENTS.

CORRECT solutions to 1,024, by J. J. Spence, W. J. Carpenter, H. Turner (variations should be given), V. S. Pochin, T. H. Billington, W. Hewson-Kilbee (see notice above to H. Turner), A. Bolus, Major, Link (but second solution wrong, as Kt-Q 4 discs. ch.), and Country Boy.

A BEGINNER.—If 1. $\frac{\text{R-Q Kt 2}}{\text{Q takes R}}$, 2. $\frac{\text{R-Q R 6}}{\text{K takes Kt}}$.

J. MACKENZIE.—If 1. R takes Q, how do you proceed if Black play Q Kt-Q 3? Respecting 1,023, see notice in last number.

F. KRASSER.—See notice above to Link.

T. H. BILLINGTON.—Thanks for your suggestion, which we intend to adopt.

GAMES received with thanks from H. Balson and C. J. Lambert; also *The Wanderer* for December.

J. MACKENZIE.—In 1,023, if 1. $\frac{\quad}{\text{Q takes Kt}}$, 2. P takes Q, becoming a Kt, and discovering (ch.) mate.

W. HEWSON-KILBEE.—We found afterwards that you were right respecting 1,023. The defect is easily remedied, but the second solution is quite as good as the author's.

USEFUL AND SCIENTIFIC NOTES.

THE needle industry of Redditch has been largely revolutionised during the last twenty years by the introduction of machinery, and the stupendous proportions which the trade has assumed—the present weekly make being not less than fifty millions—necessitates an increased employment of the most improved machinery. The latest move has been the introduction of a machine for the grooving of sewing-machine needles, which bids fair to entirely supersede the old stamping process. At the present time there are about 8,000 persons engaged at Redditch in the manufacture of needles alone.

Locomotives.—A rough average of dimensions and weights derived from the corresponding engines of those respective types as in use on the London and North-Western, the Midland, the Great Northern, the Great Western, the North-Eastern, the London and Brighton, the Caledonian and the Lancashire and Yorkshire Railways, presents the following figures, given by Mr. Ed. Woods, as fairly representative of modern practice:—Express passenger engines: Weight of engine in working order, say 42 tons; greatest weight on a single axle, 15 tons; area of fire-grate, 19 square feet: heating surface, 1,300 square feet; pressure of steam in boilers, 140lb. per square inch. Tractive power, assuming an average effective pressure of steam in the cylinders of 90lb., per square inch, 8,900lb.:—Merchandise or mineral engines not being tank engines: Weight in working order, 38¼ tons; greatest weight on an axle—N.B. axles coupled—14 tons; area of fire-grate, 18 square feet; heating surface, 1,300 square feet; pressure of steam in boiler, 140lb. per square inch; tractive power, assuming an average effective pressure of steam in the cylinders of 90lb., per square inch 12,690lb.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 332, *Strand, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, Jan. 12, and unacknowledged elsewhere :—

J. H. PRENTICE.—V. Buhot.—J. A. Maclean.—Prof. Thompson.—F. Hazeldine.—C. L. L.—Architectus.—J. B.—J. Brown, Belfast.—G. Edwinson.—Broscenius.—Cautery.—Electrical Student, No. 2.—Alex. Fraser.—One in a Fix.—D. Evans.—Young Beginner.—A. Baines.—J. C. Kelly.—M.I.C.E., Bath.—Milverton.

BELA BUCKEN. (When we refer correspondents to back numbers, we do not insert the query unless there is some special reason. We can form no idea of what particulars you require; but we are quite certain that all the particulars necessary to enable anyone to construct a Schanschieff cell have been given in our columns, in the pages to which you were referred. The special solution forming the subject of a patent was described on p. 78 of this volume.)—E. W. (The earth forms the return in submarine telegraphy: as a rule, it is the metallic sheath of the cable itself which forms the "earth-plate.")—H. YOUNG, JUN. (Most of the questions are against the rules. See Hints No. 4. The other questions have been answered recently. You should make a Wimshurst machine, and for that you will find full directions by the inventor in No. 1127, p. 192, this volume. Instructions for making the two-plate machine were given by Mr. Wimshurst in No. 1073, p. 142, Vol. XLII. If you must have the other, see No. 969.)—SEEKER. (You will find full information in our columns, by reading up the volumes from Vol. XXIII. (There is not a complete treatise giving the history of the telephone; but there is much information in Prof. S. P. Thompson's biographical sketch of Reis, published by E. and F. N. Spon, 125, Strand, W.C. For Prof. Hughes's experiments with the microphone, see No. 686, and the indices of Vol. XXVII. and subsequent volumes.)—JOHN LIVINGSTONE. (Answered several times in last volume. Some are made of glue 12, treacle 3 parts; others of gelatine (purified glue) itself; but all have the addition of a little tannic acid or of bichromate of potash to render them insoluble, and some for use with much undercut work contain also a little glycerine. Almost any oil will do, provided it is clean.)—DARENTH. (Encastrer is a French verb, meaning to fit into a groove or frame.)—WILKINSON AND DAVIS, Keokuk, Iowa. (We do not think they have any agent here. The address we gave will find them.)—WM. BOWN. (You will find in back volumes many preparations recommended; but it is absolutely necessary to know the character of the water before offering an opinion as to which is the best remedy. For instance, is the lime sulphate or carbonate, and is it impossible to take the greater portion out of the water before the latter is fed into the boiler. The simplest "composition," and perhaps the most effective, is common washing soda; but there should be frequent and regular blowing out.)—H. HALL. (There are obvious reasons why such a query would remain unanswered; but perhaps any of the locksmiths would give you the requisite information privately. In a simple form you will easily understand that locks might be so fitted with wards that each would require a key with special clefts; then a master key would be one of the same size, but without clefts at all, so as to pass round the wards in the lock case, and shoot the bolt.)—GREATLY BORED. (Answered recently. Line the wall with canvas stretched on battens.)—A. J. G. (We have not heard of it. Perhaps you mean the method described on p. 66, No. 445, in which the leaves are immersed in a solution of caustic soda. We believe the slower process is preferred by the professionals.)—J. K. (As to Woolwich Arsenal, you must apply there, to the superintendent of the factory you think you could be useful in; but we imagine they employ only those men who have been regularly apprenticed to their trades.)—TRANSFER. (Perhaps those you mean are like the so-called Swiss transfer pictures, and are varnished over.)—W. J. DIXON. (The matter is of too much personal importance for a query. Surely you would not accept advice except from a medical man who has had an opportunity of examining you. Teeth can be extracted painlessly by means of a local anæsthetic.)—H. W. POSGATE. (Heat it carefully in a flame until soft enough in all parts, and then bend round a former. Plug one end and be prepared to blow into the other should any sign of collapse be detected. It is work requiring much practice.)—JOE. (You can get a set of tools at almost any tool shop, and you will find full directions in back volumes. See Nos. 922, 935, 936.)—ENTERPRISE. (Only by application at Lloyds, or in the case of the Board of Trade, by examination when surveyors are advertised for. Full particulars of such examinations from the Civil Service Commission, Cannon-row, Westminster.)—C. W. TRANTER. (The Wimshurst machine has been described in our pages by its inventor. See p. 192, this volume, and the indices. A little book on it by Mr. T. Gray is published by Pewtress and Co., Little Queen-street, High Holborn.)—W. C. ROBERTS. (All Government reports can be obtained from the Queen's printers, East Harding-street, E.C. Such a report would, no doubt, be on sale at the Government publishers in Dublin.)—AN AMATEUR, Aberdeen. (You will find plenty of information about electric motors, lamps, and dynamos in back volumes, and lately scarcely a number has been issued without something about them.)—LAMP TRIMMER. (How can anyone say why you do not get a maximum light from your duplex lamps without examining them? Perhaps you expect too much. 2. The snow that falls in the gauge is melted and measured as rain. Roughly, 1in. of snow represents 1-12th of an inch of rain.)—VULCAN. (Mount cutting described many times. See Nos. 891, 892, 954. Usually they are cut by a knife guided by a former; the edges dressed with glair or gold size, and the gilding applied in the usual way.)—C. KEMP. (With a preparation of isinglass dissolved in acetic acid. The bottle containing it is immersed in warm water, and the letters are made warm. Hold in position until cool.)—PERCY. (Any book of games will explain. There is no special object in the game.)—M. N. (We do not suppose you will find a better negative varnish than you can make by dissolving picked shellac in pure methylated spirit. 2. Nothing better than starch for mounting prints.)—NEGATIVE. (The most transparent paper is probably that prepared by the patent process described on p. 475, No. 1114.)—WILLIAM TELL. (Prints can be purchased of any print-seller; the price varies with the value or assumed value. 2. The question was answered the other week. They are made up of several thicknesses of pine with grain reversed, and faced with pear, boxwood, or sycamore.)—T. R. S. (According to the patent law of the United States, "every patent granted for an invention which has been previously patented in a foreign country shall be so limited as to expire at the same time with the foreign patent.")—OLD POT. (Can be mended with solder, or brazed.)—J. TUN WELLS. (Vulcanite is made by heating a mixture of rubber and sulphur under pressure. Steam is generally used, as it gives both heat and pressure.)—J. W. D. (If you mean an electrical telephone, see p. 233, Vol. XXXVI.)—JANUARY. (You will find a variety of diagrams for connecting up telephones in back volumes. Perhaps one in No. 1006 will suit you. 2. The amount of light given depends on the size of wick and the quantity of oil consumed. The circular wick, with the button over it, as in the Doty, gives the best light for a given consumption of oil.)—T. WOOD. (Probably a seidlitz powder with the two packets mixed in one, or perhaps some Lamplough's pyretic saline. 2. The directions issued by the Metropolitan Board of Works for preventing lamp accidents contain all that is requisite.)—AMERICUS. (You will find methods of setting out tunes on barrels for organs in several back volumes. Try Nos. 330, 473, 490.)—A. C. (There are full directions with diagrams for making pedals and pedal action for organ in No. 594; but you should look through the back volumes for much information on the subject, which may probably give an idea for your special purpose.)—E. B. (Where water is soft, the boilers always get rusty. In No. 1104 a correspondent said he had been successful in cleaning the surface with sandstone and painting with two or three coats of boiled linseed oil.)—A TO F. (Yes, it can be had post free for 2½d. Your newsagent must be very lazy or neglectful, and we should recommend you to change him.)—G. EDWINSON. (Quite outside our sphere.)—CHAS. NORTH. (We really do not care to invite more details of G.N.R. fast runs, or those of other lines. They have appeared in back volumes *ad nauseam*, and we have good reason to know that the great majority of our readers, with ourselves, are tired of the repetition in which many correspondents on railway matters indulge.)

How to use Gas-Lime.—This substance should be freely exposed to the air for two or three months before applying to any soil on which is a growing crop, because, besides many sulphides, it contains a compound of sulphur and cyanogen that is very deadly to plants. In anticipation of a turnip crop, it may be applied to the fallow up till, say, February, which would allow sufficient time for oxidation to alter the poisonous qualities of the cyanogen. It is, perhaps, best to slightly harrow it into the stubbles after they have been ploughed, because in this case the ammonia—or a portion of it—resulting on the conversion of the cyanogen will be retained in the soil if there is in it lime, salt, kainit, or substances containing bases on which the ammonia can form as nitrates. This simple view of it may be borne in mind in making it into composts, for unless there are substances on which the ammonia can form, it will combine with carbonic acid and escape into the air. The compost should therefore contain a little superphosphate, salt, or kainit, or even a small portion of old lime. But in making a compost heap it must be kept well away from a growing fence or the roots of valuable trees, or it will kill them. I may add, that in my experience it is the most effective substance that is to be had for the destruction of fungoid and insect pests in the soils, and applied to the fallow as above, at the rate of about five tons per acre, there need be little fear of finger-and-toe.—("Farmer," in the *North British Agriculturist.*)

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

6s. 6d. for Six Months and 11s. for Twelve Months, Post Free to any part of the United Kingdom. For the United States, 13s., or 3 dol. 25c. gold; to France or Belgium, 13s., or 16f. 50c.; to India (via Brindisi), 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office Order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 4d. each to cover extra postage.

Messrs. JAMES W. QUEEN and Co., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes, they must be paid for at the rate of 4d. each copy, to cover extra postage.

Vols. IV., VII., XXVI., XXVIII., XXX., XXXII., XXXIII. XXXIV., XXXV., XXXVI., XXXVII., XXXVIII., XXXIX., XL., XLI., XLII., and XLIII., bound in cloth, 7s. each. Post free, 7s. 9d.

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in February and August, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d. each, through any bookseller or newsagent, or 2½d. each, post free from the office (except index numbers, which are 3d. each, or post free, 3½d.).

Indexes for Vols. I., VI., VII., VIII., and IX., 2d. each. Post free 2½d. each. Indexes to Vol. XL., and to subsequent vols., 3d. each, or post free, 3½d. Cases for binding, 1s. 6d. each.

CHARGES FOR ADVERTISING.

Sixteen words	0	6
For every succeeding Eight words	0	6

*** It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions and in cases where the amount sent exceeds One Shilling, the Publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement, and charged for.

Advertisements *must* reach the office by 1 p.m. on Wednesday, to insure insertion in the following Friday's number.

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a PINK Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

OUR EXCHANGE COLUMN.

The charge for Exchange Notices is 3d. for the first 24 words, and 3d. for every succeeding 8 words.

What offers for 52in. **Bicycle**, in good condition, with lamp, bell, spanner, &c., strong, and suitable for a beginner. Can be seen by appointment. Wanted good air-gun, and part cash. For value see Sale Col. advt.—C. E. K., Lady Cross, Gayton-road Harrow.

Medicines (Homœopathic), strong tinctures, powders, exchanged for Belladonna Seeds by the DISPENSER, at the Medico-Botanical Gardens and Free Dispensary Company Lydney.

Wanted, 7 or 8-horse nominal compound **Launch** ENGINE. Brotherhood 3-cylinder, 6in. by 7in., as part exchange.—S. S., 63, Palmerston-road, Southsea.

Medical Coil, complete with battery, very powerful and compact, in mahogany case, with draw for handles, &c., cost £5. Wanted, Lathe for small metal work.—R. LEVERSUCH, Stanmore, Middlesex.

Good Value Offered (cash or instruments) for all kinds of sound or repairable Scientific Appliances.—CAPLATZI, Science Depot, Chenies-street, near British Museum. Established 1862.

Organ, 8 stops, 312 pipes, pedals, bourdon, composition pedals, interior new, noble mahogany case. Take Harmonium or American Organ, and cash.—J. HOLT, Ormskirk.

Exchange magnificent 12-bore, double, modern, London made Breechloader, value 6 guineas, for Dog Cart. What offers?—C. E. HILLSDON, Woodman's-cottage, Sandgate, Kent.

Wanted, good **Box of Mathematical Instruments**, in exchange for Crown postage stamp album, containing 386 stamps, first-class condition.—FOOTE, 15, Fraser-street, Bedminster, Bristol.

6 perfect vols. of "**English Mechanic**," unbound. What offers in exchange for one or all?—J. BRYAN, Photo., Bridlington, Yorks.

"**Muspratt's Chemistry**," 2 vols., 64 shilling parts, illustrated, unbound. What offers in exchange?—J. BRYAN, Photo., Bridlington, Yorks.

Medical Coil.—Large handsome ten-guinea coil, 12 powers, good as new, in polished mahogany case.

Cornet.—Besson's best eleven-guinea plated cornet, perfect, good as new, accessories and case.

Saloon Pistol, in thorough order. Wanted, large opera-glasses by known maker, good microscope, modern tricycle, or offers.—BARNETT, 40, Poland-street, London, W.

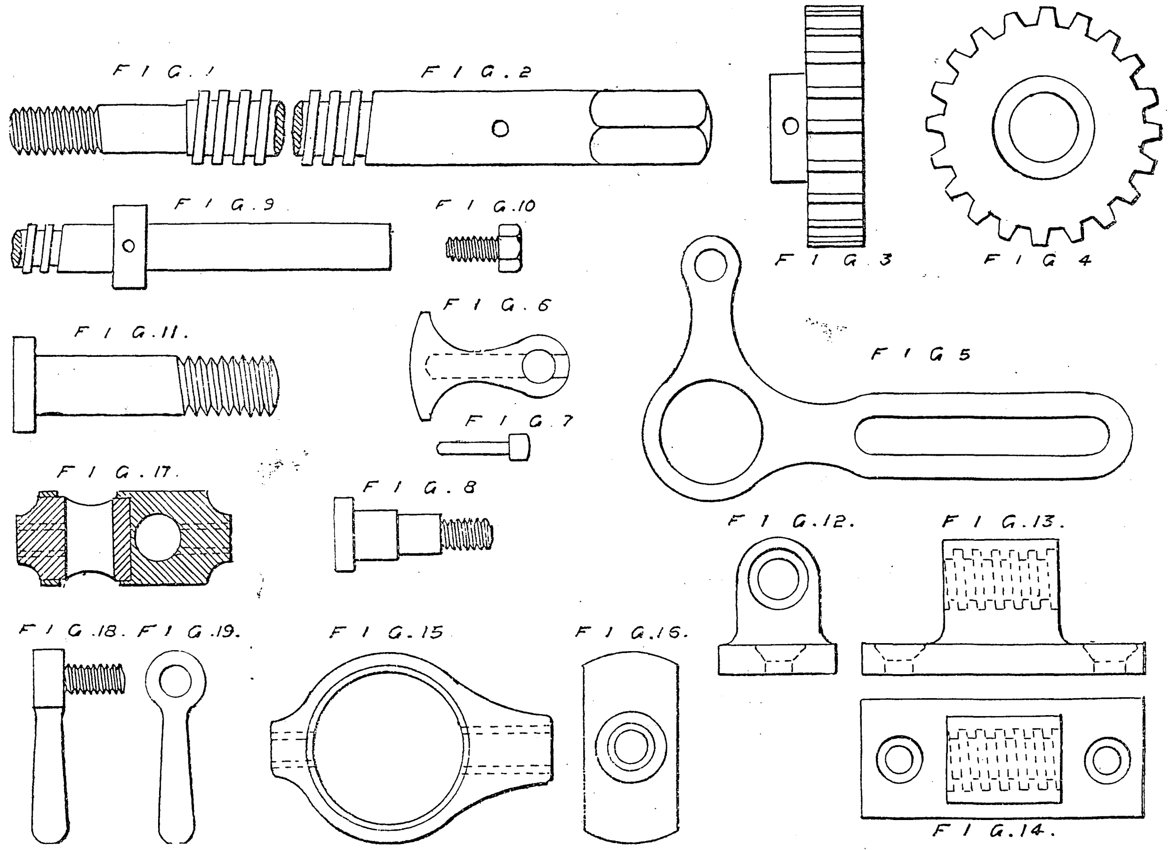
HAND-PLANING MACHINE CONSTRUCTION.—III.

CONTINUING the description from p. 316: the four square threaded screws for the several slides may be next proceeded with. The largest of these screws is the one for the main cross slide seen in the front view on page 273. It is ¾in. diam. and 26in. long over all. The square threaded part being about 20½in. long, either a right or left-handed thread will serve equally well. Mild steel or good iron is the material best suited for screws of this kind. A rod fully ¾in. diam. carefully straightened and metal has been cut from the groove. Generally the time taken in making a rough but effective solid die will be saved over and over through not having to fit, by the usual method, with a single tooth-cutter on the screw-cutting lathe. The subject of screw-cutting does not, however, claim more than a brief mention under the heading of these papers; moreover, there are cheap treatises devoted entirely to the subject.

The small end of the screw has a ½in. Whitworth thread upon it about 1in. long. This is to take the pair of lock-nuts, shown in the drawing of the complete machine. The large end is squared to take the handle used for turning the screw when moving the saddle across the machine. The toothed wheel, which is moved by the self-acting feed, is fixed on this screw just beyond the square by a round steel pin put through diametrically. This pin may be 3-16in. diameter. It is a mistaken idea with many people that a hole such as this causes the which the pin is put, is turned to 1⅛in. diam., and takes the arm of the self-acting feed shown at Fig. 5, and to be referred to later on. The wheel may be turned when in its place on the screw, and if this is made just a trifle tapering, and the wheel made a tight fit, so that it will only drive on when made hot, they will fit as firmly as though solid. After the wheel has been once secured on its place, it need never be removed.

The screw for the vertical tool slide is ½in. diam. left handed, and its plain end is shown at Fig. 9. The collar shown secured by a transverse pin is made of the same metal as the screw, and should be made hot before driving on. A steel pin ⅛in. diam. will suit very well. This collar confines the end motion of the screw in both directions, the lower side bearing against the casting, and the upper side against a plate fixed to the casting by two bolts, as shown in the illustrations on pp. 273 and 274. The screwed part is simply a plain thread, and



centred will be large enough. Take one fine cut all along, using the back steady, and reducing the rough rod to exact diameter Next turn down a length of about 1½in. at one end to the exact diameter of the bottom of the square thread: this will be 9-16in. bare for the usual square thread ¾in. diameter. The rule being—the pitch of square threads is double that of V-threads, and the depth is equal to 19-20th of the pitch. Whitworth's ¾in. V-thread has ten threads per inch, so the square should have five, and the depth of thread on both sides the screw will equal 19-20th of 1-5in., so that 9-16in. bare diameter for the core of the screw is as near as can be without going into dimensions too minute to caliper. This 9-16in. part will serve to show the depth for advancing the tool when cutting the threads. Square threaded screws necessitate more care in cutting than do V threads, and the fact that the pitch of this particular thread is a prime so far as ½in. and ¼in. pitch guide-screws are concerned, will cause additional trouble to an inexperinced screw-cutter. It is certainly a good plan to tap a piece of bar steel and make a solid die with which to regulate the size of the thread after the screw to be very weak at that part. The strength of the threaded part of the screw is much less.

Reference to the accompanying illustrations show several parts of the planing machine drawn to a large scale, and measurements may be taken from them. The diameter of the toothed wheel (Figs. 3 and 4) is 2½in., and by measuring the size (it is reduced in the engraving) a scale can be made for measuring other objects shown on the block.

Fig. 1 shows the small end of the cross-slide screw just spoken of. The extreme end has a ½in. thread to take the lock nuts, and for a distance of about 2in. the diameter is ½in., to fit the hole in the casting. Fig. 2 shows the large end of the screw. The square has rounded shoulders, instead of having them filed into a sharp angle, which latter plan has no recommendations. The hole for the transverse pin is shown.

Fig. 3 is an edge view of the wheel to be pinned on the screw; the side of the wheel is shown at Fig. 4. It has 20 teeth, and these may be of the usual shape, though the form shown may be used if the wheel is cut specially. The boss of the wheel, through the end is left perfectly free. The hand-wheel is fitted on the plain end slightly tapering, and has a key to prevent its turning without the screw. A ¼in. bolt, Fig. 10, tapped into the end of the screw, fixes the hand-wheel.

The two vertical elevating screws for the cross slides are made from plain rods of ⅝in. metal. One is right-handed, the other is left. The mitre wheels on their top ends serve as collars, and are secured by cross pins. It is most essential that these two screws be cut precisely alike in pitch, or the cross-slide will not travel up and down level. The pin holes for the mitre wheels should not be drilled till the screws are put in their places, and are adjusted to nearly a uniform height. The position of the pin holes may be marked through the holes drilled in the bosses of the mitre wheels. The nuts for these screws, which are fixed on the back at the ends of the cross-slide, must be made before the mitre wheels are fixed. Three views of one of these nuts are shown in Figs. 12, 13, and 14, which are respectively end, side, and top views. These nuts are best made of cast-iron; but brass or gun-metal is often used in its place. The hole for

the screw is drilled and tapped, also the two holes for countersunk screws which fix these nuts. The base of the nut is then surfaced to bring the screw in line with the hole in the standard. This process need not be a very long one. One screw hole is then marked, drilled, and tapped, and the nut fixed by the one screw. The position of the square threaded screw is then carefully verified before drilling the hole for the second holding screw. The cross slide must be carefully leveled and fixed securely against the standards before the nuts can be fitted.

The bolts used to fix the cross slide are ⅝in. diameter, and one is shown at Fig. 11. The whole bolt is shown round, head and all. A small pin may be put through both head and casting to prevent the bolt turning when the nut is screwed up, or the shank of the bolt may be squared just below the head, and fit a square hole in the casting. The former plan is, perhaps, preferable. The thickness of the cross-slide casting at the part where these bolt-heads go is not sufficient to allow a thick head, but the dimensions shown give ample strength. Hexagon nuts and good washers are wanted to complete these bolts.

The self-acting cross-feed may next be taken in hand. The piece shown in Fig. 5 is made of the shape shown, and is ⅜in. thick, though ¼in. would amply suffice. A piece of bar iron can soon be worked out to shape if the precise form is carefully marked, and a series of holes drilled all round. The large hole is 1⅛in. diam., and fits on the boss of the wheel shown at Figs. 3 and 4. The hole in the vertical arm takes a ⅝in. stud, on which the pawl works. The slot, 2¾in. long, is to take the bolt (Fig. 8), which forms the hinged fulcrum of the long, vertical rod of the feed motion. This bolt, Fig. 8, has a round head and a parallel shank, ½in. in diameter and ½in. long, to take the eye of the vertical rod; the remainder of the ½in. part is flattened on two opposite sides to allow it to pass in the slot. A 5-16in. thread is cut upon the remainer to take the nut which secures the bolt at any desired position. This nut is much best in a form similar to that shown at Fig. 19, that it may be tightened by the fingers alone. These "permanent tommys" are a great convenience when nuts require to be altered often. The time and trouble wasted in looking for wrenches, &c., would be well spent in fitting such nuts as these.

The pawl itself is designed to be self-acting in both directions. The shape is shown at Fig. 6. A ¼in. hole is drilled down the centre of the pawl from the end where the hole is, as shown by the dotted lines. The hole takes the plunger shown at Fig. 7. An open spiral spring is made to go freely inside the hole and around the tail of the plunger. The effect of this spring is to keep the plunger pressed outwards. The stud fixed in the vertical arm of Fig. 5 has three flat places filed upon it, about equidistant, one being at top. By pressing the plunger in, the pawl may be placed on its stud. If the pawl is now placed vertically the plunger will bear upon one of the flats of the stud, and if moved through a small arc either way will resume its vertical position through the action of the spiral spring. Similarly, the spring will act when the pawl is turned over sufficiently for the plunger to bear on either of the other two flats. Thus the pawl has a spring that may be used to keep it entirely out of gear, or to make it engage in the wheel teeth either way round.

Fig. 15 shows side view, and Fig. 16 an end view, of the wrought-iron strap which fixes on the cannon that rides upon the main spindle; this strap is clamped where required by the screw shown at Fig. 18. The dotted lines show where this is screwed, also where a ½in. bar is screwed; this bar forms the horizontal rod of the self-acting feed. The method of connecting these two rods of the self-acting feed is shown by Fig. 17; this consists of two distinct pieces, one fitting inside the other. Each piece is drilled to fit one of the rods, and has a screw like Fig. 18 to fix it. The outer piece in which the other is fitted has a large segmental slot to allow free motion to the rod. This connecting piece is capable of being shifted along each rod, and so the length of either or both may be altered without trouble. The sectional drawing will probably suffice to explain the construction of this joint coupling.

The horizontal rod, which forms the shaft carrying mitre wheels which turn the vertical screws, is 21in. long and ¾in. diam. One end is squared to take the same handle that is used for the cross-slide screw, and which is shown in position on page 273. The mitre wheels are fixed on the rod by pins put through their bosses. The pairs of mitre wheels require to be fitted so as to gear together properly. The teeth and the spaces between them must be smoothed if cast wheels are used. Then the depth of the gearing is regulated by turning metal from the back of the boss. This should be done before the wheels are finally pinned in their respective positions.

The handle which fits on the main spindle is made by screwing four rods of 1⅛ iron into the cross piece shown on p. 274. This cross is a casting, and it must be carefully centred so that each arm will stand out at right angles to its two neighbours. Also all the arms must be in flat. The main spindle itself does not require much labour spent upon it. The rod is turned true and the key ways sunk in it. The pinion used to drive the rack has shrouds on both sides, so these confine the end motion of the main spindle.

In the next article the slide which is attached to the cross slide, and its belongings, will be taken in hand, and the construction concluded.

DURNFORD'S IMPROVEMENTS IN CAMERAS.

THE improvements in photographic cameras patented by Major C. D. Durnford, of the Ordnance Store Department, Edinburgh, consist in making the base of the camera in two parts, hinged together, on the edge of one of which he erects the front of the camera. The front part of the base is of sufficient size to enable the hinder part to be turned up to inclose the back and other parts of the camera when desired, and a rod is fitted which may slide in one or more sockets, and enter a bracket on the front part or edge of the base to make the whole base very rigid; and, to assist in producing this effect, the end of the rod, and the aperture in the bracket into which the same enters, are preferably bevelled, whereby the rod is wedged in position. To the rear of the base on each side are fitted extension pieces which are so hinged as to be capable of folding in alongside the rear edge of the base, and of being opened out in continuation of the lines of the sides of the base in all positions, being on the same plane therewith, and on these two extension pieces may be the usual racks for the extensions of the camera. When these two pieces are closed alongside the rear edge of the base, the same may be held in position by a T piece on the end of the sliding-rod or otherwise, and when these two pieces are opened out the same may be held in position by blocks or chocks on the bottom of the back of the camera, or otherwise. The back of the camera is made, as is usual, of a frame divided into two complete frames or parts, which are extensible; but the two parts are not connected together by the ordinary transverse bar and other appliances, but by two L-shaped levers, one on each side. One end of each lever is pivoted on a bracket projecting from one part of the back, while the other end is jointed in the proper position to the other part of the back, and a tail-piece may be fitted on the rear side or elsewhere of the lever, which can work in a socket, and can act as a stiffener, and, if required, as a stop. A sliding stop also is preferably fitted to clamp the lever when the two parts of the back have been duly separated, or are in other desired positions in respect of each other, and the parts of the stop and lever so in conjunction are preferably bevelled, whereby the stop and the lever are wedged in position. On the top of the back may be fitted a suitable slotted bracket projecting from one part of the back, in which slot travels a pin fixed in the other part of the back, and a sliding stop can also be fitted to clamp this bracket on. The bellows of the camera is formed in the usual manner, but to render unnecessary the usual size and depth of the back frame of the camera required by reason of the very deep folds of the bellows, all the rear or back part of the bellows is formed with extremely shallow folds for such a distance as may be deemed necessary, and these extremely shallow folds may be either very gradually or suddenly increased in depth, with the object of not intercepting the rays of light from the lens, thus permitting the use of a smaller back than is usual. The dark slide may be fitted to, and used with, the back of the camera in any usual manner, or may conveniently be supported in position by an extension of the bottom of the back, being retained thereon by studs and sockets, while the upper edge of the slide could be held by a catch or otherwise, and the sensitive plates can be held in the slide in any usual or convenient manner. The camera can be hinged on one edge of the top of table of the tripod or other support; or, still more conveniently, the camera can be secured as usual to this top or table, which top or table can be hinged to the tripod or support at and on one side, and in either case the camera could be maintained in position by a hinged stay passing through a socket on the opposite side of the top, and clamped by a screw.

INCREASING THE ILLUMINATING POWER OF GAS.

OF the various methods of increasing the illuminating power of gas at the point of consumption, two only seem to have achieved any degree of popularity—viz., the method of carburetting the gas as it nears the burner, and that of heating the air, and sometimes the gas too. Of the former the albo-carbon light is a well known and successful device; of the latter, the Wenham and the Bower "regenerative" burners are coming into use. Of the so-called incandescent methods, in which the gas is made to raise some substance to a dazzling whiteness, on the principle of the well-known limelight, little has been heard since the exhibition at the Crystal Palace, which we described in No. 930. Lewis's system is a sort of Herapath blowpipe, with a cap of platinum gauze, while Clamond's consists in the use of a little basket or cone, made of threads of magnesia, supported by platinum netting. The latter seemed at the time to give the most promising results, and it is not surprising that the lead of Clamond has been followed by other inventors. Not long ago it was stated that Dr. Auer, of Vienna, had succeeded in discovering a material which could be rendered incandescent on an ordinary Bunsen burner, and which would last for a reasonable time without requiring replacement. Dr. Auer caps the Bunsen burner with a cowl of specially-prepared cotton or woollen material about 2½in. high, and of a diameter suited to that of the burner. This cowl is supported by a platinum wire or ring held by iron rods, but any arrangement which will keep the cowl up will answer. The preparation of the cowl has not been fully described, but it is stated that a solution of zirconia and nitrate or acetate of lanthane or of yttrium is used for impregnating the woollen or cotton material; this material is then carbonised and leaves a kind of network which seems more favourable to the production of the light than the solid cylinders of zirconia tried in 1868 by Tessié in oxyhydrogen burners. The cost of manufacture of each cowl is about a farthing, and its durability is said to be 1,000 hours, at the end of which time it has become so incrusted as to diminish its illuminating power. Another method of increasing the lighting power of gas has been recently patented in this country by Mr. J. Mactear, of Victoria Mansions, S.W., who employs strontia, baryta, and thoria separately, or in combination with zirconia. He prepares a wick as a vehicle for supporting the incandescent material,

making the same of cotton fibre or of other suitable fibrous material and of any desired form. He prefers to wind the fibrous material around a thin platinum wire, which is subsequently bent into a spiral, helical, or grid-like form for suspension in or over the gas flame (preferably in a glass chimney to avoid cross air currents), as such a construction and form of wick has several advantages and affords a good support to the earthy matter after the fibre has been burned away, and renders the same capable of continued use for a considerable time. To prepare the wick for use, it may be saturated with a solution of hydrate (or other suitable compound) of strontia, and then dried; this on ignition leaves oxide of strontium. Or the wick may be coated after saturation with the strontia solution, and after being dried, or before such saturation, with hydrate of zirconium, which on ignition, leaves a film of oxide of zirconium or a zirconiate of strontia—a compound which is intensely incandescent when applied and used in the manner referred to. The hydrate of zirconium may be prepared from a soluble salt of the earth in the usual manner by precipitating it with an alkali—e.g., ammonia. Or to obtain the coating of zirconiate a sulphate of that earth or such of its organic salts as will leave on calcination the oxide of the metal zirconium. Baryta may also be similarly used as the incandescent material to be applied to the fibrous wick alone, or in combination with the strontia, or in combination with the strontia and zirconia. Or the wick may be coated with oxide of thorium alone, or with this in combination with oxide of zirconium or in combination with the strontia or baryta. In the use of such improved means the organic matter is destroyed upon ignition by the gas flame, but the earthy matter incorporated in the wick retains the form and disposition of the fibre which has been saturated or impregnated with it, and becomes highly incandescent, causing the luminosity of the gas flame to be very considerably increased.

THE HAMMER-BLOW IN LOCOMOTIVES.*

AN ordinary locomotive, when balanced for the horizontal action of the moving parts by means of counter-weights disposed within the rim of the driving wheel, cannot possibly be balanced in a vertical direction, excepting so far as the moving-gear has a vertical component of motion. Thus, the coupled-wheel of an ordinary four-coupled engine may be counter-weighted to balance the half-weight of the coupling-rod, for this revolves, in a sense, wholly about its crank-pin; but the driver, which is counter-weighted for the piston, cross-head, &c., is evidently out of balance vertically, owing to the fact that the pistons and all parts having a rectilinear motion only have no vertical component of motion, and so do not counteract the vertical action of the balance-weight in the rim. It is thus easily seen that the action of these parts would be best balanced by an equal and opposite force generated by similar moving parts. Theory and experiment alike show that a pair of engines working on to the same crank-pin with their cylinder-axes inclined at right angles to each other are arranged most advantageously. It is difficult to see how such an arrangement could be applied to a locomotive, and even if applied, there would be set up so many other disturbing actions, due to inclined cylinders, as to more than neutralise any benefit obtained. It is, indeed, difficult at first sight to see in what way the vertically-unbalanced force in the wheel-rim can be eliminated in a practical manner.

Dismissing the first suggestion of inclined cylinders at right angles, as unsuited to the question of locomotive balancing, let us proceed to inquire whether the ordinary engine can be made to exert an even pressure on the rails at every period of the wheel revolution. The so-called "hammer-blow" in locomotives is the irregularity of the pressure exerted between the wheel and rail, which arises from the vertically-unbalanced action of the counter-weights placed in the wheel to neutralise the horizontal action of the piston and other moving parts. This vertical action of the balance-weights, as stated above, is not counteracted by any corresponding action in the moving parts, for of these the connecting-rod alone has any vertical movement due to the rotation of that end which is attached to the crank-pin. The big end, then, directly, and the remainder of the rod to a lesser degree, has some influence in a vertical direction; but there still remains a large unbalanced action corresponding with the weights of piston, rod, and cross-head, and part of the connecting-rod. Hence, when the balance-weight is at its nearest position to the rail, the vertical action adds to the pressure on the rail, whilst when at the opposite, or upper side of the wheel, a relief of pressure occurs, and it is this alternate addition and relief which constitutes the supposed hammer-blow. At high speeds, this action certainly partakes of the nature of a blow, but may be represented by a wave-line diagram, where the mean weight on a wheel is represented by the ordinates between two parallel lines (say ten tons). The alternate variation of pressure is shown by a curved line, the space from crest to crest of wave being one circumference of a driving-wheel, or 22ft. in the case of a 7ft. wheel.

In order to fix the mind, let us assume the case of a 7ft. diameter single engine, with an unbalanced vertical action, resulting from 43lb. of a counter-weight acting at a radius of 32in., this weight being the excess left unbalanced by the vertical action of the connecting-rod, the total balance-weight, perhaps, being 86lb. The centrifugal force due to 43lb. at 60 miles an hour, may be found by the well-known formula, $F = \cdot 00034\ w r N^2$, when N, in this case, is 240. Then $F = 2{,}240$lb. fully, say one ton, which acts alternately upwards and downwards, with a difference of two tons.

Now, an investigation into the deflection due to one ton load upon a spring 24in. span, composed of twelve plates 5in. by $\frac{3}{8}$in., and a top plate 5in. by $\frac{1}{2}$in., will show such deflection to be about $\frac{1}{16}$in. The downward action of the balance is resisted by the rail, and cannot affect the steadiness of the engine. The upward action is resisted by the weight of the engine, acting through the springs. It must serve, then, to support the weight of the engine, and by so doing it relieves the weight upon the rail; but as it now exceeds the weight of the engine, it cannot affect the steadiness in any way. The net result is simply a constantly-varying pressure on the rail on either side of the mean.

We have just seen that one ton represents a spring deflection of $\frac{1}{16}$in. It thus appears that an arrangement whereby the spring could be caused to vibrate one-sixteenth on each side of its mean deflection would serve to equalise the rail pressure at the speed of 60 miles per hour. This spring action might be brought about by placing the wheel upon the axle eccentrically to the amount of $\frac{1}{16}$in., the eccentricity being so arranged that at the counter-weight side of the wheel the radius from the axle centre to the wheel tread would be 3ft. $5\frac{15}{16}$in., whilst on the side opposite the radius is 3ft. $6\frac{1}{16}$in. Then as the wheel revolved, or rolled along the rail surface, the axle centre would be raised and lowered through $\frac{1}{8}$in., and with it, of course, the axle-box and spring-pin, so causing a constant action of $\frac{1}{8}$in., representing the alternate addition and subtraction of one ton of load. This, of course, rests on the assumption that the engine remains fixed in a vertical direction, and does not partake of the action of the springs. The practical action, however, would not altogether conform to the assumption, and there would be to some extent a transference of the "hammer-blow" action to the other wheels of the machine, though to a very reduced amount, and also, to some extent, an absorption of the spring action by the inertia of the general mass of the locomotive. It has been stated above that the excess of action on the rail cannot affect steadiness of running.

The relief action, however, of one ton, when in excess of the weight of the wheel and half-axle, &c., with centrally-fixed wheel, is resisted by the spring. A little thought will show that this can have no action in deflecting the spring, its action being merely to support the weight of the engine, relieving the rail-load to that amount. With an eccentrically-fixed wheel, however, the speed at which the centrifugal action was calculated would require to be constant. It may, however, be taken for granted that at low speeds, such as four or five miles per hour and upwards, the irregularity of action due to the radius difference of one-eighth would not be more severe than the present pressure variation existing in a normal engine. In the example of this paper, with 7ft. wheels the "blow" occurs every quarter second in each wheel, at sixty miles velocity. The two wheels together give blows following each other in one-sixteenth and three-sixteenths of a second respectively, the cranks, however, being at right-angle. With 6ft. wheels, the action is more severe and oftener repeated (F varying with r and N^2). Here we see one advantage attendant on the use of large wheels which may perhaps explain why in America the question of the hammer-blow has received far greater consideration than in England, where wheels of 7ft. and 8ft. are employed to run at speeds which in America are run with wheels of 5ft. and 5ft. 6in. Hence the hammer-blow is at least of double the intensity in America, compared with England, and varies inversely as the square of the wheel diameter.

Assuming our reasoning to be correct in principle, it is clear that for every speed there is a certain eccentricity which will render nugatory the present unbalanced counter-weight action. It by no means uncommon to find the eccentrics of steam-engines made compound, the main eccentric driving the valve being seated upon an inner and smaller eccentric on the shaft. By this device, the throw of the combination may be varied between limits by any desired amount, depending upon the angular displacement of the eccentrics relative to each other.

The application of this principle to the axle-seat of a locomotive wheel would, if it could be safely and practically effected, supply a means of giving to such driving-wheel any desired eccentricity between nil and a maximum of, say, the above calculated $\frac{1}{8}$in. A suitably designed governor, revolving at a speed proportionate to the forward velocity of the engine, could be so arranged as to vary the eccentricity to suit the speed, exactly as in the case of the steam-engine.

The writer, however, does not propose this as a practical solution of the question, so much as an indication of the principles involved. It does, however, appear that a certain speed might be calculated for, and a fixed eccentricity given to suit the speed at which the engine will run. So arranged, an engine would run its calculated 30, 40, 60, or 70 miles per hour with perfectly even rail pressure, and at no speed would this vary so much as in a normal engine.

Fast express engines would be best ex-centred at, say, a mean speed of 60, local trains for 40 miles, whilst freight engines would count for, say, 20. We have seen that in a large wheel there is a total action of two tons; this seems severe, but it does not appear probable that such action can be very dangerous to bridge structures. The real action of the hammer-blow is gradually imposed; excess and deficiency of rail-pressure and the mean culminations of the two wheels may be taken as the true vibratory cause. Should these culminations synchronise at the train speed with the period of oscillation of the bridge, the effect might be serious, especially if the culminations also at the same time coincided with floor-beams. Any want of coincidence between these three might entirely nullify vibration by their mutual interferences. Such a concomitancy of vibration, panel length, and culminations as above described, is not likely to occur, and in considering the question of bridge vibration, it would appear that if anything be done, it should be in the direction of so arranging panel lengths as not to correspond, at average speeds of train, with the period of vibration of the bridge, or with wheel circumferences—this latter possibly the better safeguard of the two.

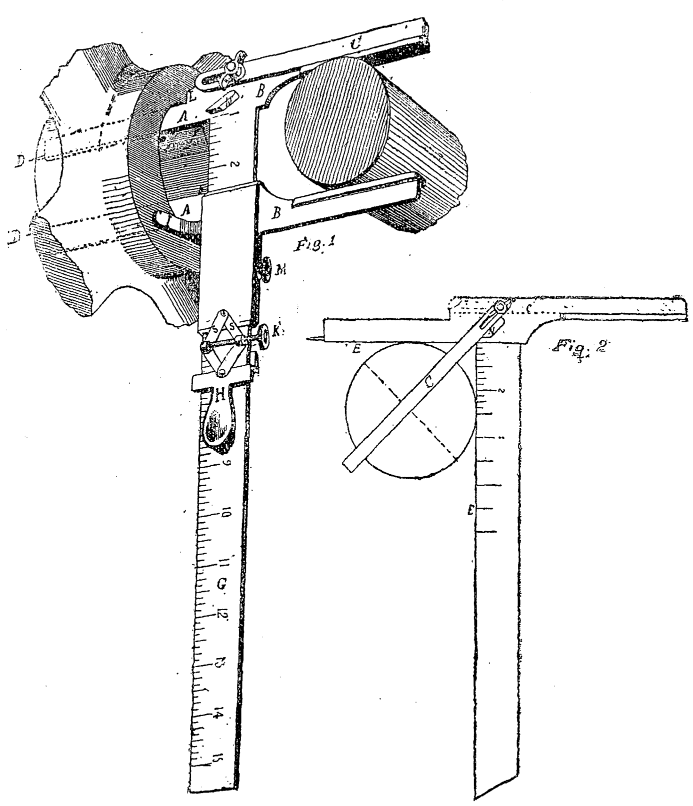
In conclusion, the writer would state that there appears every reason to believe that the vertically unbalanced action of locomotives is very severe. The writer's house is only 40 yards from the centre of a double-track railroad, on which some trains pass daily at a speed of 60 miles, or upwards.

The vibration set up apparently coincides with the wheel revolutions, and is very severe, and of a vertical nature in the ground; but great differences are observable in different engines. Heavy four-coupled engines set up greater vibrations than single engines. The four-coupled wheels are from 5ft. 6in. to 6ft. 6in. diameter. The single engines have 7ft. wheels, and also inclined cylinders. Now, whatever may be the faults of inclined cylinders, it is easy to see that the vertical action of the steam against the cylinder-covers and through the connecting-rod, upon the rail, will serve to counteract the "hammer-blow," which must also be less severe than in the smaller wheels. These appear to be the chief reasons why the vibratory actions of the small wheels are greater, apart from their greater frequency.

* From a paper by W. H. BOOTH, in *Journal* of the Franklin Institute.

A COMBINATION TOOL FOR MACHINISTS.

THE machinist's tool herewith illustrated, the invention of Mr. John C. Eckert, of Dayton, Ohio, is a combination of seven distinct tools, but, unlike most combined tools, it is so constructed that in the use of any one it does not conflict with the others. Fig. 1 shows the tool complete. It consists of an internal and external caliper; a centre square attachment C (an indispensable tool which is expensive individually, but costing only a trifle in this connection); a pair of compasses or dividers, D D; a square, E E; a gauge, F F, and rule, G. The small arms A A are inserted in the bore of a pulley until coming in contact with cross-bar I on movable arm, and corresponding shoulder L, when the movable arm is adjusted to the caliper of the bore and secured by set-screw M. The large or shaft arms B B are represented as embracing a section of corresponding shafting, by which it will be seen that it is only necessary to caliper one or the other to obtain the positive gauge of both at one operation, and at the same time read the exact dimensions on graduated beam



thus insuring accuracy. Fig. 2 illustrates the centre square attachment with movable arms removed, and with the slotted bar G thrown into position at an angle of 45 degrees for making centre lines on a shaft, and which bar is securely held in that position by the thumb screw J and lug N, and when not in use is thrown at rest as at C, Fig. 1, and entirely out of the way. The bar C has at pivot end a longitudinal slot extending about one-fourth its length, which permits of lengthening or shortening to that extent. An improved adjuster connected with this tool has a central bearing on sleeve of movable arms, thus avoiding any lateral friction on sleeve or side of beam, and preventing any undue wear on the most essential and delicate parts. The clamp H is held by the thumb, thus dispensing with an extra set-screw, the sleeve is finely adjusted by screw K up or down, and the operation is greatly facilitated. The adjuster can be instantly removed from the beam if desired, as the plates S S are simply hooked on the sleeve, and by slipping it off the beam, it may be unhooked. —*American Machinist*.

ORTHOCHROMATIC PHOTOGRAPHY.*

ORTHOCHROMATIC photography, although not new, is at the present time receiving a large amount of attention both by dry-plate makers and photographers. It is a curious fact that a discovery to render the yellows lighter than the blues was not taken up with more zeal at the time of its discovery, and that it should have laid semi-dormant for some years until a commercial firm takes to supplying the public, which starts it into life again. I am referring only to England, as on the Continent they have employed it for some years; but we English are always somewhat behindhand in taking up a new discovery.

I am not going to discuss who is the legitimate claimant of producing orthochromatic effect in photography; but it is my intention this evening to give you the results of my experiments as far as I have gone (there is nothing original in the chemical I employ, it being erythrosin, and that was discovered years back), and to place in your hands a really good orthochromatic formula, but with one drawback—they will not keep many days.

The formulæ which have been published, compounded with eosine and ammonia, into which dry plates are to be dipped, have in my hands proved useless, and I believe others have found the same. One of my experiments shows me that chloride of silver, dissolved in ammonia with eosine and used as a bath, gives orthochromatic effect, and I should imagine that if a plate is made containing chloride of silver, and then bathed in a solution of ammonia and eosine, it ought to answer: probably this may account for the failures of those using the ammonia eosine bath with ordinary plates. After various experiments with different compounds with eosine or erythrosin, I found that carbonate of silver, dissolved in excess of carbonate of ammonia and mixed with the erythrosin, gave me the best effect.

The orthochromatic effect in a plate is due not to eosine or any other stain being an optical sensitiser, as some state, because you may stain the film as much as you please, still the yellows will refuse to impress themselves upon the film; but I believe it is due more to a chemical change, which is produced by having free silver present as well as a compound formed with the erythrosin.

Although I discovered the above (*i.e.*, the use of silver carbonate with eosine) quite independent of anything that had been published, I see that I have been somewhat forestalled in the publication of the formula, as last week in the *News* appeared a formula with ammonia, silver, and eosine, by Vogel, and, I think, the week previous another formula containing fluoride of silver, carbonate of ammonia, and eosine, which practically amounts to the same as I have given above. Mr. Hastings will bear me out in what I say, as I confided my formula to him some four or five weeks ago. However, I need hardly trouble you with all this.

After trying various proportions, I find the following to work fairly well:—

Silver nitrate	20 grains
Ammonium carbonate	90 „
Water, distilled	16 ounces
Erythrosin (2·100)	10 drachms

The plates are placed in this for two minutes. A rinse in distilled water gives less chance of stains, and then placed in a rack to dry. Let me here state that if they are used in the moist condition the orthochromatic effect is practically *nil*; they must be used quite dry. By this treatment the plate is rendered three times more sensitive. I must insist upon the necessity of using only ruby light, the plates having now become so sensitive to yellow that the greatest precaution must be taken in handling them. My chief reason in not giving you this formula before was the great difficulty of developing the plates free from fog; this I am glad to say I have now overcome. I pass round a plate half of which is quite free from fog. This was got rid of by soaking the exposed plate before developing in the following:—

Potassium bromide	120 grains
Ammonia	½ ounce
Water	12 ounces

Do not allow to remain more than thirty seconds, well rinse under the tap, and proceed to develop with any of the usual developers—ammonia, potash, or ferrous oxalate. If there is much blue in the object to be copied, a yellow screen must be used if exposure is to be made by daylight, although by gas or lamplight it is quite unnecessary. The best effect is always secured by gaslight exposure.

A very good substitute for coloured glass is to colour a collodion film and strip it from the glass. The glass should be rubbed over with talc or a solution of wax in ether, and well polished off, and coated with collodion containing methyl orange. The dried film should appear decidedly orange. The stripped film can then be gummed to the cap of lens, having cut out the centre first, and used preferably behind the lens. The carbonate of silver and erythrosin may be mixed with an emulsion, but requires great care. It should be mixed at as low a temperature as possible, and the plates used as soon as they are dry, as their life is very short. The orthochromatic effect is very marked, and the speed increased about ten times. If any one is desirous of trying this, I give the following:—

Emulsion (containing, say, 200 grains silver)	10 ounces
Silver nitrate	10 grains
Ammonium carbonate	45 „
Erythrosin (2·1000)	5 drachms

Before development they must be treated with the ammonia and bromide.

Very fine results can be obtained from collodion emulsion—in fact, the results far surpass gelatine, and can be used by daylight without the necessity of employing a yellow screen at all, but, alas! like gelatine, do not appear to keep any better. The bath for a collodion emulsion plate is best made as follows:—

Silver nitrate	10 grains
Ammonium carbonate	45 „
Water	2 drachms
Spirit, methylated	8 ounces
Erythrosin (2·1000)	5 drachms

Dissolve the silver in a test-tube by heat in two drachms water, and add the carbonate of ammonia bit by bit till all dissolved. Add the spirit gradually to the hot solution, and finally the erythrosin. Place the dried collodion plate in this solution for two minutes, and dry; the plate, before development, to be treated with the ammonia and bromide, and developed by ferrous oxalate, three to one, to each ounce of which add three grains of bromide. If mixed with the emulsion, it begins to fog at the end of three days, so it is better to dip the plates as required. The exposure is only four times more than a fairly ordinary rapid gelatine plate by daylight, and by gaslight they are about equal. The action of the erythrosin silver compound renders the collodion film exceedingly tough, very much like an alumed gelatine film, and is very difficult to scrub off the glass afterwards.

* By J. B. B. WELLINGTON. A communication to the London and Provincial Photographic Association.

USEFUL AND SCIENTIFIC NOTES.

Speed of Atlantic Liners.—The following statements of the average speed of Atlantic Liners are given by the U. S. Superintendent of Foreign Mails; the figures being reckoned from actual times, which include all delays in getting under way and to berths:—

From New York to Queenstown, 2,820 nautical miles: Cunarders (each three trips).—The Aurania 15·6 nautical miles per hour; the Bothnia, 13·4; the Umbria, 16·8; the Etruria, 17; the Servia, Guion liners (three trips).—The Alaska, 16·4; the Arizona, 15; (one trip) the Wisconsin, 11. White Star Liners (three trips).—The Germanic, 14·9; the Celtic, 13·4; (two trips) the Britannic, 14·5; the Republic, 13·8. The National Liner America (five trips), 15·7. Inman liners (two trips).—The Baltic, 13·2; (one trip) the City of Berlin, 13·7; the City of Chicago, 13·3; the City of Richmond, 12·8. The Anchor liner City of Rome (two trips), 16·3.

New York to Southampton, 3,192 miles: North German Lloyd's (three trips).—The Trave, 16·6; Saale, 16·3; the Eider, 15·2; the Aller, 15·8; the Ems, 16·4; the Fulda, 16; the Elbe, 15·7; (one trip) the Werra, 16·2.

New York to Plymouth, 3,062 miles: Hamburg American liners (three trips).—The Hammonia, 13·9; the Wieland, 13·7; the Lessing, 13·8; the Gellert, 13.

New York to Glasgow, 2,926 miles: Anchor liners (three trips).—The Furnessia, 12·2; the Ethiopia, 11; the Devonia, 11·2; the Anchoria 9.5.

New York to Havre, 3,200 miles: French liners (five trips).—The Bourgogne, 16.4; (four trips) the Normandie, 15·5; (three trips) the Champagne, 16·8; (two trips) the Gascogne, 16·2; the Bretagne 15·9.

New York to Antwerp, 3,444 miles: Red Star liners (four trips).—The Noordland, 11; the Rhynland, 12·2; (three trips) the Westernland, 13·3.

Boston to Queenstown, 2,682 miles: Cunarders (three trips).—The Cephalonia, 12·8; the Scythia, 12·8; (two trips) the Gallia, 13·9.

Tempering Springs.—The following method is recommended for large springs:—Make a bath of 6 gallons lard or fish oil, 1¼lb. gum arabic, and ¼lb. rock salt. Mix well and it is ready for use. Heat the steel to a dark cherry-red; cool and do not draw the temper.

SCIENTIFIC SOCIETIES.

ROYAL ASTRONOMICAL SOCIETY.

THE January meeting was held on the 14th inst., J. W. L. Glaisher, Esq., President, in the chair. The following gentlemen were balloted for and duly elected Fellows of the Society:—The Rev. W. Birks, Wanstead Villa, Villiers-road, Southsea; Capt. Thos. Exham, Officer's Club, Canute-road, Southampton; Mr. Shelley Fisher, The Priory, Larkhall-rise, S.W.; Mr. Cuthbert Hutchinson, Rock Lodge, Roker, Sunderland; Mr. W. E. Jackson, Constantinople; Capt. Thos. Mackenzie, R.M.S.S. *Moselle*, Southampton; Mr. Horace Pearce, The Limes, Stourbridge; Mr. Jas. Cruikshank Roger, The Grange, Walthamstow.

The names for suspension were read by Col. Tupman; amongst them was the name of Miss Pogson, a daughter of Mr. N. R. Pogson, Director of the Madras Observatory, who had been proposed for the fellowship of the Society by three Fellows in the usual manner.

The President said: There can be no question that at the foundation of the Society the admission of women was not contemplated; but it seems doubtful, as a matter of law, whether the Council, either by their charter or under the by-laws of the Society, can exclude women if they are proposed. The Council has had several legal opinions before them, and the majority of the Council were of opinion that they were not justified in refusing to let this certificate go forward to the general body of the Fellows, to be dealt with by them as they think fit. It was not so *primâ facie* invalid that the Council felt it their duty to keep the nomination from the Fellows. On the part of the Council, he expressed no opinion whatever upon the general question. Those who felt that the admission of women was undesirable had only to record their votes accordingly at the balloting in March. One black ball in four excluded. In voting adversely there could be nothing personal, as those who brought forward the candidate knew that it was a new departure, and that her eligibility was questionable.

Mr. Knobel read a paper by Dr. Copeland on "The Variability of the Spectrum of γ Cassiopeiæ." The paper stated that Miss Clarke, in her "History of Astronomy during the 19th Century," made the assertion that the bright lines indicative of hydrogen in this star died out during the nine years from 1874 to 1883. There were two records of these bright lines having been seen at Dun Echt about the middle of this period. At present C is extremely bright, but it was not visible in June, 1872. There could not be the slightest doubt as to the variability of the spectrum, as pointed out by Mr. Von Gothard several years ago. It was remarkable that the C line was more variable than the F line, and there is certainly a colour change in the whole light of the star which accompanies these changes in the spectrum.

Mr. Maunder agreed with Dr. Copeland that he had observed the F and C lines two or three times during the interval named. Indeed, he had never looked at the spectrum of γ Cassiopeiæ without having seen the F line, though it was variable in brightness.

Mr. Knobel read a letter from Mr. Penrose on the occultation of γ Virginis, observed at Athens on the 18th of December. At the reappearance there were clouds which prevented the dark body of the moon being seen, and the power used was not sufficient to separate the two components of the double star. A bright flash showed the reappearance of γ_1, and five seconds later another flash, which seemed to double the brightness of the star, showed that the other component had appeared.

Mr. Knobel said the older Fellows of the society will remember the great interest that attached to an observation of an occultation of this star observed by Admiral Smythe in 1832. On that occasion neither he nor Mr. Dawes were able to see any second flash; both components seem to have reappeared at the same moment.

Mr. Downing said: This occultation was observed at Greenwich, but the observer was unable to see any second flash like that described by Mr. Penrose. I do not know the distance between the two components.

Mr. Sadler: The distance is now about $5\frac{1}{2}$ seconds I think.

Mr. Ranyard: It does not follow that because the phenomenon was not observed at Greenwich, that it could not have been seen at Athens, for the distance between Greenwich and Athens is so great that the reappearance would take place at quite a different part of the moon's limb. The one star may have appeared over a valley, and the other above a mountain, as seen from Greenwich, while the reverse may have been observed from Athens.

Mr. Knobel read a paper by Prof. Pritchard on the "Application of Photography to the Determination of Stellar Parallax." Since last May a series of photographs had been taken of the components of 61 Cygni and the neighbouring stars, with which its place was compared by Bessel in 1840. About 200 plates had been taken, and the distances of the four nearest stars made use of by Bessel had been measured upon them. Some doubt had been expressed as to whether there was any dislocation or unequal stretching of the photographic film, due to the unequal way in which water flows upon the plate while it is being washed. In order to check this, four photographs had been taken every evening; but out of the 200 plates taken only seven showed any evidence of such unequal stretching, and these had, of course, been rejected. The provisional parallax obtained for the centre of the binary system was 0·438 second of arc, the parallax obtained by Bessel was 0·348s., that obtained by Struve 0·564s., Ball 0·4756s., and Asaph Hall 0·270s. The research will be continued till the end of the cycle.

Mr. Ranyard said: It is a matter of very great interest whether the parallax of stars can be determined from the measurement of such photographs as these. For undoubtedly this photographic method offers some great advantages: it permits of opposite phases being directly compared side by side and measured over and over again. These photographs were taken, I conclude, with the reflector of the Oxford Observatory, which has a focal length of 10ft., and I conclude that the original negatives have been measured. With a focus of 10ft. they would be on a scale of about $2\frac{1}{4}$in. to the degree, or about one 1600th of an inch to the second of arc—or less than one 3,000th of an inch to half a second of arc—that is a very small quantity, much smaller than could be distinguished by the naked eye. I once made some experiments as to what length could be measured with the naked eye, and concluded that the 400th of an inch was about the minimum I could attain to for sharp lines. But let us assume that the centre of a small point could be fixed to one 500th of an inch, we should need a power of six to enable us to make readings to the 3,000th part of an inch. A photographic negative, when examined under the microscope, does not show an even shading; but it breaks up into a number of definite dots or granules, which, in the case of the dry plates now used, are larger than in the old wet plates. Some years ago, when measuring some prominences on eclipse photographs taken with the old wet collodion process, I came to the conclusion that I could not with advantage make use of a magnification higher than five diameters. With a higher power you see too distinctly the granulation, and the problem of measuring the distance between two small dots on a photograph would be like measuring the distance between two heaps of shingle, and not from the edge of one heap to the edge of the other, but from a point which you select as the centre of one heap to a point which you select as the centre of the other; and then systematic errors would come in, which would prevent your combining different readings and deducing a probable error according to the ordinary method. I think, therefore, that with such photographs as these one ought not to rely on the results of measurements to less than half a second, a quantity which does not differ much from the difference between the estimates of the parallax made by different observers. When we get telescopes with 100ft. focus the problem will be changed; but we shall then not get within the limits of probable error which some of these observers have thought that they have attained to.

Mr. Common said: I should like to point out that all the disadvantages which Mr. Ranyard has mentioned apply equally to the image as seen in the telescope. The focal image needs to be magnified, and no better measure can be got by the eye than can be obtained by the photograph, measuring at your leisure, with the opportunity of repeating it as often as you like.

Mr. Ranyard: There is this difference—you can magnify the image in the principal focus of the telescope 200 or 300 diameters, or as much as you like, without seeing any lumpiness of the image which would tend to give rise to systematic errors.

Mr. Common: Mr. Ranyard must not forget that the image is already magnified in the focal image, by reason of the focal length. The eyepiece does not do all the actual magnification.

The Astronomer-Royal: I think that a pretty good answer is given to Mr. Ranyard's criticisms by the fact that Prof. Pritchard's measures agree with one another to much less than half a second of arc. I have had an opportunity of looking them over, and can say that the agreement is fairly good. One cannot from *à priori* reasoning get at such accurate numerical estimates. The results show that the readings are much closer together. I am inclined to think that Prof. Pritchard's results are more accurate than Bessel's made with the heliometer, and the photographic measures can be made with much less labour. By this method stars at much greater distances may be utilised for parallax measures than was possible before.

Mr. Knobel read a paper by Mr. Isaac Roberts, on "Photographs of Nebulæ in Orion and in the Pleiades." An enlargement from an over-exposed photograph of the Orion Nebula, showing an extension of the nebulosity over an area about seven times as great as that covered in Mr. Common's photographs, was exhibited. The detail of the central portions was, however, quite blotted out. This photograph was exposed for one hour and twenty minutes. An enlargement from a photograph of the Pleiades Nebula, exposed for three hours and six minutes, was also shown. This confirmed the photographs shown by Mr. Roberts at a former meeting, and proved that the nebula extended over the whole group.

Mr. E. J. Stone read a paper entitled "Observations of the Moon made at the Radcliffe Observatory, Oxford, during the Year 1886, and a Comparison of the Results with the Tabular Places from Hansen's Lunar Tables." He said that these observations showed that the moon was still running away from Hansen's places. He could not believe in such a change taking place per saltum without some theoretical explanation which ought to be forthcoming. If the one he had offered with regard to the change of the solar year was not correct. Hansen's tables agreed with the observed places pretty accurately, from 1754 to 1864, and since that time, the moon has run away more, some $15\frac{3}{10}$ seconds, which is a quantity larger than can be accounted for by anything like personality in the observations.

Capt. Noble made some remarks on the present condition of the *Nautical Almanac*, pointing out that no change had been made in the tables of Jupiter's Satellites used. They were founded on observations made more than 50 years ago. And no change had been made in the dimensions of the Saturnian system published, though those used obviously did not agree with any modern drawings of the planet.

The meeting adjourned at ten o'clock.

LIVERPOOL ASTRONOMICAL SOCIETY.

THE fourth meeting of the session was held on Monday, the 10th inst. Mr. C. A. Defieux occupied the chair. In presenting a list of thirty-eight candidates, the secretary pointed out that eight were from Scotland. He thought this was important, as Scotland had hitherto taken but little interest in astronomy; indeed, of the 1,000 odd Fellows who formed the Royal and Liverpool Societies, only 20 were from Scotland. He attributed this better feeling to a correspondence which had lately appeared in the Edinburgh papers, where, amongst other reasons given for this apathy, was a supposed reluctance to accept their astronomy "from across the Border." This expression, however, only proved how little was understood of the constitution of the L. A. S., for of the communications before them that night one was from Glasgow and others from Vienna, France, and Dublin. If, therefore, there did exist a "borderland of science," it certainly would not be determined geographically. Mr. W. D. H. Deane, M.A., thought the indifference was rather caused by the system of education. Technical astronomy formed part of the curriculum at the Edinburgh and Glasgow Universities, and at most of the public schools, but this was dry work, and little calculated to arouse an interest in the science.

The president contributed a list of 33 red stars which had been detected by the late Prebendary Webb, but had not hitherto been published. They had been identified in Argelander, and, in some cases, re-observed with his, Mr. Espin's, $17\frac{1}{4}$in. Calver reflector; though ill-health has, unfortunately, compelled him to relinquish the hope of re-observing them all. The stars had been brought approximately to their places up to 1885, and the list was accompanied with remarks and notes by Mr. Webb, so that the whole formed a valuable appendix to "Celestial Objects."

Comparing occultations past and present, the Rev. S. J. Johnson, F.R.A.S., remarked that the occulation of γ Virginis, which took place on the 19th of last December, was observed under very different circumstances to what would have been the case half a century ago, for it was just 50 years since Smyth observed γ Virginis as a single star. So few conspicuous double stars lay in the moon's path, that when the occultation of one happened it was attended with great interest. β Scorpii was occulted in September, 1871, but this did not seem to have been observed. The immersion of γ Virginis took place when the moon was low down, so that it was impossible to see the star separate, but at the re-appearance things were more favourable, though, unfortunately, he just missed the emergence of the companion by turning his head to note the exact time. From an observation in 1756, Mayer found the position angle = 54° 21′, and inferred a revolution in 700 years; but in 1781 Herschel found it = 40° 44′; whilst in 1830 it had altered to 30° 20′, so that it seemed pretty certain that the period could not much exceed 180 years. It was from an observation of this occultation that Ferguson endeavoured to prove the moon devoid of an atmosphere.

Mr. W. H. S. Monck, F.R.A.S., reviewed the

different theories as to the origin of meteorites. The one which accounted for their existence by projection from terrestrial volcanoes was open to many objections, but principally on account of the enormous velocities which had at times been observed. The great detonating fire-ball of 23rd Nov., 1877, had, for example, been estimated by Col. Tupman to have moved with at least parabolic velocity, and many other instances of a like speed had been observed. No such velocity could be imparted by volcanoes; therefore, if the theory were defensible, it must be in connection with Mr. Proctor's hypothesis of planetary, or even stellar, origin.

Mr. S. M. Baird Gemmill had observed a star which he suspected of variability. The position was *p.* the fine orange star which formed a triangle with 119 and 120 Tauri. In October, 1884, he had estimated it at 8 mag., but in the following October he had found it quite half a magnitude brighter. In a note on the recent maxima of U Geminorum, Mr. J. Baxendell, jun., referred to a former paper on the subject by Mr. George Knott, which he thought should form a standard for future estimates. The star was well worthy of careful observation, both on account of the varied phenomena it presented, and from the fact that it seemed to form a kind of connecting link between the so-called new or temporary stars and those of more regular period.

M. C. M. Gaudibert described the crater and neighbourhood of Condamine (Webb 237), which he had observed on the 6th of December, when the libration was very favourable. The air would not permit of a higher power than 100 on his 8½in. reflector, but he had distinguished several markings which were not included in Neison. There was also a wide opening on the N. W., and a much smaller break at the opposite wall. Besides these two ruptures, the whole ring was very uneven, particularly on the S. W. side, where there where four craters—the smallest on the wall itself.

In a continuation of his papers on telescopes, Mr. W. F. Denning, F.R.A.S., dealt with the influence of wind on definition. The east wind was rarely favourable, though the rule was far from absolute. They should remember that several distinct currents sometimes prevailed, with the air strata in different degrees of humidity. A mere surface breeze from the east might therefore underlie an extensive and moist current from the south-west, when the definition would be very fair. Calm nights, with a little haze, were often the best of all; whilst, with sparkling and brilliant stars, there was generally wretched definition. In the course of a night the definition would sometimes fluctuate in a most remarkable manner, so that an observer who found it impossible to obtain satisfactory images might an hour or two later have no reason to complain. It frequently happened that a morning following a turbulent night became so fine that it might be included in the 100 hours which had been assigned by Sir W. Herschel as the annual limit.

Mr. W. S. Franks, F.R.A.S., described Saturn as a beginner might expect to view it with a 3in. telescope, and Mr. T. G. Elger, F.R.A.S., continued his illustrated papers on "The Moon Surveyed in Common Telescopes."

The meeting concluded with an exhibition of photographs of Nebulæ star clusters, Saturn and Jupiter, by MM. Henry and Herr Gothard. An examination of the Nebulæ in Andromeda disclosed the remarkable fact that the 4½in. stellar camera photographed considerably more detail than the 17in. refractor of the Brothers Henry, or even the 3ft. telescope of Mr. Common. This was accounted for by the shortness of its focus, which would concentrate the more delicate rays into a smaller compass, although the larger instruments photographed from six to eight times the number of faint stars.

Mr. R. S. Newall, F.R.S., F.R.A.S., was elected on the Council in place of Mr. John Stead, deceased. The meeting adjourned at 9.45 p.m.

Gasholders.—The famous South Metropolitan gasholder, 214ft. diameter, over 150ft. high, and 5,500,000 cubic feet in capacity, long held its position as the largest in the world. It is now exceeded, however, by a pair of holders which have been erected at the Birmingham Corporation Gasworks, the dimensions of which are indeed prodigious; each of these is contained in a tank measuring some 240ft. in diameter, is 150ft. high, and holds 6,400,000 cubic feet.

Welding Steel.—The following is said to be an excellent compound for welding steel. High-class steel can be welded by the use of this better than with borax, because it is not necessary to heat so high. The pieces should be held together when heating:—Copperas, 2oz.; saltpetre, 1oz.; common salt, 9oz.; black oxide of maganese, 1oz.; prussiate of potash 1oz. These should be pulverised and mixed with 3lb. of good welding sand, the mixture being used the same as sand.

SCIENTIFIC NEWS.

A TELEGRAM from Cambridge, Mass., forms the subject of Dun Echt Circular No. 131. Dr. B. A. Gould finds the star D.M. + 34°, 4184, to be a variable of the Algol type. The latest minimum occurred on Jan. 17 at 10h. 19m. G.M.T., the star changing from 7·1 mag. to 7·9 mag. with a period of three days. Dr. Gould asks observers to watch the star, as it cannot be seen after January on account of twilight. Dr. Copeland adds that the new variable is identical with 40373 Lalande, and is situated 4m. 52s. *f.* and some 16′ N. of T Cygni. According to the new Armagh Catalogue, its place is 1887·0 R.A. 20h. 47m. 32·5s., N. Dec. 34° 13′ 59·5″.

Circular No. 62 of the Liverpool Astronomical Society, issued by Mr. T. E. Espin, states that the star announced in Circular 10 as invisible has reappeared, and was observed on Jan. 16 at Wolsingham, Darlington, by Mr. W. H. St. Q. Gage with the 17¼in. eq., as a red 9-mag. star. It is therefore a star with a long period probably, and a variation from 9 ± to below 12. The star's place for 1885 is R.A. 4h. 21m. 25s.; N. Dec. 15° 50·7′ preceding Theta Tauri by 0m. 35s., and 0° 8′ N. of it.

The report of the superintendent of the United States Naval Observatory for the year ending June 30, 1886, has been received, and we learn from it that the plans for the new observatory provide a place for, and contemplate the eventual mounting of, a suitable photographic telescope. With regard to the 26in. refractor, it has been used mainly in observations of double stars, of satellites, and of Saturn, but stellar parallax has also been attended to. No deterioration of the objective has been noticed since it was repolished 10 years ago; but the report refers to the lack of sufficiently good atmospheric conditions to bring out the full powers of the instrument. During the year there have been 1,853 visitors, and 1,553 permits were issued for night visitors.

Major-General De Lisle, R.E., of Ipplepen, Newton Abbot, has sent us some copies of "Tables for the Reduction of Latitude and Log. radius of the Earth for Spheroid Ⓔ," a few misprints having been discovered in those issued last year. The fresh copies have been forwarded to all purchasers with one exception —the address having been lost; but those who have not received them will know where to apply.

The Lalande prize of the Paris Academy of Sciences has been awarded to Dr. O. Backlund, of Pulkowa, for his work on the motions of Encke's comet, in which he shows that the acceleration of the mean motion is subject to a progressive diminution, and amounted between 1871 and 1881 to scarcely half what it was between 1819 and 1865. The Valz prize was awarded to M. Bigourdan for his investigations into the effect of personality in the observation of double stars. The Damoiseau prize was awarded to M. Souillart, of Lille, for his revision of the theory of the motions of Jupiter's satellites. M. Obrecht was awarded an "encouragement" of 1,000 francs for his "Etude des Satellites de Jupiter"—a thesis written for his doctor's degree. The subject of the prize for 1888 is "Perfectionner la théorie des inégalités à longues périodes causées par les planètes dans le movement de la Lune." The memoirs must be sent in before June 1, 1888.

Prof. A. W. Rücker is delivering a course of five lectures on "Molecular Forces" at the Royal Institution. They are delivered on Thursdays, and extend to Feb. 17.

Amongst the papers promised for the meetings of the Society of Arts, we note Jan. 26, "Photographic Lenses," by J. T. Taylor; Feb. 2, "Electric Locomotion," by A. Reckenzaun; Jan. 16, "Handicraft Training," by H. H. Cunynghame; Feb. 23, "Recent Advances in Sewing Machinery," by J. W. Urquhart. Papers for which dates have not been fixed, include "Miners' Safety-Lamps," by E. H. Liveing; "Development of the Mercurial Air-Pump," by Prof. S. P. Thompson; "Progress in Telegraphy," by W. H. Preece; "Railway Brakes," by W. P. Marshall; "Living Organisms of the Air," by Dr. Percy Frankland; and "Cultivation of Tobacco in England," by E. J. Beale.

The fortieth annual general meeting of the Institution of Mechanical Engineers will be held on Thursday and Friday, February 3rd and 4th, at the Institution of Civil Engineers. The president, Mr. Jeremiah Head, having been in office for two years, will retire, and will induct the president-elect, Mr. E. H. Carbutt. The following papers will be read and discussed, as far as time permits: "Notes on the Pumping Engines at the Lincoln Waterworks," by Mr. Henry Teague, of Lincoln; "Description of a Portable Hydraulic Drilling Machine," by M. Marc Berrier-Fontain, of Toulon; "On Copper Mining in the Lake Superior District," by Mr. Edgar P. Rathbone, of London.

Sir Charles Bright, president of the Society of Telegraph Engineers and Electricians, delivered the opening address of the session last week, and took advantage of the fact that this is the jubilee year of the electric telegraph, to give its history at some length. He also showed that the postal telegraph promises to develop into a profitable Government department.

Several suggestions have been made to celebrate the jubilee of the electric telegraph, Cooke and Wheatstone's patent having been taken out a week before the Queen's accession. There is some little rivalry, but it is expected that it will be determined by the Society of Electricians, and that it will take the form of an exhibition showing the development of the several branches of telegraphy and telephony.

The number of applications for admission to the Normal School of Science and Royal School of Mines being greater than the accommodation the school affords, it has been determined to make a sort of selection of candidates for admission. Applications must be sent to the Registrar before the end of May, accompanied by a statement of the studies pursued and examinations passed, with a reference to a teacher or teachers. A knowledge of elementary mathematics will be held to be of the first importance, while in the case of "occasional students," some preliminary knowledge of the branches of science they wish to take up will be expected.

The total number of applications for patents during 1885 was 16,101, of which no fewer than 7,237 were abandoned at the preliminary stage. That is about 45 per cent., a higher percentage than prevailed under the old law. It must be remembered, however, that the first ten years of such a reform as the new Patents Acts will scarcely show the true effect on the progress of invention; for many utterly useless devices, such as perpetual motion, &c., have found their way to the Patent Office since the reduction in the cost of stamps.

The Upper Table Rock at the Niagara Falls fell into the river on the night of the 13th inst. The mass of rock is estimated to have measured 150ft. long, 60ft. wide, and 170ft. deep. The mean rate of regression of the Falls has been variously estimated, some putting it at a yard per annum, while a more moderate computation considers 12in. sufficient, taking one year with another. Table Rock was the favourite spot for viewing the Horseshoe Fall, and its displacement leaves a perpendicular wall, where one can stand and look behind the cataract into the dark chasm through which the spiral stairway goes down to the path behind the Falls.

After a residence of nearly three years at Torrens Observatory, near Adelaide, Mr. Clement L. Wragge has accepted the appointment of Government Meteorologist of Queensland, and, according to the papers received, would leave Adelaide for his new post about Dec. 19 last. His work will consist of daily reports and weather charts showing the meteorological conditions prevailing throughout Australasia, but especially Queensland, and he intends to publish quarterly *The Queensland Meteorological Record*, similar to the publication of the Royal Meteorological Society. He also intends to introduce the Royal Meteorological Society's system at all stations.

The new Orient liner *Ormuz* is designed to make the trip from London to Australia in 28 days. Within less than ten months from the signing of the contract the vessel steamed

out of the Clyde, although she is of 6,500 tons measurement, and was fitted and embellished complete. The *Ormuz* has the largest triple expansion engines yet made, the cylinders being respectively 46in., 73in., and 112in. in diameter. Her dimensions are 465ft. long, 37ft. deep, and 52ft. greatest beam. The pitch of the screw propeller is 29ft.

At the meeting of the San Francisco Microscopical Society on Dec. 8, Dr. Ferrer described the new Zeiss photo-micrographic camera and stand. The camera itself is of very large size, permitting a range of nearly 8ft. from the object, when fully extended. Its front bears a metal sleeve or nose-piece which racks out to the body tube of the microscope, forming a light-tight connection with it. In addition to the ordinary ground-glass focussing plate, one of clear plate-glass is provided, furnished with a focussing glass sliding vertically between brass guides. By this means an exceedingly delicate adjustment can be obtained. The fine adjustment is regulated by a milled head attached to a long brass rod, which latter translates the movement to the fine adjustment micrometer screw by means of two very ingenious universal joints. The illumination used on this occasion was a very large oil lamp, with a bull's-eye condenser interposed between it and the Abbe condenser in the sub-stage, and for work with low powers, Dr. Ferrer stated that he had found the light fairly satisfactory, but he hoped to improve upon it by using the electric light in some way, and several patterns of incandescent lamps were now being tested by him. He also stated that he had ordered the best obtainable heliostat, for photographing with sunlight, and he, therefore, hoped soon to be in a position to do excellent work with high amplification. Hitherto he had dispensed with the oculars, using only the objectives and specially-constructed amplifier; but he intended very soon to make a thorough test of the new "projection" oculars of Zeiss, in combination with the apochromatic objectives of the same maker.

At the meeting on Dec. 22nd Prof. Runyon, who was present as a visitor, exhibited a number of photo-micrographs made by him with the Walmsley apparatus, and only a common oil-lamp as a source of illumination. The subjects chosen comprised sponge spicules, single and arranged diatoms, insects, and anatomical specimens. William Norris stated that several series of interesting slides had been received by him, which he would turn over to the Society. The first set was composed of diatoms collected and mounted in Australia, by Dr. Thomas Porter, and comprised many rare and beautiful forms. The second lot was from William H. Pratt, Taunton, Mass.; and the third from Gerald Stuart, F.R.M.S., London. The last-named set consisted of diatoms from New Zealand and the East Indies, and was of special interest from the fact that it contained *Navicula Durandii*, a form recently discovered and named in honour of Mr. Durand.

At the annual meeting of the Society of Public Analysts, held in the rooms of the Chemical Society, Burlington House, on the evening of the 12th inst., Mr. A. H. Allen, of Sheffield, analyst for the West Riding of Yorkshire, &c., and author of the well-known work on "Commercial Organic Analysis," was elected President of the Society for the ensuing year.

Mr. Sydney T. Klein, F.R.A.S., has reprinted his paper read before the County of Middlesex Natural History and Science Society last November entitled, "Thirty-six Hours' Hunting among the Lepidoptera and Hymenoptera of Middlesex, with Notes on the Methods adopted for their Capture." It will be found interesting and useful by all entomologists. It is published by C. Seers, Argyle-street, Bath.

A SWEDISH mechanic at McKeesport, Pennsylvania, has invented three nail machines to work together that will turn out 250 nails per minute, any size from the smallest to 7in. One of the machines makes the common nail from the plate. The wire nail is cut and headed by the second machine. The third cuts a fluted nail with guttered sides, which the inventor claims will cling to wood better than any made.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, *332, Strand, W.C.*

All Cheques and Post-office Orders to be made payable to J. PASSMORE EDWARDS.

*** *In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks, a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

OCCULTATION OF ALDEBARAN.

[26717.]—WELL observed on Jan. 6th with $12\frac{1}{2}$ Linscott, lat. 54° 44′ 23″ N., long. 1° 48′ 43″ W. Disappearance at 12h. 9m. 24s., and reappearance at 12h. 58m. 47s. by my watch. Slow $6\frac{1}{2}$ minutes on G.M.T. By Shadwell's tables for facilitating the approximate prediction of occultations, I obtain the following results:—Disappearance G.M.T., 12h. 16m. 2s.; reappearance G.M.T. 13h. 5m. 17s.; angles from north point respectively, 140° and 235°.

Would some kind reader work out this occultation for me by the most approved and reliable method; say, at same time, what dependence can be put upon this class of observation for the obtaining of Greenwich Mean Time? **H. P. Slade.**

66 CETI (Σ 231: 6, 7·8).

[26718.]—I HAVE lately been observing this interesting pair, and I find the *comes* of almost equal magnitude with its primary.

Would Mr. Sadler kindly tell me whether the *comes* has brightened of late, or the primary dwindled?

"Celestial Objects" gives it thus: 7 (Gore 6, 1874) 8·5; and the "Star Guide" has it 5·9, 7·5.

Unless I am very much mistaken, there is nothing like the difference of a magnitude and a half between the stars. I am much indebted to Mr. Sadler for former courtesies. Would he, at his convenience, kindly give a note on 66 Ceti?

Jan. 17. **H. Dowsett.**

CONCERNING THE LUMINIFEROUS ETHER.

[26719.]—WE must assume ideal pictures as the advanced mind delineates them, although a "mental reservation" is nearly always necessary.

If we delegated all hypothetical computations from the domain of science, and worked more upon evident truth, we should have far greater respect for the One who said, "Let there be light, and there was light, and He *saw* the light, that it was good." Light is invisible "to us." Its effect upon matter makes us cognisant of its existence; but again, the omnispective power is even able to scrutinise everything that is, and therefore, if we banish all theoretical deductions, we must then look upon those deep gaps in wonder and awe. We should not think of or respect Him as we do if He had not made some things preternatural and beyond the ken of us "worms."

The true man of science must not fly shy of the gaps and enigmas that present themselves. Certainly, this is not the way to advance research. If we had shunned every phenomenon we should assuredly have remained in our primeval state, instead of elevating our mind with those beautiful theories in speculative science.

It is not mere idle talk to advance postulates when we consider their *primum mobile.*

It is upon experimental data that our "all space-pervading medium" has been founded; in short, by its analogy to the other undulating force—viz., sound. By analogy the scientist classifies and arranges all natural objects, and the behaviour of those objects in his category of specific genera, species, and other sub-families, and is it not perfectly logical to admit "that sound and light being alike in their many dogmata, that they are analogous in their wave-like motions? How else can it be conceived? Can we explain the abstruse theory of the beautiful prismatic colours of the soap-bubble, or the bending of light round corners which so annihilated the corpuscular theory of Newton, without the assumption of that *hypothetical luminiferous ether.*

"Are we to wait," with our hands in our pockets until someone discovers the real translation or wave-motion, whichever it may be, of light? Surely this does not tend to advance our knowledge? One great objection have I against the undulatory theory, and that is the peculiar formation of the (photographic) invisible image by the catalytic impact of the waves or undulations of the elastic etherial medium. We are taught by physicists to assume that the luminiferous ether pervades the interstices of the ultimate particles of matter, and that we may look upon these microcosms as analogous to the planetary bodies of visible magnitude.

Assuming that indestructible atoms of matter have a spheroidal figure, then a heap of such spheroids (whether held together by cohesion or chemical attraction), must necessarily have *spaces between;* as in a vessel full of marbles we can "pack away" sand, or even shot, to a certain limit without making any rise in the neck of the containing vessel. The sand or shot filling the interstices, of course, represents that "subtler fluid than air, the luminiferous ether." Then if a set of wave-motions were set up in the interstices of a sensitive body, such as a dried emulsion of gelatine and silver haloid, these waves, owing to their non-synchronisation with the oscillations of the ultimate atoms of the haloid salt, would undoubtedly produce some effect; but it is not so. The action of light is superficial, and does not insinuate itself between the ultimate particles of matter.

Newport, Mon. **A. Treyer Evans.**

[26720.]—I QUITE sympathise with "Sigma" in his vigorously-worded attack on the above "precious jelly"; but at the same time I do not believe that Mr. Grey or any other really scientific man looks upon the idea of an "ether" as anything else than a "working hypothesis," and a convenient mode of representing the actions and phenomena of light to our gross material imaginations.

Nevertheless it is, as Sir David Brewster once called it, a "clumsy contrivance"; which will, we may hope, soon go the way of heat fluids, electrical fluids, and magnetic fluids, about which precisely the same kind of controversy was carried on until it was recognised that the molecules of ordinary matter were quite capable of taking up and transmitting energy in its various forms without the help of any "go-between" medium.

To take one point mentioned by Mr. Grey—the enormous velocity of light. The absolute velocity of transmission of electricity is almost certainly the same as that of light. Electrical changes are transmitted to the earth from the sun at the same rate as the variations of his light; witness Mr. Carrington's remarkable observation of an outburst of a facula on Sept. 1, 1859, simultaneously with a disturbance of the magnetic instruments at Kew. Yet no one thinks it necessary to assume the existence of an electriferous ether, but acquiesces in the view that the molecules of bodies can and do take up the peculiar movement, whether of vibration or revolution, which presents to our senses the phenomena called electrical.

Those who have not done so already, should read the remarks made by one of the clearest and most profound of modern scientific thinkers, Sir W. R. Grove, at the end of the chapter on Light in his "Correlation of Physical Forces."

A. X.

[26721.]—IN my schoolboy days our atmosphe was said to extend five miles above the earth's surface; then it suddenly jumped to ten miles, next fifteen, twenty, and twenty-five. Where will the limit be placed a few decades hence? At the moon, or our nearest planetary neighbour, or the sun, or the uttermost star? For my own part, I had "fifty years ago" seen enough of air-pump experiments, and learnt enough about the "diffusion of gases," to prevent my putting any limit to the extent of our atmosphere, but rather to feel assured that it existed throughout the universe. Undoubtedly, the further you go away from the earth's attraction, until you reach another attraction, the more rarefied it becomes; but it must be just as impossible to obtain a perfect vacuum in space by going away from the earth, as it is to obtain one by relieving a vessel of the influence of that attraction by the action of the air-pump.

I have seen some very great changes in the ideas of scientific men, and I may yet live to hear the "wonderful jelly" and the "luminiferous ether" as much laughed at as the "windows of heaven" are in the present day. I think I am much more likely to do that than to hear Mr. Grey, by "scientific reasoning *from experiment*," prove that this wonderful and incomprehensible substance has any existence except in the imagination.

If I suspend several balls by separate strings in a line, so that they touch each other, and then drawing back one of the end ones, I swing it against number two, none of the balls seem to move, except the one at the other end, which immediately bounds away from its neighbour. Is not this a third kind of "motion known to us" that may be designated transmitted motion?

During the nearly threescore years and ten of my existence the daily production of carbonic acid

gas has immensely increased in England and throughout the world, while the area of vegetation has been constantly diminishing, yet we have no evidence that the proportion of it has at all increased in the atmosphere. How is this? Where does it go to? Does it pass through the "luminiferous ether?" May not its corpuscles be subject to this third kind of motion? I have my ideas on this question, but fear I am too old, and that my time is too much occupied to permit me to test those ideas by "scientific reasoning from experiments."

January 4th. **Abergwili.**

THE COST OF LOCOMOTIVE WORKING.

[26722.]—AN interesting work, entitled "Railway Problems," is about to issue from the pen of Mr. Jeans, the secretary of the Iron and Steel Institute, and the following preliminary remarks by the *Engineer* refer to a problem which will interest some of your readers. There are a good many problems in railway working, and not the least puzzling is the cost of loco. mileage.

It is, for example, says the *Engineer*, well known that the cost of locomotive power is a large percentage of the whole cost of working a railway. Mr. Jeans gives a table dealing with ten first-rate British railways, from which it appears that the difference in total cost per train-mile is comparatively small. At the one end of the list is the North British Railway, with an expenditure of 2s. 2d. per train-mile; at the other end is the South-Western, with 3s. But we find that, while the cost of working the London and Brighton line, for example, is 2s. 4d., the cost of engine power per train-mile being 10·1d., the total for the Midland is the same as for the Brighton, but the cost of engine power is only 7·7d. Here we have a curious unexplained compensating action, which is not confined to the cases named. The figures refer to 1884. Mr. Jeans hardly attempts to supply any explanation of the apparent discrepancies, yet it may be possible to cast a little light on the matter, and so your contemporary proceeds to point out that, although the work done by all the railways named varies, the total expenditure is remarkably constant. If we reject the London and South-Western line, with its exceptional 3s. per train mile, we find that the difference between the North British with 2s. 2d., and the North-Eastern, with 2s. 7d., is only 5d., or, say, one-sixth. The relations between the cost of the locomotive power and the total cost are so obscure that they appear to have no relation to each other. Thus, although the cost of locomotive power on the London, Brighton, and South-Coast system is 10·1d., while on the Midland it is 7·7d., the total cost per train mile is the same. Again, on the North British the cost of locomotive power is 6.5d., while the total expenses are 2s. 2d. On the London and North-Western the total cost is 2s. 7d., while locomotive charges amount to 7·9d. It appears, then, that the causes which determine the cost of locomotive power are largely distinct from those which determine the whole cost; and it will be found, further, that there are really no grounds for drawing any deductions as to the relative economy and efficiency of locomotive engines on British railways from such figures as those we have quoted. For example, let us take the cost of coal; we shall not be far wrong if we say that on the North-Eastern it costs about 7s. per ton, while on the London, Brighton, and South Coast it costs on the engine £1. If we reduce the total consumption to a dead level of 30lb. per mile per engine, we shall have the cost of coal per mile on the first-mentioned railway in round numbers 1d., and on the latter 3d. Here, then, we have at one swoop 2d. a mile against the Brighton engine. But this comparison is not fair, because the coal used on the Southern line is better than that burned on the Northern line, although, of course, nothing like 2d. a mile better; probably we shall be correct if we say that it is about ½d. a mile better. The London and Brighton Company has a very large metropolitan traffic, which seriously affects the engine expenses; but of this Mr. Jeans takes no cognisance. Its goods traffic involves a great deal of shunting and standing about at stations, which means waste of fuel. Again we have to bear in mind that the total annual mileage of an engine has a very important effect. Now, on the Brighton Railway the mileage is 19,848, while on the North-Eastern it is 16,240. But the average annual expenditure on a Brighton engine is £742, while that on a North-Eastern is £728. The wages paid in the Brighton locomotive shops are higher than those paid in the North; and the cost of coal is, as we have said, nearly three times as much. It follows, therefore, that Mr. Stroudley's engines are, by comparison, kept up for less money by a good deal than are the North-Eastern engines, although the actual cost is considerably more. But further, the work done by the engines on the North-Eastern is very different from that done on the London and Brighton lines, so different that there is hardly any room for comparison.

The *Engineer* proceeds in quite a long article to notice some of these minor problems, which really have considerable interest on the balance-sheet; but they are worth some attention by those who write in your columns about locomotives. How, for instance, do Mr. Webb's compounds compare with other engines of the older type; and how do the coupled engines compare with the single when the mileage worked by each is compared with its total expense for a year? Mr. Jeans' book will evidently contain some matter about which to talk and write. **N. B. R.**

GOODS TRAINS AND PARTING COUPLINGS.

[26723.]—I SEE that "W. F." (p. 436) admits the cord suggestion "to be very good, so far as it goes, but it does not go nearly far enough." It does not go "far enough," it is true; but I demur to it being considered "very good." It was put forward as a simple device to which the most cheeseparing manager could not object on the score of expense; and it would serve a useful purpose, although "W. F." "repeats" that it would not enable the driver of a parted train to prevent the hindmost portion running back. Perhaps he will point out where it has been asserted that it would. However, it is usually—in these columns at all events—considered that a critic of a suggestion should be provided with a better. What is "W. F.'s"? At present it is not discoverable. I do not want to quote Latin, so I will give a free translation of a hint which an old Roman writer penned years ago—I am not sure about his "penning" it, but done into English it reads, "If a better system's thine, impart it freely, or make use of mine." Will "W. F." give us his "better system," for I presume he has one? I should be sorry to regard him as merely a "destructive critic." **Nun. Dor.**

EXPRESS TRAINS.—II.

[26724.]—

GREAT WESTERN RAILWAY.

3 p.m. ex Paddington to Swindon. The best run. October 10, 1886.

Miles.	Stations.	Booked Time.	Actual Time.	Speed.
		p.m.	h. m. s.	
	Paddington	3.0	3 0 0	
$5\frac{3}{4}$	Ealing		3 10 30	$32\frac{6}{7}$
$12\frac{3}{4}$	Slough		3 23 0	$61\frac{1}{5}$
$6\frac{1}{4}$	Maidenhead		3 29 0	$62\frac{1}{2}$
$10\frac{3}{4}$	Reading (A)......		3 41 0	$53\frac{3}{4}$

$6\frac{1}{4}$	Slough		2 48 0	$62\frac{1}{2}$
$12\frac{3}{4}$	Ealing		3 2 0	$54\frac{9}{14}$
$5\frac{3}{4}$	Paddington	2.45	3 9 30	46

REMARKS.—Arrived at Swindon 1.20 p.m. Delay owing to luggage being in wrong van.

Load, 7. Loco., 2,009. Chief dimensions:—Cylinders, 17 by 24; carrying wheels, 4½ft.; drivers, 8ft.; heating surface, 1,952 sq. ft. Water in tender, 2,560 gals. Coal, 2½ tons. Consumption of coal per mile, 25¾lb. **French Loco.**

[26725.]—I QUITE concur in Mr. Rous Marten's views as expressed in letter 26659, especially the concluding portion. When timing trains I usually take both mile-posts and stations, if possible; but at night it is, of course, impossible to take posts. For station distances Bradshaw is worse than useless, as the distance is only given to quarter miles, and not always accurately then. One requires the distance to chains, and this, I believe, can only be obtained from Airey's railway maps.

In reply to "Practical Man" (26661) the driver told me that the night Scotchman runs the 124 miles from Newcastle to Edinburgh without stop, provided the load does not exceed ten coaches, and the weather is moderate; but otherwise, he said, he would require to stop for water.

"French Loco" (26663) quotes as his best run on the Midland one which is decidedly below the average. He takes the booked time from Bradshaw, which gives arrival time at Kentish Town and departure at Kettering, so that 3.6—4.27 should be read for 3.4—4.30.

The following run shows a speed as high as is likely to be found in ordinary practice:—

Miles.		H. M. S.	Speed.
$105\frac{1}{4}$	Grantham.	4 17 20	—
100	mile post.	4 26 19	—
97	"	4 29 26	57·7
94	"	4 32 3	68·7
92	"	4 33 42	72·7
90	"	4 35 18	75·0
87	"	4 37 48	72·0
80	"	4 44 11	65·7
—	Peterbro'.	4 48 23	47·8
72	mile post.	4 54 13	
67	"	4 58 58	63·1
61	"	5 5 48	52·6
54	"	5 12 21	64·1
45	"	5 21 45	57·4
—	Hitchin.	5 36 25	51·3
22	mile post.	5 48 36	
15	"	5 55 36	60·0
4	"	6 7 10	57·0
—	King's Cross.	6 13 20	—

REMARKS.—8ft. single No. 773 and 6 coaches Usual slack to 10 miles an hour through Peterbro', and slacked by signals at mile-post 7, speed being reduced to about 20 miles an hour. Due to leave Grantham 4.17 and arrive King's Cross 6.15.

On the occasion of the above run we left Manchester at 2h. 0m. 13s., M.S. and L., No. 500, and 5 coaches, and arrived Sheffield 2h. 58m. 41s. (due 2h. 59m.), although delayed over two minutes by signals outside Sheffield. A coach was added at Sheffield, which was left at 3h. 3m. 46s. (due 3h. 3m.) and Grantham was reached 4h. 11m. 38s. (due 4h. 13m.), with a signal slack at Newark and a stop outside Grantham station waiting signals. The highest speed attained by the M.S. and L. engine was 72 miles an hour between posts 129 and 128 (from London).

It should be known that the 9.12 a.m. from Peterbro' to London (Mondays only) is due Finsbury Park 10.32, being 73¾ miles in 80 minutes, or over 55 miles an hour, decidedly the fastest timing in this country. **Kappa.**

ELECTRIC LOCKING FOR RAILWAY SIGNALS.

[26726.]—YOUR correspondents "Electric" (61171), and Mr. Stretton (26710) describe Spagnoletti's system of electric locking for railway signals. That the system is imperfect in its present aspect is evident, so without repeating what has been urged against it by Mr. Stretton, with whom I entirely agree, I ask What is electric locking for —to prevent mistakes? Well, but if it has to trust to the very men who make mistakes, what good is it? It fails in its object. If signalmen always did right, and worked their levers and instruments properly, why wish for electric locking?

The action of the men must be mechanically controlled so as to make mistakes impossible.

Rover.

ELECTRIC LOCKING FOR RAILWAY SIGNALS.

[26727.]—IN your issue of the 14th inst. you publish a letter from Mr. C. E. Stretton, dated the 7th January, pointing out imaginary defects in my system of electric locking of railway signals. Now, when a man makes a statement in error, doing another an injustice, and his misconceptions are pointed out to him, and he admits his mistake, it is pardonable; but when he is told of his errors by the best authority to correct him, and persists in publishing his erroneous ideas, I consider, as I believe every other reasonable man would do, that such conduct is unpardonable.

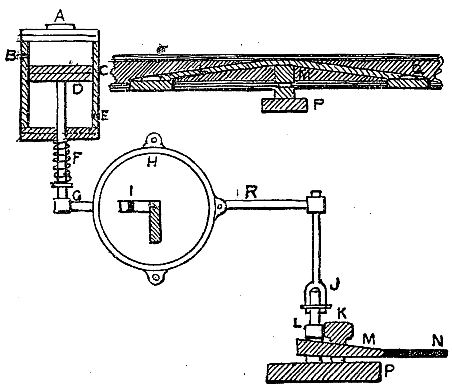
Mr. Stretton wrote a similar letter to *Iron*, which appeared in the issue of that journal of Dec. 3rd, finding the same imaginary faults, and wrongly describing the principle and working of my system, as he does in his letter which appeared in your journal of the 7th instant. I replied to this letter, and my answer appeared in *Iron* issued Dec. 10, informing him of his errors. Still, in spite of this, he perpetuates his mistakes by writing to your journal as above referred to, and this nearly a month after his mistakes were pointed out to him. He states he has examined the system and finds such and such things to exist, which I most distinctly say do not, and

never did exist. He has certainly misunderstood both the principle and working of the system, and I think, as a representative man and an adviser to a society, it would not only have been more prudent, but have shown better judgment on his part if he had properly understood the system, and obtained a correct knowledge of its working, before venturing to give an opinion upon it, or attempt to describe it, as it is evident from his own showing that he is ignorant of its working and capabilities. I ask you to be good enough to allow me to reply to this letter, as such statements are not only misleading to your readers and the members of the society to which he belongs, but unfair to the inventor. He, in this letter, also states that I admit that such "defects" exist; here, again, he has misunderstood my letter, by which I endeavoured to correct the wrong conclusion he had arrived at in his first letter to *Iron*. I admitted the point he raised was an important one, and said it was provided for; but I never admitted the defect existed, and no doubt if he reads my letter again he will see that he is wrong. I can only say the system does exactly what he says it ought to do; that he has wrongly described it, and that provision is made to effectually and surely prevent any chance of accidents arising from the cause he states. It is satisfactory for me to be able to state that my experience has not been with such unreliable and careless signalmen as it appears to have been his lot to have worked with. I have always found them a steady and careful class of men, and most anxious to do their best for the safe working of the traffic.

C. E. Spagnoletti, M.I.C.E., &c.

SIGNAL RECORDER.

[26728.]—I SUBMIT to the readers of this paper a device for recording the signal about 100 yards before the train reaches it, and I think it would be of great advantage for the safe working of the line, as on a foggy night, for instance, it would show the driver of the train if the signal was at danger or not, and I think the drawing will explain itself. A is piston for working signal in the gauge, B a



very small hole to let in the air after signal is recorded, C cylinder, D piston, E small hole to let in and out any air that would stop the free play of the piston; F spiral spring to pull piston down after train has run over plane; G a slotted joint to raise piston, H gauge to show signal, I signal arm, J small wheel to be hung from engine, to run over plane which lifts up signal in the gauge; K rail, L plane, M wedge to lift up plane at the same time as signal on post; N rod to signal-box, O foundation for wedge to run on.

D. Evans.

MIDLAND GOODS ENGINES.

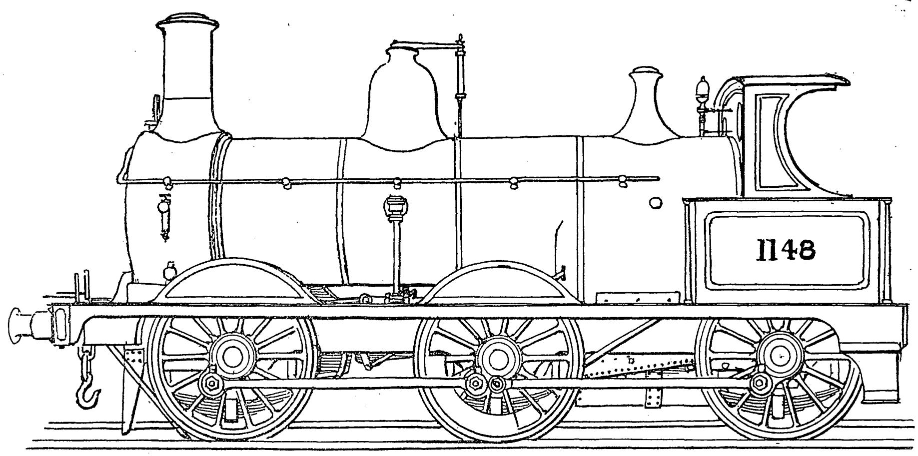
[26729.]—IN your issue of this date I notice a correspondent, who signs his letter "Rover," p. 442, (61422), asks me to furnish a diagram of a Midland engine of the 1142 type. I therefore beg to inclose diagram of No. 1148, which is one of those designed by Mr. S. W. Johnson, and constructed by Kitson and Co., Leeds, 1875. These engines are required for heavy mineral traffic, and have cylinders $17\frac{1}{2}$ by 26, and six coupled wheels of 4ft. 10in. diameter; the tractive force for each pound of effective pressure on the pistons being therefore—

$$\frac{17\frac{1}{2} \times 17\frac{1}{2} \times 26}{58} = 137{\cdot}284.$$

The engine illustrated has done very good work on the Midland Railway, and the following numbers are of the same dimensions:—

381 to 385
400 to 404
1142 to 1251

It will be observed that there is no brake upon the engine wheels. Some of these engines have,



however, been since fitted with brakes, and it is to be hoped all soon will be, as at present they are capable of conveying trains which they are unable to stop or properly control on inclines.

Clement E. Stretton.
Consulting Engineer Amalgamated Society of Railway Servants.

306, City-road, Jan. 14.

COAL ECONOMY—GOODS TRAINS AND PARTING COUPLINGS.

[26730.]—I AGREE with "Nun. Dor." (26692) that we are using a deal more coal than is necessary, and I have given this subject my special consideration, and the result is that I have found out how to use one quantity of steam over and over again in a steam-engine. (One writer quoting a former letter of mine called it "regenerating the steam.") I want to guard against this. I would not regenerate it, for I would not allow it to die, but keep it alive from the starting of the engine until it stops, no matter how long it worked. I also have to say that an engine on the plan suggested would do more than double the work that the engines are doing at the present time, reducing the first cost one-half.

"Nun. Dor." says: "There are plenty of firms who will make engines so that a ton of coal would yield 700H.P. an hour." I calculate that 8,960H.P. can be obtained from one ton of coal per hour. Our coal is being literally thrown away, and it is no exaggeration to say that one-tenth would suffice for the steam-engines, and less than one-half for many other purposes, and at the same time the smoke nuisance entirely done away with.

I am sure that it is as necessary that goods trains should have as good continuous brakes as passenger trains. I have seen a deal of runaway trains in my time, and the relating of them would make my letter too long; but I will just give one. A goods train got to the top of Checkerbent bank, and had to stop, so that the men could pin some brakes down; it was very slippery, and if they stopped a yard or two too soon they could not start again after the brakes were put on, and besides, from the slippery state of the rails, the brakes would not hold the train after they turned the head of the bank. Although they were moving very slowly, the train got on too great a speed before the brakes were put on: result, they knocked Bolton station down, and the fireman met a terrible death! The question is, How is this to be remedied? I would suggest an inquiry into the matter by the companies appointing a few earnest, good, and qualified men to see if some plan could be devised to cure the evil. I believe it could be done. I never see a mishap on the line but I set my wits to work to find a cure, and I believe I can do it. I am willing to work with any others in this matter. I have no faith in electricity: it has failed so often in signalling that I distrust it. I invented a mechanical communication that was automatic, and had it before the Board of Trade and the L. and N.W. Company, so that if the train parted it would have warned both driver and guard, and communication could have been kept up whilst shunting operations were going on.

I have by an accident been rendered unable to work as a driver, so no one need be afraid of me taking his job. I believe railway work can be made more safe, efficient, and a deal more economical, and I have no doubt but the plan that I have recommended will be the best to effect the object in view. Let every one do his duty, and assist in this difficult task. I hope to see the work of my life accomplished—namely, improving railway work, so that higher wages, safer work, and greater dividends may be paid. Ten per cent. per annum could easily be made on every railway in England is the opinion of

Benjamin Bagshaw.

10, Brook-street, Crewe, Jan. 17.

THE DUPLICATION OF THE CUBE.

[26731.]—IN your last issue is a letter (26698) on this subject, in which a solution is put forward as being exact. I will show in the first place that it is only a near approximation, and then show why it must necessarily fail to be exact.

Referring to the figure given in the letter, we have, by similar triangles, A G : A I : : A E : A H; and, therefore—

$$AG = \frac{AE^2}{AH} = \frac{36}{\sqrt{45}} = \frac{12}{\sqrt{5}}.$$

Again, since K L = A L, we have at once that—

$$KL = \frac{AK}{\sqrt{2}} = \frac{12}{\sqrt{10}}.$$

Consequently—

$$KL^3 = \frac{1728}{10\sqrt{10}} = 54{\cdot}644.$$

This is evidently approximately double of 27, which is the volume of the 3in. cube, but not exactly so.

Now, suppose x and a to be the sides of two cubes, such that the first is double the second one in volume; then $x^3 = 2a^3$, and hence $x = \sqrt[3]{2} \, . \, a$. Consequently, to find the value of x when a is known, we must be able to find the cube root of 2 geometrically. But no lines that can be drawn on a plane surface, by the help of Euclid's postulates only, are so related that the length of one is the cube root of the length of the other; hence any attempt at the duplication of the cube by means of Euclidean lines on a plane surface must inevitably be a failure.

Inverness College. **C. W. Bourne.**

[26732.]—THE following will dispose of Mr. Williams's plan (letter 26628) for duplicating the cube. Taking the diagram as given:—Let A D = 1. A G = 2 the sides of their respective squares, D H must = 2, and E H = 1; A D H forms a right-angled triangle; $\therefore$ $(AH)^2 = (DH)^2 + (AD)^2$; therefore $AH = \sqrt{5}$; the diagonal of the square on $AG = AF = \sqrt{8}$; now, A E = A I radii of the same circle. Now, the triangles A E H, A J I are similar and proportional; $\therefore$ A H : A I : : A E : A J, that is, $\sqrt{5} : 2 :: 2 : \frac{4}{\sqrt{5}} = AJ$. Again, A J = A K radii of the same circle, and the triangles A E F and A L K are similar and proportional; $\therefore$ A F : A K : : E F : L K—that is, $\sqrt{8} : \frac{4}{\sqrt{5}} :: 2 : \sqrt{\frac{8}{5}} = LK$. Now, $\sqrt{\frac{8}{5}}$ is not $\sqrt[3]{2}$; therefore, L K is not the base-line of the double cube.

Helix.

LATHE MATTERS.

[26733.]—I AM about setting up a lathe at home, and, thanks to the writings of some of our contributors and the advice of a friendly mechanic, I have little doubt of being able to secure a serviceable tool. Now, except for the occasional making of some little piece of scientific apparatus, my tastes do not lie in the direction of mechanical engineering, neither do I look forward to spending my leisure in perfecting the tool itself, and adding ingenious adjuncts thereto; but I find, now and then, that in making various things for use and ornament about the house I want round forms, and, it may be, a screwed fitting of some sort, and I expect to find a lathe, equipped with a few necessary appliances, helpful from time to time.

But surely it must be possible, and would be very pleasant, to do much more than this with a lathe; and yet nothing is more remarkable to me, in looking over the columns of the "E. M.," than the almost total absence of any reference to the results of lathe work, apart, as aforesaid, from mechanical engineering. *Engineering*, a few months since, recommended "ornamental" turning for its value in hand-education, and illustrated specimens of geometrical ornament. Well, no

artist would for a moment allow such things to be classed as ornament: they and all their kind go to enforce the truth that geometry, without feeling, cannot produce ornament. In our museums there are plenty of pretty pieces of turned work, plain turning all of them, often pole lathe or bow lathe, and mostly things that we either don't want or can't afford to produce now, such as spinning-wheels and Cairo window-lattices.

In these pages we have had, in the last year or so, one capitally lucid article by "O. J. L." on a turned photograph frame, and as a handicraft lesson nothing could be better; but if a pretty frame were the result desired, a hint was given that a fret-saw and a penknife would be more useful than the lathe. Now, surely this is not making the best of the tool; there must be things about the house that would be better made between the centres of the lathe than at the bench. It is not credible that all the lighter sort of lathes are—like the Duke of Marlborough's now going a-begging—toys, costly in money or in time and brains, and I cannot but believe that some who may have read this could recount experiences of lathe produce, as distinct from lathe production, which would interest others besides

W. A. S. B.

LATHE MATTERS.

[26734.]—I THINK "F. A. M." is somewhat of a "thirsty soul" where the lathe is concerned. Perhaps a number of contributors are mentally solidifying the late discussions and ideas advanced —perhaps some are materially embodying some of the notions. Can anyone tell us the fate of Mr. Hartley's apparatus? I intended going to the sale, but was prevented by other matters. I was much interested in the article on Mr. Evans's book, and intend getting a copy; but do not as yet know the price and quarter to apply.

The radial index is quite new to me, though an index that traverses all the circles without altering its length, and is able to return to its starting point, was published in the ENGLISH MECHANIC last "season," together with my first letter on the "Division Plate." It is not so simple as radiation, but has the advantage of being always tangential; and again, it was not specially designed to allow intermittent use of the various circles, but to maintain the tangent. It appears to me, however, that with an arc to start with, it would be only at No. 1 hole in each circle that they would be all on the arc, and capable of usage by the one index. I should prefer a second index, lifting the first to clear plate, as the second index could be set and used anywhere in the circle, and the first would remain quite free from disturbance. As some of those who have plates with the holes starting from a radius may wish to have the advantage of the arc —which, perhaps, I do not quite understand—I will again briefly describe my arrangement. A stem, parallel to radius and surface of plate, stands fixed over the circles; on this stem the index slides, being formed with a suitable socket to fit thereon, and being provided with a pinching screw. The index has also provision for lengthening or shortening. The stem can carry any number of pawls; for constant use I should use one to each circle for my plate. I am scheming to make the last named device give any number; if I discover a suitable way, I will endeavour to explain it.

Vulcan.

THE EDMUNDS MANDREL.

[26735.]—TWO years ago there was a discussion in the "E. M." about the "standard interchangeable lathe mandrel" proposed by Dr. Edmunds, a subject of wide practical interest to our readers.

I have been looking through the back numbers of the "E. M.," but cannot find that any final decision as to the dimensions of the standard mandrel and the pitch of its screw was arrived at. It seems to me that the advantages of such a standard lathe mandrel are so great as to insure its general adoption if the interests of the user only were consulted.

Dr. Edmunds has been frequently asked by other readers to recur to this subject, and as it is of such general interest alike to amateurs and the trade, many of us would, I am sure, be glad if Dr. Edmunds would give us any final conclusions at which he may have arrived.

If "F. A. M.," "Vulcan," "O. J. L.," and other readers would then favour us by discussing the subject with a view to determining the best form to adopt, we may perhaps bring the question to an intelligible conclusion. A. Gray.

THE WIMSHURST MACHINE.

[26736.]—IN all ordinary forms of the Wimshurst machine, the collection of the electricity produced is effected, as far as I am aware, by means of wire combs. But whether this is the best method or not, appears to me to be open to question. Of course, in the ordinary glass frictional machines, the use of such collecting points is imperative, because, the excited surface being non-conducting, the action of a conductor opposed to it is merely local, and therefore a sufficient number of such conductors, or discharging points, have to be opposed to the glass to cover the whole extent of excited surface.

But in the Wimshurst machine the conditions are wholly altered. Here the electricity (or at least the effective portion of it, for I suppose the glass between the sectors behaves in the same manner, only much more feebly, as the sectors themselves) has to be collected from metal surfaces, and a conductor in contact with the smallest portion of those surfaces, serves to reduce their whole area in the same electrical condition.

I therefore substituted for the combs on each side, two guttapercha covered wires, bent so that the ends pointed towards the glass, each terminating in a short brush, similar to those on the neutralising rods, which nearly touched the surface of the glass. The results obtained from the machine so fitted appear to be fully as good as those obtained with the combs, while the collecting wires are much more readily made and attached. I should imagine that compound machines especially would be more conveniently put together in this manner.

One advantage is, that the wires exposed much less surface than the combs usually do, and therefore afford less facilities for escape of electricity.

No doubt Mr. Wimshurst, or perhaps other of your correspondents, have already tried this method, and if so, I should be glad to know what their experience has been. Crispin.

SACCHARINE.

[26737.]—"R. S. T." asks what is meant by attributing "antifermentive" and "antiseptic" properties to saccharine.

In the *Gaz. Chim.* Turin, 1886, experiments are quoted to show that saccharine acts as an antiseptic in retarding the fermentation of sugar, wine, and milk. Further, it has been found that peptonisation and diastasis are stopped, and it is stated that it is also useful for certain disinfecting processes in the intestines.

Few experiments have been made with saccharine in England owing to the extreme difficulty of obtaining supplies. Orders which have been given over six months ago to the wholesale German houses have failed to be executed up to date.

E. J. Millard.

SUGAR ANALYSIS.

[26738.]—IN reply to Mr. A. H. Allen, letter 26695, I regret that I should have mistaken his meaning in the statement he made in letter 26549, that Pavy's solution cannot be employed for the detection of small quantities of sugar. I took the statement to mean that Pavy's process would not quantitatively estimate small proportions of sugar. I am pleased to find that he agrees with me that it will.

I had no desire to keep any "special knowledge to myself": the method was I supposed well known to analysts, and has been detailed and illustrated in the *Lancet* so long ago as 1879.

Alf. W. Stokes.

TRICYCLES.

[26739.]—IN reply to "Gamma Sigma" (26708, page 435), I have long ceased to experiment with tricycles that seat the rider on the driving-wheel axle. I think they will go out of use in time for reasons too long to state here.

I am only speaking of tricycles that carry part weight on the steering wheel. Years of riding and observation have convinced me that the axles of the driving wheel and steering wheel should work nearly in the same parallel line. This would, of course, bring the three wheels to about the same size. This brings us to the question, How large ought wheels to be? I say for a 6ft. man the wheel diameter should not be more than his own height, 72in. This would bring us to three 36in. wheels for the tricycle. Of course, the two driving wheels turn as one double wheel, and only value as one wheel. The next point to consider is how to get a 36in. steering wheel in a tricycle. In a bicycle it is easy to do it with a vertical fork, as the machine balances perpendicularly; but a tricycle, with its double driving wheel, follows the contortions of the road, and is best steered by a horizontal fork, I think.

I prefer 30in. or 32in. wheels, double or single, for driving, always keeping the steering wheel a little larger than the driver. One of my favourite machines is called an "Emperor." It drives on one 30in. wheel geared to 48in., and steers on two 42in. wheels. This is an extreme size for steering wheels; but I expect the "Rover" pattern bicycle will be much used next season. This machine has the steering wheel the same size or a little larger than the drivers.

My tricycle pedals I allow to reach about 3in. or 4in. off the ground; safety bicycle pedals about 6in. from road, lowest point. A tricycle follows the slant of the road, and the pedals are kept the same distance off; but the safety bicycle is vertical to the road, so that if the pedals are too low the inside one might strike a stone on the rising ground.

PUMPING HOT WATER.

[26740.]—IF you want to pump hot water, you must bear in mind that the pump will not act by suction, owing to the steam spoiling the vacuum created by rise of plunger. You must have the whole of pump *below* the supply of hot water, so that it lifts valve and runs into barrel on rise of plunger; once in, you will have no difficulty in forcing it as high as you please. You will have to have a pipe in or near bottom of the open copper—it will not lift (if above 150°) even to top of vessel.

T. C., Bristol.

[26741.]—THE vapour (see letter 26714) fills the space under piston and prevents the formation of a vacuum.

Put pump so low down that the piston, when at top of its stroke, is below the level of the hot water in copper: make the valves of metal or of some substance not affected by hot water, and you will have no trouble. Glatton.

[26742.]—THE failure of "Zulu's" pump (letter 26714) is due to the high vapour tension of hot water as compared with cold. As "Zulu" is no doubt aware, the water rises in an ordinary cold-water pump because the action of the buckets removes the atmospheric pressure from the water in the barrel, which is then forced up by the atmospheric pressure on the water outside it. Suppose, however, we generate vapour from the water in the barrel by heating it, we shall force it back against the outer atmospheric pressure.

In an ordinary pump water will rise, say, 26ft.; but to depress it down to 12ft. we have only to heat it sufficiently. I calculate from a table of vapour tensions that a temperature of about 76° Centigrade (169° Fahrenheit) will do this. Therefore it will not rise to 12ft. in "Zulu's" pump unless the temperature be below 76° C., perhaps several degrees lower. The water could, of course, be raised by a force pump placed at or near the level of the water in the copper. J. Brown.

Belfast.

[26743.]—"ZULU" (letter 26714, page 436) is not quite correct in his supposition, because it is not the steam from the boiler that acts upon his pumps, as he surely has the supply-pipe near the bottom of his boiler; but the real cause of his failure is, that the moment the pressure is lowered upon the surface of the hot water by the action of the lifting bucket, steam or vapour, as the case may be, is released, and destroys the partial vacuum. Easiest remedy: Lower the pump-barrel below the level of the horizontal part of the pipe; thus the hot water will flow in by gravity.

A., Liverpool.

[26744.]—I SEE a correspondent on p. 436 wants to know why he can't pump hot water by an ordinary suction pump which works well with cold. If he places his copper containing the hot water above the level of the pump-barrel he will be able to pump hot water; but he must remember that when he puts his pump, as at present arranged, at work, he really produces a reduction of atmospheric pressure in the barrel, and that consequently the hot water becomes steam, and fills the barrel instead of water. If, then, he puts the hot water above the pump-barrel it will flow into it, and he can "force" it up the desired height.

Saml. Ray.

HOW THE SUN PUTS OUT THE FIRE.

[26745.]—IF a small room has a large window facing the west or south-west, it is found that the afternoon sun puts out the fire, especially in spring, when the sky is clear and the sun is low. The reason is that at this time of the day the fire is often allowed to get dull, and the sun's rays warm and rarefy the air in the room as much as the fire warms the air passing over it up the chimney. Hence the draught ceases, and the fire goes out. To remedy the inconvenience open the door or the window, to let warm air out and cold in. K. E.

PATENTS AND LAND.

[26746.]—A CORRESPONDENT, in letter 26696, has pointed out one of the absurdities of our property laws, which I have frequently mentioned in conversation. We have the *Pall Mall Gazette* and other papers raving on behalf of the landlords, saying that "the English people will not steal," and quoting the eighth commandment as to *land*, but showing utter blindness as to *patents*.

When a man brings out a good invention, he *creates* a new combination. The landlord does not create the land; he merely buys or inherits it. Now let us see where the thief is. The nation gives the patentee a right to bring an action at his own cost, *on condition* that he pays the nation an average of £11 a year for fourteen years. It takes away his property at once if he fails to pay the taxes; and, if he does not fail in these, it takes his property away at the end of the fourteen years! Is not this stealing?

To be consistent with land. Let a man reclaim a piece of land from the sea: let the nation charge him £154 for a fourteen years' tenancy of this land, and then take it from him. This they would call stealing; the former they do not. Yet this would be equitable if the former is equitable.

But the landlord does not create his land; he buys or inherits a right (query, wrong) to tax a naturally increasing population for his, and his successors', luxury *for ever*. He is such a favourite with the nation that all the forces of so-called civilisation are enlisted on his behalf; while the poor inventor has the same forces against him. Who is the thief? **Thomas Moy.**

WEATHER REPORT (IN JERSEY) FOR 1886.

[26747.]

—	Mean of Three Barometers.	Mean Lowest Night Temperature.	Mean Highest Day Temperature (in the Shade).	Rainfall in Inches.	Days on which Measurable Rain Fell.
	In.	°		In.	
January ...	29·79	37	No record kept	4·75½	25

I, for one, am much obliged to "B. A." (letter 26656, page 410) for his interesting report of the "Temperature and Rainfall in 1886" at Handsworth; and, believing that a meteorological report for Jersey during last year would likewise interest many of "our" readers, I take the liberty of furnishing a rough digest of the same, though it is not as complete as I could have wished. The last three months here have been marvellously wet; and there is this peculiarity about the Jersey climate that a good deal of rain often falls with a high barometer.

The total rainfall for 1886 was (as above) 42·64in.
" " 1885 " 29·41
" " 1884 " 31·78
Mean rainfall for last three years, 34·61in.

Wm. Locke Lancaster.

St. Helier's, Jersey, Jan. 11.

THE HOP APHIS AND THE PHYLLOXERA.

[26748.]—THE ravages of the hop aphis in this country are probably not quite so ruinous as those of the phylloxera in France; but it will no doubt surprise many to learn that the loss in the hop failure of 1882 was estimated at a million and three-quarters of pounds sterling. Many experiments have been made with insecticides, some of them with a measure of success; but it is obvious that little could be done until the nature of the pest was understood. It is believed that the *Aphis humuli* and the *A. humuli*, var. *Mahaleb* are practically identical, and that the first attack on the hop begins in spring from wingless females and their young, which come up from the hop-hills; but that the main attack is made by aphides, which come on the wing from sloe and damson bushes, where they are developed. Of the remedies used hitherto, the most successful have been a mixture of the mineral oil sold as paraffin, with ashes, sawdust, &c., which is used for dressing the hills, and is apparently effective in destroying the wingless females which are located in the soil. If that could be carried out on every hop plant throughout the country, it is not unlikely that the aphides might ultimately be materially reduced in numbers, especially if measures are also taken to destroy the aphis which develops on the sloe and damson. To do that effectually, more knowledge is required of the life-history of the insect, and here is an object of study which cannot fail to serve a useful purpose.

As regards the phylloxera, the loss in France last year caused by its ravages must have been very great; but as has been pointed out by a recent writer, unfortunately, the vine-grower is not interested in killing the swarm before it flies, for he knows it will be miles away before it can do harm. Again, the vinegrower on whose vineyard the swarm alights makes no sign, for he shrinks from publishing that his vines are infected, fearing that destruction of the vines might be decreed. To him the immediate loss would be great, for the vines bear more fruit for at least the first year after being attacked. Thus in too many, perhaps the majority of, cases has the evil been allowed to go on undisturbed, and not till the damage is patent to all the world have remedies been prayed for.

The life of the insect, which somewhat resembles a beetle, goes on in a continuous round, called by the French a vicious circle. Like the silkworm, it undergoes many changes—always three, sometimes five. Those which have five changes possess wings, are called nymphs, and are capable of flying in a swarm for five miles or so. Let our circle begin in August with the nymphs busily moving on the ground and on the stems of the vines. When ready the swarm takes to flight; and, being aided by a fine sense of smell and vision, alights a few miles off on a vineyard then in its greatest fragrance. The nymphs are all females, and soon begin to lay their eggs, of which the large ones are females, the small ones males—the only appearance of the male in the vicious circle. In 20 days the young insects are fully grown, when the pairing at once begins, and in a few days more one egg is laid, generally in the exfoliations of the stem. It is called the winter egg. The parents die, and the egg remains where it is laid until the following April, when it is hatched. The young insect, a female, travels usually down the stem and enters the ground. There it fixes its proboscis into the root, lays 30 eggs, all females, and dies. The eggs soon come to maturity, and the young ones, behaving as their parents, pursue their course further into the ground, when each lays 30 eggs, all females, and dies. There may be eight generations in one year, but if only five generations the number produced at the same rate would be 25,000,000 insects from one ancestor. In winter the process is suspended, but is continued during the summer months of the three following years, at the end of which period it is supposed to be exhausted, having produced from one ancestor a number of millions of insects far beyond the power of the human mind to conceive. Who, then, can wonder that the vines no longer retain their vitality?

After a variety of researches only one method has been found to effectually kill this insect, and that is by inundation, begun in November and continued for 40 days. The experiment was made for many successive years by M. Fauçon at Mas-le-Favre, near Avignon, by means of the water of the splendid Durance Canal, which commands the vineyard. The canal is supplied by the River Durance, and runs southward for 80 miles at an immense elevation to supply Marseilles with perfectly pure water. This vineyard was the first to be attacked. In 1867 the wine produced was 925 hectolitres; in 1868, 40 hectolitres; in 1869, 35 hectolitres; in 1870, the first year of submersion, 120 hectolitres. After 1870 the produce of the vineyard gradually increased until it nearly reached its normal quantity, and the vines regained their vigour. But how few are the vines placed in such a fortunate position!

The chemical chiefly relied on is sulphide of carbon, which is introduced into the ground in any required place by means of an injector with a pointed end, and comparatively slight success has doubtless attended the application of this and other chemicals. Still, the course of the roots must always be difficult to follow, and there is too much chance that many more insects will escape the poison than will be brought under its influence.

The phylloxera is not microscopic, so that, after a very little tuition by the aid of a magnifying glass, most peasants are able to detect the movements of the insect when above ground with the naked eye. While it is important to do the utmost to exterminate the insect from the roots, for which purpose it is hoped that better means will still be found, no effort should be neglected to kill the swarms before they take the wing, to kill them after alighting on their new vineyard, and to destroy the winter egg. Either of these three processes effectively performed for four successive years would probably rid France of her potent and deadly enemy.

It seems useless for one man to attempt to destroy insect pests when his neighbours allow them to breed; but if combined action could be brought about, there does not appear to be any reason why many of the insect pests should not be so materially reduced as to be practically of no importance. At present the actual loss of money they occasion is a serious matter in a densely populated country. **E. G. M.**

JOY'S VALVE-GEAR.

[26749.]—IN reference to "G. S.'s" query in letter No. 26713, *re* Joy Valve-Gear in Great Eastern engines, I may state that Mr. Holden has only replaced the valve-gear referred to by the link motion in one engine at present, viz., No. 562, a 4-coupled radial express engine, built at Stratford in 1882; the splashers have also been altered. Radial tank engine, No. 674, has link motion; the Joy's gear intended for that engine was put in goods engine No. 696 (Stratford, 1885; particulars of this engine will be found in back numbers). The new radial tank engines Nos. 790, 791, &c., the express engine, No. 710, and the new goods engines No. 810, 811, &c., all have link motion. No. 710 has valve-chest underneath cylinders, but all the other new engines have valves between cylinders. Mr. Holden's radial tank engines have cylinders 1in. smaller in diameter than Mr. Worsdell's engines.

Could "G. S." kindly supply sketches of new N.E. engines? **A. B. Campling.**

NON-FLESH DIET AND HARD WORK.

[26750.]—THE "Lydney Dispenser" makes a gratuitous assertion when he says that men cannot work hard without flesh. (See reply 60982.) I here copy for his benefit an extract from a work by Sir Francis Mackenzie, of Gaerloch. It was published in 1838, and is entitled "Hints for the Use of Highland Tenants and Cottagers." It is in English and Gaelic. At page 16 it says: "An English contractor for building the Conon Bridge informed me of his surprise at the exertion of the natives whom he employed, and that having contracted for excavating a canal in England, he engaged about twenty Highlanders to accompany him southwards. Several disputes occurred between those thus introduced and the native workmen, and many jeers passed relative to the fare (bread and milk) on which they were contented to exist, saving the greater part of their wages to bring back to their friends and families. To settle these bickerings, a match was made and considerable sums of money betted that twelve of the Highlanders could not excavate a certain number of solid yards in the same time as an equal number of the better-fed Englishmen. And everything being fixed, a table was laid out with meat and ale for one party, whilst the other had no preparation for refreshment beyond what a can of fresh water afforded. But the point in dispute was, after a fatiguing day's labour, decided in favour of the latter; and whilst the former were totally exhausted by their exertions, the latter, full of spirits at their success, danced their national strathspey in token of victory." Besides this example, I can give him the instance of men in the Thames Ironworks doing their work without the flesh of animals, and other cases as well were it necessary. I hope the "Dispenser" will for the future recollect Montaigne's advice and tell only what he knows, and not what he conjectures.

T. R. Allinson, L.R.C.P.

Author of "A System of Hygienic Medicine," &c.

ROAD REFORM.

[26751.]—I ALSO agree with "B. B." as to pleasure in seeing the subject of road reform discussed in the columns of the "E. M."; but I think the advocates of Macadam overlook the fact that there are now, owing greatly to the abolition of turnpikes, ten vehicles on the road, against one in Macadam's time. Also that he did not have traction engines weighing 14tons, drawing loads of 45tons in three waggons, and I think if stones were only 1in. square, they would stand a poor chance against such heavy traffic.

On wide roads, and for the traffic they used to have upon them, no doubt the smaller the material the quicker it became consolidated, and the light traffic went over it much more smoothly; but I don't think that would apply now. I don't mean to say that stones are to be 3in. square; but I think 1in. too small when you take the nature of the subsoil and the formation of the roads. To bring the roads up to a proper state would be a very heavy tax upon tenant farmers, who now have to contribute the greater portion of the cost of maintenance, and surely those people who complain so much about the roads ought to contribute towards the repair of them. **G. F. F.**

HORIZONTAL WINDMILLS.

[26752.]—SEEING that considerable interest exists among our readers in the horizontal windmill, and that doubts of its efficiency are felt by many and expressed by some, I will state a circumstance that took place soon after we had applied the mills to ploughing the land.

Being at Lewes market, a millwright named Midhurst, who had a business at Lewes, asked me why I did not use vertical mills instead of horizontal, stating that a vertical mill of equal length of sweep and 4ft. sail would give off four times the power of the horizontal. I replied that if that were the case I should use vertical; but I doubted it. He then offered to make a vertical mill of that size for trial, and I said, Our mills cost us about £5 each; if you make a mill of the size you mention, and it gives off four times the power of one of the mills we now use, I will pay you £40 for it. If it gives off double the power of our mill I will pay you £20 for it. If it gives off equal power I will pay you £10 for it; but if it does not give off so much power as one of our mills, I will have it for nothing. This was agreed to, and in about a fortnight he wrote to say the mill was ready, and I sent for it. A day of trial was appointed, and he came over to be present.

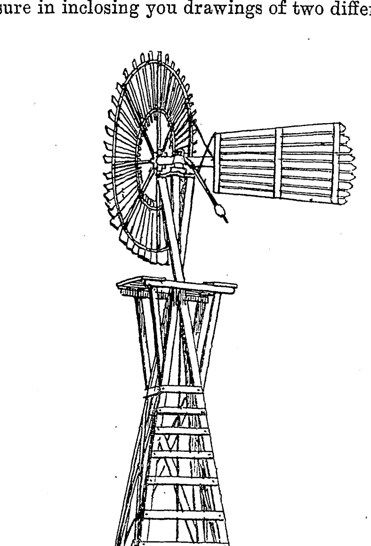
We fixed the vertical mill at the bottom of the piece to be ploughed, and a horizontal mill at the top, the rope to draw the ploughs going through both mills, as explained in the former number. The sails were put on the horizontal mill first, and it drew two ploughs steadily, and at the usual pace of about $2\frac{1}{2}$ miles per hour. The sails were then taken from that mill, and the cloth of the vertical mill spread; but not a motion of the two ploughs could be got. We then took off one plough, and the mill moved it now and then when the wind was stronger than usual, but nothing like the other mill which drew the two ploughs. We then altered the sails, putting only three out of the six on the horizontal mill, and it drew the one plough better than the vertical mill.

I made many experiments with this vertical mill, and from them I have reason to believe that, with equal spread of sail, the horizontal mill is quite equal to the vertical. The mills we used for ploughing had six sails, 6ft. wide and 12ft. high = 72ft. on each sail, making in all 430ft. of sail. The vertical had four sails, 12ft. long and 4ft. wide = 192ft. Of course Mr. Medhurst had no more to say. I gave him £5 for his mill.

Philip Vallance.

WINDMILLS.

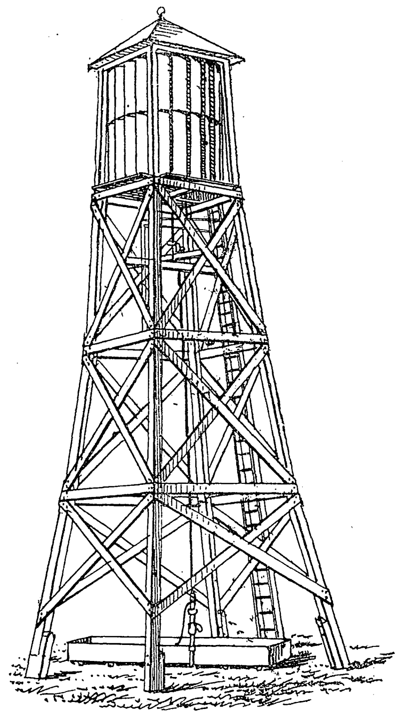
[26753.]—I HAVE observed a good deal of correspondence lately in your paper (which I read regularly) in regard to windmills. I herewith have pleasure in inclosing you drawings of two different



The "Stover."

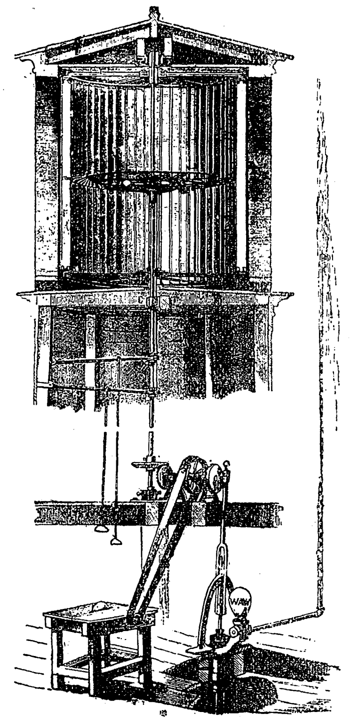
kinds of American windmills, the one named the "Stover," and the other the "Hercules."

The first mentioned is one that I know a good deal about, having had one working on this farm for the last seven or eight years, pumping water for farmhouse, steam-engine, cattle courts, and boxes, &c., and during that time it has given me most entire satisfaction, and it could do a great deal more work than I required of it. This mill is so constructed that if left running, and it encounters a storm or gale, it will quietly turn itself



Open Frame Tower, with 6 × 8 "Hercules" Wind Engine.

partially out of work, by simply presenting the wheel edgeways to the wind, and continue to run slowly, and when the storm subsides will commence working again as usual. My mill is used and made only for pumping, having an up-and-down stroke;



Sectional view of "Hercules" Wind Engine in operation, showing counter shaft and connections for running force pump and buzz saw.

but they are now made also with geared wheels for a rotary motion. In regard to the "Hercules," I don't know so much about it yet; but I am corresponding with a view to get one for drying a meadow by pumping about 500 gallons per minute. I think the principle of this mill is good, something of the "Turbine water-wheel" applied to a wind motor: the wheel is cylindrical in form, with adjustable sails or wings around the periphery of the cylinder. Each sail is pivoted, and attached to the governor, which automatically varies the angle, according to the velocity of the wind. The mill is inclosed in a cupola, around which deflecting boards are placed, which deflect the wind upon the sails; at the proper angle the wind thus exerts its force upon the sails, both at the front and back of the wheel where it enters, and where it leaves. When you do not want the mill to be in operation, by simply drawing a rod the sails are folded around cylinder, and motion ceases.

Æolus.

[26754.]—AS Mr. Albert Collingridge has been good enough to answer my inquiries (p. 434), for which I thank him, I cannot object to answer his, which, indeed, have no discourtesy in them. The age of miracles having passed away for ever, as we are taught, and having some doubts in my mind as to the wonderful doings of horizontal windmills on Mr. Vallance's construction, it seemed to me that the best test of their merit would be the work they were doing in a good breeze of wind. A wind engine so cheap, so powerful, and so portable as it was represented, wanted only to be found pretty generally in use or in demand, to convince the most incredulous of its value. I therefore inquired where I could get a sight of it at work.

We have since heard from Mr. P. Vallance himself—who claims to be the inventor—that it was brought conspicuously before the public long years ago, when two of them accomplished the feat of the seven ploughs as aforesaid at the agricultural show, and had performed wonders in other places as well; but all the answer I can get from those who are acquainted with the machine is that one of them is going to be erected "before long," which, in fact, is quite sufficient, and my curiosity asks no more. The idea of a wooden fly-wheel of that bulk being of any use up in the air if the wind suddenly dropped is rather amusing. It would still have the atmosphere to contend with, and must be going at a good velocity when the wind fell to accomplish half a turn afterwards by its own momentum. A hundredweight of lead distributed among the outer ends of the arms, which would offer no appreciable resistance to the breeze, would, I have no doubt, be much more effective in that way than a ton of wood.

Mr. Collingridge also says "canvas will not do." Not for his machine, possibly; but it does not follow that it may not be the best for a good working horizontal windmill for all that. Mr. Hosken, for instance, on the same page, evidently believes it is, though he frankly confesses that his machine, of which, by your favour, Sir, he gives us a drawing, "does not give satisfactory results." His plan is to use a segment of a boat's fore-and-aft sail, not quite sheeted home, and his difficulty that of keeping the mast in its place without twisting the arm which holds it. How if he prolonged his mast or spar at the end, and carried it as much below as above the arm? He might double his power—the same sheet or rope would do, and the strain in a puff of wind would be equal on both ends of the spar, so that it would have no tendency to wrench what he terms "the crossbeam" to which it is attached, and need not, therefore, be of any inconvenient scantling. But the chief defect in all wind motors, which set their sails at or near a right angle with the arm that carries them, is that every sail as it comes to the point right before the wind, *where the chief pull is wanted*, is comparatively useless, presenting only its after edge to the wind till it jibes, and again settles itself to its work. Mr. Hoskin shows this, in his sketch, by the fluttering rope, and this happens at the precise moment that the opposite arm on the return side comes to its stiffest point of resistance against the wind. Mr. Hosken will, I dare say, hit on some better way of keeping his mast perpendicular than my crude suggestion. The under side of a horizontal wind motor should be free from all awkward projections, especially at its outward extremity.

I avoid points of controversy of no general interest, regarding them as so much trespass on your valuable space. I ventured into your instructive columns to ask for information on a specific piece of mechanism and its variations. Much I have already obtained, and the discussion is not yet exhausted. I believe, with Mr. Collingridge, that wind-power has still a future before it; but I am not sure that the best mode of turning it to account on land has yet been discovered.

London, Jan. 17th. **Raymd. Browne.**

[26755.]—THERE are many fallacies to be noted in the statements of A. Collingridge (26701 p. 434), which may be sufficient to pass unnoticed, as no sane person is likely to contemplate the erection of any such unwieldy affairs?

With regard to windcatchers, as described by P. Vallance in p. 346, I take it that the machine which develops the quickest speed "must be" that one which is capable of giving off the most power, and any one who constructs a model with, say, four arms of any given size upon both systems

and compares results, will find that the vertical is infinitely superior in power to any horizontal, and would not require nearly so strong a framework of any description to resist storms, as would be necessary for such a cumbrous and top-heavy concern. No one need trouble with the idea that it could be induced to run away by any pressure of wind; and will "A. C." (see p. 434, end of letter) explain the statement that "when in work, a part of the weight is taken off the step-brass by centrifugal tendency." The spindle of such a mill could not develop any centrifugal force practically; but were it to develop any conceivable amount, this could not reduce the weight one fraction.

A., Liverpool.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[60987.]—**Organ Query.**—I am much obliged to "Uranium" and "T. D." for their replies to above query; but "Uranium" must have overlooked the size of room, as his specification appears to me to be too large. "T. D.'s" specification seems more suited to the room, and if not troubling him too much, would ask him to send a few more particulars of the organ he speaks of—viz., way in which the S.D. bass is placed, depth including keyboard, size of bellows, and if one or two feeders, how blown, any octave couplers, way front is finished off, width of windchest, and sliders on same.—A. C. AND J.

[61048.]—**Electric Conductor.**—I have noticed that your query of Dec. 24th has not been replied to, and as the question is no doubt of usefulness and interest to many readers of the "E.M." I have roughed out an approximate table of size leads, &c., which will, I think, explain itself, and possibly be of service to you.

Dynamo.	Distance. miles.	Size of conductor, B.W.G.	Resistance of conductor.	Difference of potential at dynamo in volts.	Current in ampères.	E.M.F. of line in volts.	H.P. absorbed by conductor.	Sec. area of cable.	Weight of copper in lb.	Loss in volts of E.M.F.
D[1]	1½	19/16	1·0734	300	100	195	13·4	·063	1914	105
D[2]	3	19/14½	1·466	400	150	195	41	·08846	5371	205
D[3]	2	19/16	1·431	345	106	195	21	·063	2552	150
D[4]	3	19/14½	1·466	370	120	195	26·9	·088	5371	175

The current per square in section of conductors is 1,400 to 1,700.

From the table you can, no doubt, work out (by varying the difference of potential at the dynamo and a current) any loss in E.M.F. you wish. The size of conductors given is the smallest advisable for a safe E.M.F., which is within the Board of Trade limits. If you have only a small given load to deal with and require increased speed, you can increase the difference of potential at dynamo, reducing the current and size of conductors. The loss along the line would depend upon its design and construction, which would have to be known before useful calculation could be made. Your maximum could be at maximum load. I regret that pressure of business has prevented me giving fuller particulars and details.—LANCASTER.

[61049.] — **Electric Lighting.** — The only primary batteries that can economically be used to charge secondaries are the Upward and the Lalande-Chaperon. To take your last question first, you will find the reason mentioned in any textbook; but I have never managed to get a Daniell to show it clearly. The action is called endosmose, and is produced by the different specific gravities of the two liquids, and partly by the current. I see you used a Woodhouse and Rawson 8-volt lamp. I have tried them; but now use Edison-Swans only, as they have a higher efficiency and can be overrun with greater safety. You would, in charging the secondaries, have a current of about $\frac{1}{25}$ ampère flowing for 12 hours; but small secondaries have a very low efficiency so that your reverse current would only be about half charging current. Charging, $E - e = 3 - 2 = 1$ volt; resist. of Daniell's about 4 or 5w. $3 \times 4 = 12$w. res. of battery. So $C = \frac{1}{12} + 1$ (resist. of secondary) $= \frac{1}{13}$ ampères; at first when working e increases to 2·25, and res. of Daniells increase to about 6w, so then $C = \frac{E - e}{R + r} = \frac{3 - 2{\cdot}25}{18 + 1} = \frac{{\cdot}75}{19} = \frac{3}{76} = \frac{1}{25}$ nearly, $\frac{1}{25} \times \frac{12}{1} = \frac{1}{2}$ ampère hour, and ampère efficiency 50 per cent. $= \frac{1}{4}$ ampère hour, or the secondaries should light your lamp for about 15 minutes, if it only takes one ampère. If you increased the size of your Daniells, or what is nearly the same thing, converted them into scrap cells, you would lower the resistance, and your charging current would rise. May I ask what size are your accumulators? You should have three or four plates, say, 6in. by 4in. punched with as many holes as possible, and filled with red lead. I am afraid you will never be able to work direct with such small Daniells. To get one ampère you would need to make $R = {\cdot}75$w. per cell, which is far lower than a Daniell even of large size usually is. Why not try chloride or granule cells? I had eight cells working an eight-volt lamp direct, two hours a night for twelve evenings, with one charge and cells untouched.—IOTA.

[61063.] — **Wheat Straw.** — HCl won't touch this. To make straw-paper pulp, the straw is boiled with caustic alkali under pressure, so a simple solution of alkali will not do unless you patiently wait for a long or unknown time.—R. S. T.

[61101.]—**Stars Visible from Bottom of Well.**—Has anyone ever actually so seen a star by daylight? I once looked up a new chimney 200ft. high, and as far as I could judge the light of the sun at the top would as effectually conceal the stars as if I had been in the open. Recollect King Charles and the fish.—DUBITANS.

[61101.]—**Stars Visible from Bottom of Well.**—I must first remind "E. D." of what I said at the commencement of my last reply. With regard to his implied assertion that I had not given "a definite answer" to the original query, I beg to refer him to my first letter on p. 352, which I think he will find a sufficient refutation of his statement. In reply to "E. D.'s" query as to the time of visibility of γ Draconis, I should say offhand that it would first appear at sunset (assuming that the word "daytime" represents the period between sunrise and sunset only) about the beginning of October, and attaining the centre of the field of view 3m. 56s. earlier each day would be last seen at sunrise about the beginning of March.—B. A., Handsworth.

[61112.] — **Do Quartz Crystals Grow?**—"F. C. S." has found out the question, but he has not answered it; unless he thinks that saying that a crystal of quartz would grow out of the mother liquor—i.e., out of water-glass, alias silicate of soda or silicate of potash. If so, he is in error. Crystals are never formed out of water-glass except crystals of soda or potash, when an excess has been used in making the water-glass, as has happened with me. But the pith, if I may say so, of my question is this—Do crystals of quartz grow, or are of sudden formation? It was to raise this question that I stated that the undissolved pieces of a piece of pure Brazilian crystal of quartz did not show any shape, as the large crystal had been built up of smaller ones. All the pieces were smooth. Again, if you take a piece of pure crystal of quartz and break it, the fracture is conchoidal like the fracture of a flint, which is crystalline and not a crystal —i.e., has no definite shape. But take a piece of Iceland spar and break it, and you will find it will split up into perfectly-shaped crystals, and each fractured piece will again split up into perfectly-shaped crystals. Take another illustration—sulphur, the crystals of S are needle-shaped—seldom seen, but easily gotten by melting some sulphur in a pot, and then when partly cooled down, pouring out the still liquid S. Again, take bismuth; the crystals of this (the origin, I believe, of the Greek pattern put as a border to a ground glass window) are formed like sulphur; at least, I should say, can be obtained like S crystals by melting and pouring out when partly cold. Can these crystals (bismuth) be formed by growing, i.e., by continual addition? Does not their shape lead to the conclusion that they are formed suddenly to their complete form (a crystal). Perhaps "F. C. S." will tackle the question and enlighten us, and not simply indulge in a sneer.—R. S. T.

[61117.] — **Horse's Action.** — The horse is trained to lift his feet by fitting them with heavy shoes, or by securing lead plates to the front portions of ordinary shoes. Youatt on "The Horse" (Longmans, 7s. 6d.) is a standard book, and will probably suit you. I do not think there is one which explains the training of trick horses.—NUN. DOR.

[61125.]—**Cobalt.**—You may perhaps find what you require in the late Mr. Phillips's "Metallurgy," or in Payen's "Industrial Chemistry." Metallic cobalt is rarely (if ever) employed in the arts, but it is used in some alloys, and when required is generally obtained by what are known as laboratory processes.—F. I. C.

[61128.]—**Paper Valve.**—The paper does pass over the reeds, but they are so placed (vertically) that the tongues are free to vibrate. What is it this querist means?—GRAY'S INN.

[61131.]—**Electric Cautery.**—I can appreciate "Ohm's" remarks in issue of Jan. 14th. A surgeon lately asked me for a battery to—1st, Light small lamps; 2nd, heat cautery; 3rd, work a coil; 4th, charge small accumulator; 5th, electrolyse superfluous hairs (*vide Lancet* a few weeks ago), and was surprised I could not produce a portable set guaranteed to do the above. The reason A. Dunlop Stewart, M.B., &c., cannot be satisfied is, I expect, that, like many others, he does not know the theoretical basis of the applications of electricity, and, therefore, does not perceive he is asking too much. A friend of mine uses a cautery often, and finds it very handy, the current required being 12 ampères, which an 11 S.E.P.S. accumulator gives easily. One charge of the secondary is sufficient for 25 or 30 cauterisations. I am afraid it would take three or four large bichromes in parallel to work the cautery properly, as even in four and a half seconds a bichrome falls off measurably; besides, the first rush of current would be apt to burn the cautery and fuse the point. A secondary gives a steady current, and is so much cleaner and handier. There is, of course, no use putting cells on in series when the external resistance is only ·06 w. By the bye, what 5-volt lamp of 10c.p. does "Ohm" refer to? It will bear pretty heavily on the battery if it takes 6 ampères. 10c.p. at 3 watts per 1c.p. = 30 watts per 10c.p., and $E = 5$ volts $\frac{30}{5} = 6$ ampères. I believe S. Bottone's instruments, though without high finish, are rough, good, and easily used—being simple, do not get out of order. An ammeter and voltmeter, one or two secondary cells, and Sprague's "Electricity" should show Dr. Stewart out of his difficulty.—IOTA.

[61131.]—**Electric Cautery.**—The cautery Dr. Stewart refers to has a resistance of ·06 B.A. ohm cold, and before using was made of No. 22 platinum wire; but was filed and hammered, so that now it is impossible to say what dia. the wire is. The point was fused and then filed thin, but when tested the cautery took 12-15 ampères to work it. By far the best means to work the cautery would be a cell or two of E.P.S. accumulators: the size giving 8 ampères' discharge with two in parallel would work it well. A larger size would sustain the action better, and not need to be so often charged. Current is always what we need; but if the resistance of an instrument is high, we need a high E.M.F. to produce a sensible current. Ohm's law $C = \frac{E}{R}$ shows the ratio in its simplest form. The resistance does not define the current required to heat the cautery to working point, as a short, thin, or a long, thick wire may have the same resistance; and the same current will make the one very hot, but hardly affect the other. An ammeter is the only practical way to measure the current, as it does not flow long enough to allow of electro-deposition. I can recommend S. Bottone's, as I use one myself, and it does my experimental work splendidly. The price of Sir W. Thomson's, about £15, is prohibitory, and Sprague's is only of use in a laboratory, far too complicated and fidgety to use in a hurry or for general work. May I ask, Does Mr. Conry recommend Leclanche's for cauterising, and how long are they expected to work? Not only Dr. Stewart, but a great many amateurs, would be much obliged I know for instructions how to make a reliable long-range ammeter and voltmeter, as it would allow of accurate calculation in much of what at present is guesswork. The good ammeters generally are rather dear, and many amateurs have spare time to devote to practical work if they only knew how to proceed.—CAUTERY.

[61131.]—**Electric Cautery.**—TO "OHM."—I fear our worthy correspondent, "Ohm" must have been in the grip of the fiend of indigestion when he wrote his communication as above in last week's number, for to the extent of half a column of the "E.M." he rails at Mr. Dunlop Stewart, myself, the medical profession, and things generally, and winds up without having in the slightest degree elucidated the question, except by the information that Mr. Stewart could do what he wants by the aid of three large bichromate cells—a matter that Mr. Stewart never inquired about. Probably Mr. S. could produce a whole battery of cells that would give the necessary current; but what he asked about was the exact current that would be required for his purpose. Prithee, kind sir, be a little less hasty in your denunciations. I never said I had had much experience in the heating of wires. I even expressly told Mr. Stewart that I should prefer to ascertain the required current by simple experiment, and measure it afte-

wards. Furthermore, the "elaborate formulæ" I quoted are, as I mentioned at the time, not my own; but are those of Mr. Sprague and Messrs. Munro and Jamieson, and as to specific heat and weight of wire having nothing to do with such matters, I think Mr. Sprague would say different. I make no apology for quoting undoubtedly "elaborate" formulæ, because (if "Ohm" will please notice) Mr. Stewart had specified that he was no novice in electrical science. "Ohm" further goes on to prove my deficiencies by data derived from an experiment of his own, the accuracy of which we have no means of ascertaining. Having thus begged one half the question, he betakes himself to an "elaborate," formula, and starts forward bravely to prove the remainder. Even Mr. "Ohm's" personal capacity as a judge is not unquestionable, since he has not the sufficient courage in his own convictions to write over his own name. As to the Leclanché jars which "he would like to see," if he will forward me the necessary cash to cover cost of procuring or making same, he shall not only see them, but have them. What would "Ohm" say to incandescent lamps being actually lit by Leclanchés, and for 20 minutes right off?—a thing I have seen and can do any day, as any practical battery maker can. Lastly, considering that Mr. Dunlop Stewart required the "exact" current, why does Mr. "Ohm" twaddle about ammeters at 5s. a-piece? He ought to know perfectly well that such very cheap instruments cannot be expected to "exactly" measure any current, let alone one so small as a current for a cautery. If "Ohm" has any real information to give, why did he not give it when Mr. Stewart first wrote, instead of leaving it to incompetent individuals like myself to tackle the subject? I asked Mr. Stewart for a particular item of information which, as far as I know, he has not yet furnished, but I will look back again and see. There is but one assertion of Mr. "Ohm's" to which I can subscribe, but which I agree to with pleasure, and that is where he says that a few hours spent in the perusal of Mr. Sprague's admirable work would be well repaid. —EDWARD CONRY.

[61138.]—**Yacht Steering.**—Why not have a wheel, or try one of the patent steering gears?—H. G.

[61145.]—**Does it Boil?**—TO "W. A. S. B."—I understand you to raise objection against view that vaporisation is a case of solution, your plea being, that process goes on more actively under air rarefied. If you refer to ebullition brought on by exhaustion of air, such evidence does not touch issue. Do you, however, really mean that water, even when so cold as not to boil at reduced pressure, will evaporate faster in partial vacuum than in natural air? Please understand query centres on evaporation below boiling-point. If you now complain of me for not having maintained "solution hypothesis at first," *vide* original query, p. 333, last three lines.—WEALD.

[61145.]—**Does it Boil?**—I have read with interest the numerous answers to this query; but I do not consider that any of them fully explain it. All of them state that water evaporates at all temperatures. This is a matter of fact which Mr. Weald knows well enough; but what he really wishes to know, if I mistake not, is the scientific explanation of this fact. A liquid consists of an aggregate of molecules whose mutual attractions restrain the individual molecules within the mass, although they are free to move among themselves. A molecule, in the midst of the mass, moves freely, because the attractions are equal in all directions, but a molecule near the surface is in a very different condition. As it approaches the surface, the attraction towards the mass of the liquid becomes greater than the attraction towards the surface, and when it reaches the surface the whole force of the inward attraction is pulling it back, and, unless the moving power of the molecule is sufficiently great to overcome this force, its motion is arrested, and it draws back on its course. It may happen, however, especially when heat is entering the liquid, that some of the molecules, through the effects of their mutual collisions, acquire sufficient energy to fly off from the liquid mass, and hence result the well known phenomena of evaporation. "When a pool abates its level," of course, the water vapour dissolves in the air; but it is not precisely similar to the solution of sugar in water, for water evaporates at a greater rate in vacuo than in air.—A. E. F., Manchester.
